(Received 4 January 2020; accepted 27 April 2020; published 22 May 2020)

Fully quantum *ab initio* calculations of the collision-induced shapes of two rovibrational H₂ lines perturbed by He provide an unprecedented subpercent agreement with ultra-accurate cavity-enhanced measurements. This level of consistency between theory and experiment hinges on a highly accurate potential energy surface and a realistic treatment of the velocity changing and dephasing collisions. In addition to the fundamental importance, these results show that *ab initio* calculations can provide reference data for spectroscopic studies of planet atmospheres at the required accuracy level and can be used to populate spectroscopic line-by-line databases.

I. INTRODUCTION

Molecular hydrogen differs in many respects from most other diatomic molecules, revealing its nonclassical nature due to a large rotational constant ($B = 60.853 \text{ cm}^{-1}$) [1]. The most straightforward example can be traced back to the early twentieth century, when the heat capacity of H₂ at low temperatures was discovered to dramatically diverge from the expected classical behavior [2]. The lack of inelastic channels in H₂ scattering, up to relatively high temperatures of a few hundred kelvin [3], results in many other atypical features observed in H₂ collision studies. In the particular case of the optically excited H₂ molecule, the lack of inelasticity causes the rate of optical excitation damping to be much smaller than the rate of velocity-changing collisions. This property results in strong collisional Dicke narrowing of the H₂ rovibrational lines [4,5]. Furthermore, the opening of the first inelastic channel leads to a strong dependence of the generalized spectroscopic cross section on the collision energy [3], which enhances the speed dependence of the line-shape parameters. Pronounced collisional effects make the molecular hydrogen well suited to study not only the potential energy surfaces (PESs) and quantum-scattering calculation methodology, but also the models describing the collision-perturbed velocity distribution of the optical coherence [3,6–9], which constitute a long-term development at the frontier of quantum optics, collision theory, and statistical physics [10,11].

Experimental studies on the interactions between two hydrogen molecules and between a hydrogen molecule and a noble gas atom have a several-decades-long history

[6,7,12–15]. Recently, the rotationally inelastic scattering of the HD molecule colliding with D₂ [16,17] and with He [18] at 1 K was observed in coexpanded supersonic beams and theoretically handled by Croft *et al.* [19]. The influence of the molecular hydrogen collisions, with perturbers such as H₂ isotopologues or noble gas atoms, on the shapes of the rotational and rovibrational lines in H₂ were already established in a wide range of temperatures, from 20 to 1200 K [20–26]. In particular, the effects of the H₂-He collisions on the widths and shifts of H₂ rovibrational lines were subjected to intense experimental and theoretical studies [3,25,27–32]. However, the collision-perturbed line profiles calculated from first principles never reached agreement with experimental data at the subpercent level.

In this work, we report a full *ab initio* description of the collision-perturbed shapes of rovibrational lines for the simplest benchmark system, i.e., He-perturbed H₂. We demonstrate agreement between measured and *ab initio* computed collision-perturbed shapes of molecular lines at the subpercent level: the root-mean-square difference (calculated within $\pm \text{FWHM}$) between experimental and theoretical profiles is smaller than one-hundredth of the profile amplitude. We merged all of the theoretical tools that are necessary to reach this agreement; i.e., we used the state-of-the-art statistical model of the collision-perturbed shape of molecular lines [33–36], we derived all parameters of this model from quantum scattering calculations [30,37–39], and we used the highly accurate *ab initio* PES [30,40], referred to as BSP3. We demonstrate that the fully *ab initio* calculations can provide reference spectra for atmospheric studies of solar system planets and exoplanets at the required metrological (subpercent) level of accuracy. Therefore, this approach is well suited for populating line-by-line spectroscopic databases such as HITRAN [41], GEISA [42], and ExoMol [43], including the

recent advanced database structures [44] involving beyond-Voigt line-shape parameters and their wide ranges of temperature representations. We show that this approach can be used to experimentally test the quality of quantum-chemical calculations of the PESs [30,38,40,45,46].

II. EXPERIMENTS

To validate our *ab initio* quantum scattering calculations, we performed measurements of the He-perturbed 3-0 S(1) H₂ line centered at 12 265.59 cm⁻¹ (815.33 nm) and the 2-0 Q(1) H₂ line centered at 8075.31 cm⁻¹ (1238.39 nm) using the experimental setups of Hefei [47] and Grenoble [48–51], respectively. Both setups, as shown in Fig. 1, are based on continuous-wave laser sources and high-finesse ring-down (RD) cavities. The two RD cavities are 1.0 and 1.4 m long, with finesse of 63 000 and 131 000, which results in effective path lengths of 20 and 59 km for the Hefei and Grenoble setups.

Acousto-optic modulators are used as optical switches to generate the RD events. The frequency of the Hefei laser source (Ti:sapphire) is set by a temperature-stabilized ($\Delta T \approx 10$ mK at 302 K) ultralow-expansion etalon reaching 10-MHz accuracy (see Refs. [52] and [53]), whereas for the Grenoble setup the external cavity diode laser is referenced to the optical frequency comb reaching 300-kHz absolute accuracy (see Refs. [54–56]). The length of the Grenoble cavity is tunable with a piezoelectric actuator, which allows the spectra to be recorded on a much denser frequency grid. The temperatures of the cavities were controlled to within 1 and 0.15 K for the Hefei and Grenoble setups, respectively. For the 3-0 S(1) line, the H₂/He mixing ratio spans between 33% and 10%, with 1% accuracy, while it has a constant value of 4.9(1)% for the 2-0 Q(1) line. The spectra were recorded at four pressures

ranging from 0.36 to 1.35 atm with an accuracy of 0.5% and signal-to-noise ratio up to 370 for the 3-0 S(1) line, as well as at nine pressures ranging from 0.07 to 1.05 atm with an accuracy of 0.15% and signal-to-noise ratio up to 2800 for the 2-0 Q(1) line.

III. AB INITIO CALCULATION OF THE COLLISIONAL EFFECTS

Our line-shape calculations [34,35,57,58], originating from first principles, are based on the generalized Hess method (GHM) [37,59,60]. To better reproduce the physics of the velocity-changing collisions, we replace the commonly used hard-collision model [61,62], which is used in the GHM, with the model based on the Boltzmann operator for rigid-sphere approximation of the potential [9]. The latter model based on the isotropic part of the PES properly reproduces the dependence of the colliding partners on the mass ratio and describes the relation between velocities before and after collision [9], which is not the case for the simple hard-collision model. Moreover, we introduce the full speed dependence [63] of the collisional broadening and shift [60,64,65] into the GHM.

For the H₂-He system, the PES is three-dimensional; i.e., it depends on the distance between the center of mass of the hydrogen molecule and the helium atom, R , the intramolecular distance, r , and the angle between the inter- and the intramolecular axes, θ . To carry out the close-coupling quantum scattering calculations [66], the PES is projected on Legendre polynomials and averaged over the rovibrational wave functions of the hydrogen molecule [3,32]. The generalized spectroscopic cross sections, σ_{λ}^q , for the electric quadrupole lines considered here ($q = 2$), as functions of the initial kinetic energy, E_{KIN} , are determined from S -matrix elements [32,60,64]. For the zero rank of the velocity tensor, $\lambda = 0$, σ_{λ}^q reduces to the pressure broadening and shift cross sections (PBXS and PSXS, respectively) [3,65,67,68], while for $\lambda = 1$ it provides the complex Dicke cross section [31,32,59,60,64] (RDXS and IDXS for its real and imaginary parts, respectively). The resulting cross sections are shown in Figs. 2(a)–2(d).

We use the generalized spectroscopic cross sections to calculate the corresponding line-shape parameters at a given temperature T , i.e., the speed-dependent pressure broadening, $\Gamma(v)$, and shift, $\Delta(v)$ [63,69,70], as well as the complex Dicke parameter, v_{opt} [30,39,44,71,72],

$$\Gamma(v) + i\Delta(v) = \left(\frac{n}{2\pi c} \right) \frac{2\tilde{v}_p^2}{v_r \sqrt{\pi}} \exp(-v^2/\tilde{v}_p^2) \times \int_0^\infty x^2 e^{-x^2} \sinh(2vx/\tilde{v}_p) \sigma_0^q(x\tilde{v}_p) dx, \quad (1a)$$

$$v_{\text{opt}} = \left(\frac{n}{2\pi c} \right) \frac{m_p}{m + m_p} \int_0^\infty v_r f_m(v_r) \times \left[\frac{2}{3} \frac{v_r^2}{\tilde{v}_r^2} \sigma_1^q(v_r) - \sigma_0^q(v_r) \right] dv_r, \quad (1b)$$

where v , v_p , and v_r are the speed of the active molecule, the speed of the perturber with the most probable value $\tilde{v}_p = \sqrt{2k_B T/m_p}$, and their relative speed with mean value \bar{v}_r , respectively, and $x = v_r/\tilde{v}_p$. m , m_p , and μ are the masses of the active molecule and perturber and their reduced mass, respec-

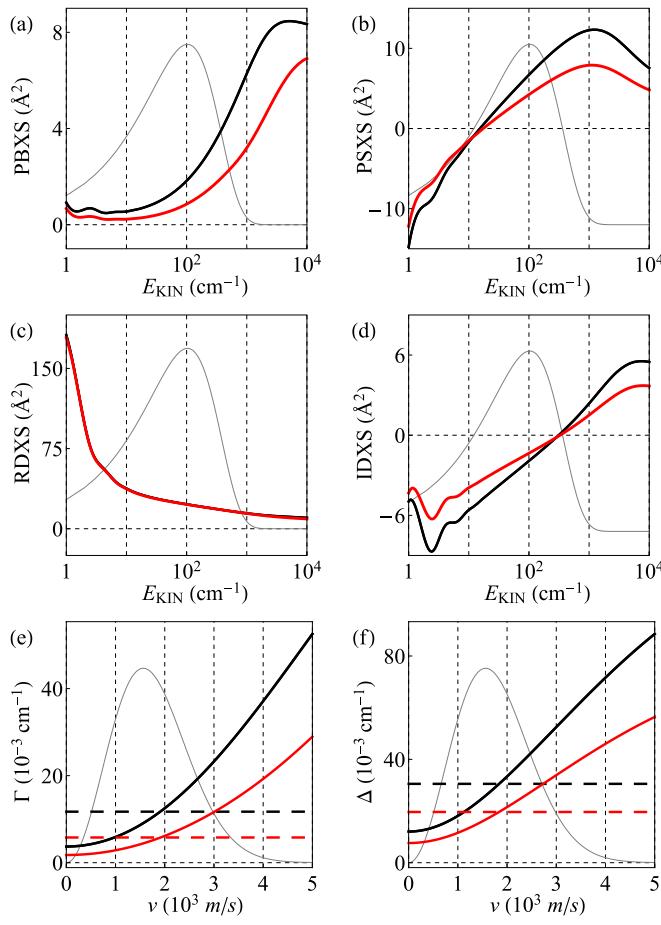

FIG. 2. (a–d) Generalized spectroscopic cross sections for the 3-0 S(1) and 2-0 Q(1) lines in helium-perturbed H₂: see the respective black and red lines, respectively. PBXS, PSXS, RDXS, and IDXS are pressure broadening, pressure shift, and real and imaginary parts of complex Dicke cross sections, respectively. The two curves in (c) are overlapping. (e, f) *Ab initio* speed dependence of the line broadening, Γ , and shift, Δ (same color notation), plotted for 1 amagat of He at the experimental temperatures. Black and red dashed lines are the speed-averaged collisional broadening, Γ_0 , and shift, Δ_0 , respectively. The gray line is the Maxwell Boltzmann distribution at 296 K in arbitrary units (vertically shifted in (b) and (d)): the distribution of relative kinetic energy in (a)–(d) and the distribution of active molecule speed in (e) and (f).

tively. $f_m(\vec{v})$ is the Maxwell-Boltzmann speed distribution, n is the number density of the perturber, k_B is the Boltzmann constant, and c is the speed of light. The *ab initio* speed-dependent broadenings and shifts are shown in Figs. 2(e) and 2(f). The calculated line-shape parameters are listed in Table I. We denote speed-averaged broadening and shift as Γ_0 and Δ_0 , respectively: refer to the dashed horizontal lines in Figs. 2(e) and 2(f). Following Ref. [35], we introduce two parameters, $\Gamma_{\text{SD}} = \frac{v_m}{2} \frac{d}{dv} \Gamma(v)|_{v=\bar{v}}$ and $\Delta_{\text{SD}} = \frac{v_m}{2} \frac{d}{dv} \Delta(v)|_{v=\bar{v}}$, that quantify the strength of the speed dependence of the broadening and shift, respectively, where v_m is the most probable active molecule speed. The $\Gamma_{\text{SD}}/\Gamma_0$ and $\Delta_{\text{SD}}/\Delta_0$ ratios, larger than 0.4, reveal extraordinarily pronounced speed dependence in the H₂ case; for typical atmospheric systems, these ratios are at the level of 0.1 [73–75].

TABLE I. Calculated values of the line-shape parameters for the 3-0 S(1) and 2-0 Q(1) H₂ lines. Calculations are performed at $T = 296.6$ K for the 3-0 S(1) line and at $T = 294.2$ K for the 2-0 Q(1) line. All parameters are given in units of 10^{-3} cm⁻¹ for $n = 1$ amagat.

Line	Γ_0	Δ_0	Γ_{SD}	Δ_{SD}	v_{opt}^r	v_{opt}^i
3-0 S(1)	11.72	30.51	5.40	12.42	37.96	-17.45
2-0 Q(1)	5.74	19.51	2.68	8.06	41.64	-11.31

We calculate the He-perturbed shapes of the H₂ lines by averaging the velocity distribution of the optical coherence [33,78,79]

$$I(\omega) = \frac{1}{\pi} \text{Re} \int d^3 \vec{v} f_m(\vec{v}) h(\omega, \vec{v}). \quad (2)$$

$f_m(\vec{v})$ is the Maxwell-Boltzmann distribution of the active molecule velocity, \vec{v} , and $f_m(\vec{v})h(\omega, \vec{v})$ is a scalar function proportional to the velocity distribution of the optical coherence. The $h(\omega, \vec{v})$ function fulfills the transport-relaxation equation [33,79]

$$1 = -i(\omega - \omega_0 - \vec{k} \cdot \vec{v})h(\omega, \vec{v}) - \hat{S}^f h(\omega, \vec{v}), \quad (3)$$

where ω and ω_0 are the angular frequencies of the electromagnetic radiation and the unperturbed frequency of the molecular transition, respectively, \vec{k} is the wave vector, and \hat{S}^f is the total collision operator describing relaxation and dephasing of the optical coherence as well as its flow between different velocity classes. This operator can be written as [34,35,57,58]

$$\hat{S}^f = -\Gamma(v) - i\Delta(v) + v_{\text{opt}} \hat{M}_{\text{BB}}^f, \quad (4)$$

where $v_{\text{opt}} \hat{M}_{\text{BB}}^f$ is the velocity-changing operator for the rigid-sphere model of collisions [80,81]. By using the complex Dicke parameter derived from the GHM, v_{opt} , we introduce the correlations between internal and translational degrees of freedom to the velocity-changing operator. The ultimate collision operator used to compare *ab initio* calculations with experiment is the sum of two contributions [9]: the H₂-He operator discussed here, Eq. (4), and the H₂-H₂ operator taken from Ref. [82].

IV. EXPERIMENTAL VALIDATION OF THE QUANTUM SCATTERING CALCULATIONS AND TEST OF THE AB INITIO POTENTIALS

The direct comparison between theory and experiment is shown in Figs. 3(a) and 3(c). Despite the fact that none of the line-shape parameters were fitted, we achieved subpercent agreement between the simulated and the raw experimental profiles; i.e., the root-mean-square error of the *ab initio* model relative to the profile amplitude (rRMSE) calculated within \pm FWHM is smaller than 1%. The pressure-average values of the rRMSE are 0.99% and 0.33% for the 3-0 S(1) and 2-0 Q(1) lines, respectively. We do not know the reason why the discrepancy is larger for the 3-0 S(1) line (one possibility is a slight nonlinearity in the Hefei frequency axis; see Ref. [47]). The main conclusion of Fig. 3 is that the fully *ab initio* line-shape calculations, including not only the collisional

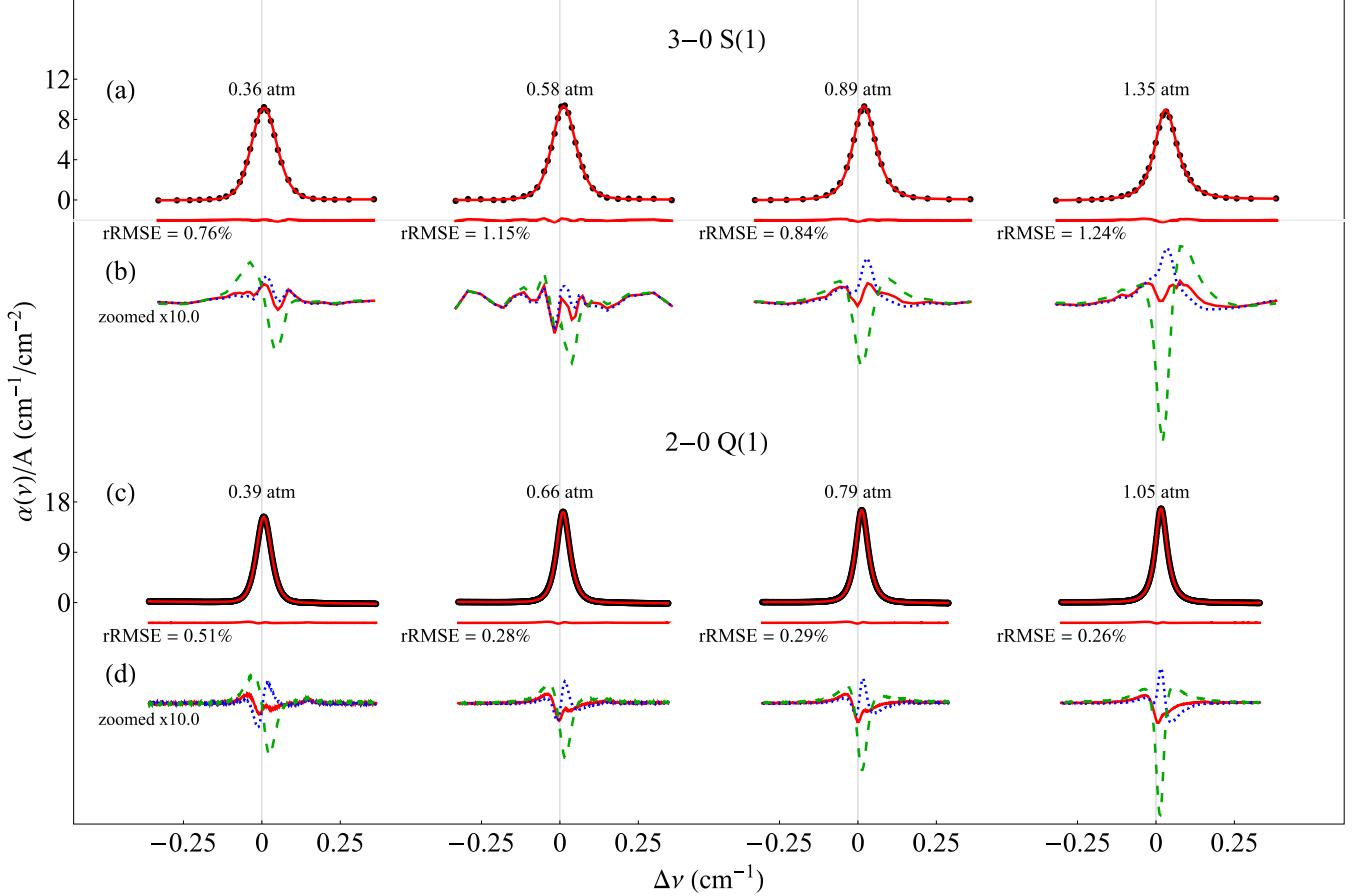

FIG. 3. (a, c) Comparison of the raw experimental spectra (black points) and the simulated line profiles (red lines). The absorption axis has been normalized to the area of the spectral line, A . Red lines under the line profiles represent the differences between experiment and theory. rRMSE values in the plots describe the root-mean-square errors relative to the profile amplitude. (b, d) Solid red, dotted blue, and dashed green lines are the zoomed residuals for the BSP3 [30,40], SK [38], and mMR [45,46] potentials, respectively. Vertical gray lines indicate the theoretical unperturbed line position [76,77]. The pressure shift is atypically large for H_2 and, despite the small pressure range, is clearly visible; see the deviation of the line maximum from the vertical gray line.

perturbations of both internal and translational motions of molecules but also the correlations between them, are validated for highly accurate experimental spectra. In addition to the line-shape parameters, whose values are directly taken from our *ab initio* calculations, several other parameters (not related to the collisional effects) were fitted: the unperturbed line position frequency, $\nu_0 = \omega_0/2\pi$, the line intensity, S , and the background slope and baseline. The fitted values of ν_0 and S are consistent with the theoretical values [51,76,77] within the declared 1σ uncertainties.

The H_2 lines are considerably asymmetric due to collisional effects (the asymmetry is much stronger than in typical cases of atmosphere-relevant molecules with a much smaller rotational constant). We tested that if we neglect in our line-shape model the main source of the asymmetry, i.e., the speed dependence of the collisional shift, the residuals are approximately 10 times larger and have almost a purely asymmetric shape. Our *ab initio* line-shape model almost completely eliminates the strong asymmetry without fitting any line-shape parameter. The small remaining asymmetry that is seen in the residuals for the Q(1) 2-0 line is not caused by an incorrect value of the line position, which was fitted in

our analysis. It is difficult to uniquely identify the source of the remaining asymmetry. Although this paper reports the most accurate theoretical line shapes, we suspect that the source may still lie on the theory side.

The advantage of the method employed in this work is that it allows the absolute value of the collisional cross sections to be accurately tested experimentally, which is not the case for most other experimental techniques [16–18]. As an example, we consider the pressure-broadening cross section [PBXS in Fig. 2(a)], which gives the Γ_0 parameter after thermal averaging: refer to the dashed horizontal lines in Fig. 2(e). At high pressures (at which the collisional broadening dominates), the relative error of Γ_0 is approximately equal to the residual rRMSE. For instance, in the case of the 2-0 Q(1) line, rRMSE = 0.26% at the highest pressure corresponds to subpercent agreement between our *ab initio* and experimental values of Γ_0 .

In addition to demonstrating that the full theoretical methodology can reproduce the collision-perturbed experimental profiles at an unprecedented level of accuracy, we show that this approach can serve as a link between high-precision spectroscopy and quantum chemical calculations,

thus enabling experimental tests of PESs in regions that are inaccessible with other techniques. In Figs. 3(b) and 3(d), we show the differences between the experimental and the theoretical profiles for three PESs: the Schaefer and Köhler (SK) PES [38], the modified Muchnik and Russek (mMR) PES [45,46], and the PES used in our main analysis, namely, the extended Bakr, Smith, and Patkowski (BSP3) [30,40]. Contrary to the main analysis, here we do not fit the line intensity but fix it to the theoretical value [51]. We do so because for the older, less accurate PESs [38,45,46] the fitted line intensities, to some extent, artificially compensate the inaccurate values of some of the line-shape parameters. This comparison clearly demonstrates that the best agreement with the experiment is achieved for the BSP3 PES. This result is consistent with our expectations, since the most recent BSP3 surface was calculated using the coupled-cluster method with single, double, and perturbative triple excitations [CCSD(T)], augmented by full configuration interaction corrections, with the relative uncertainty in the minimum estimated as 0.4% ($\pm 0.045 \text{ cm}^{-1}$). Two other potentials studied here, SK and mMR, were obtained using much smaller Gaussian basis sets and lower levels of electronic structure theory. Moreover, the BSP3 PES involves the consistent treatment of a large range of intramolecular H-H distances and ensures a proper asymptotic behavior for large H₂-He separations [30].

V. CONCLUSION

We have demonstrated that the calculations from first principles are able to reproduce the experimental collision-perturbed molecular spectra at a subpercent-level accuracy. We used quantum scattering calculations to construct a collision operator that describes not only the dephasing and damping of the optical coherence, but also the flows of an optical coherence between different velocity classes. We solved a Boltzmann-like transport-relaxation equation to determine the velocity distribution of optical coherence and, hence, the collision-perturbed shapes of molecular lines. The calculations were validated on the highly accurate experimental spectra of the H₂ S(1) 3-0 and Q(1) 2-0 electric quadrupole transitions perturbed by helium. In addition to validating the theoretical methodology of accurate determi-

nation of the collision-induced shapes of molecular lines, we demonstrated that this approach can be used to test quantum-chemical calculations of the potential energy surfaces. This work demonstrates that theoretical calculations are capable of delivering line-shape parameters with the accuracy necessary to interpret experimental spectra for atmospheric, planetary, and astrophysical applications. With this approach, we show the possibility of calculating and validating beyond-Voigt line-shape parameters in order to populate line-by-line spectroscopic databases such as HITRAN [41], GEISA [42], and ExoMol [43] with requested accuracies in a wide temperature range for recent advanced database structures [44]. This approach is important for the lines relevant for atmospheric and astrophysical applications, especially for those which have not been accessed with laboratory experiments yet.
