Two-XUV-photon double ionization of Ne, induced by an intense few-pulse attosecond train with a  $\sim$ 4 fs envelope duration is investigated experimentally and theoretically. The experiment is performed at ELI-ALPS (Extreme Light Infrastructure Attosecond Light Pulse Source) utilizing the recently constructed 10 Hz gas phase high-order harmonic generation SYLOS GHHG-COMPACT beamline. A total pulse energy up to  $\sim 1$  $\mu$ J generated in argon in conjunction with high-reflectivity optics in the XUV region allowed the observation of the doubly charged state of Ne induced by 40 eV central XUV-photon energies. The interaction of the intense attosecond pulse train with Ne is also theoretically studied via second-order time-dependent perturbation theory equations of motion. The results of this work, combined with the feasibility of conducting XUV-pump-XUVprobe experiments, constitute a powerful tool for many potential applications. Those include attosecond pulse metrology as well as time-resolved investigations of the dynamics underlying direct and sequential double ionization and their electron correlation effects.

# I. INTRODUCTION

When an atomic or molecular system is exposed to an external electromagnetic field a wide variety of processes may occur, depending on the interaction strength and wavelength of the radiation. At low intensities linear processes are occurring which can be described by first-order time-dependent perturbation theory. At increased intensities, typically >  $10^{10}$  W/cm<sup>2</sup>, nonlinear processes [1,2] start playing a significant role, as theoretically predicted [1] and experimentally inaugurated in the 1960s [2,3]. Here the wavelength of the radiation is a decisive parameter whether the interaction is multiphoton, commonly treated through lowest-order time-dependent perturbation theory (LOPT), or strong field (nonperturbative) type [4–7]. Besides higher-order harmonic generation (HHG) [8–12], which possesses the most exciting applications, of particular interest among these nonlinear processes is the double (or multiple) ionization. Double ionization can be a direct (without formation of intermediate ions) or sequential (with formation of lower charge states

Although extensively explored in the visible and infrared (IR) regions, the extension of the studies of such processes to the extreme ultraviolet (XUV) is limited mostly to acceleratorbased facilities such as free electron lasers (FELs) [13-15] (and references therein), offering remarkably high pulse energies, but with shot-to-shot instabilities [16,17] and, until recently [18,19], relatively long pulse durations. On the other hand, coherent, tabletop, laser-driven sources based on gas phase HHG are versatile, provide routinely subfemtosecond temporal resolution, and have relative good shot-to-shot stability. The inherently low conversion efficiency of the generation process, however, limits the number of emitted photons. To this end, extended efforts in several laboratories have led to the development of novel HHG beamlines that have reached pulse energies and durations that have allowed the observation of nonlinear XUV processes [20–30], recently even beyond the two-XUV-photon ionization [31-34], as well

2469-9926/2022/106(4)/043117(8)

that ionize further) process. The particular interest is due to the possible electron-electron correlation effects and their dynamics that may underlie the process. Electron-electron correlation effects may be present in either a direct (without formation of intermediate ions) or a sequential (with formation of lower charge states that ionize further) process.

<sup>\*</sup>chara@iesl.forth.gr

as strong-XUV-field effects [35]. Inducing such phenomena is a vital tool in studying ultrafast dynamics, that can be used to initiate, probe, or even control processes that are occurring on the few femtosecond (fs) to attosecond (as) timescales in atomic and molecular systems (see [36-44] and references therein). The key feature in intense coherent XUV sources, based on HHG in gaseous media, is loose focusing. This allows the interaction with high laser pulse energies without depleting the generation medium. Loose focusing geometries are exploited in the so-called SYLOS GHHG-COMPACT beamline at the ELI-ALPS (Extreme Light Infrastructure Attosecond Light Pulse Source) user research infrastructure [45]. With this beamline, high-order harmonic emission with pulse energies in the  $\mu$ J range has recently been achieved. These pulse energies in conjunction with very short pulse durations were evaluated as sufficient for inducing nonlinear processes in the XUV region.

In this work, we investigate the two-photon double ionization of Ne induced by intense XUV radiation. The doubly charged Ne species are produced by a few-pulse train with an estimated envelope pulse duration of 3-4 fs, synthesized by a comb of harmonics (23rd-31st) centered at 40 eV photon energy and intensity of the order of  $10^{12}$  W/cm<sup>2</sup>. The experimental results are supported by theoretical calculations that evaluate the possible double-ionization pathways of Ne, indicating that both the direct and the sequential processes are significantly contributing to the double ionization. Thus, we observe a two-XUV-photon double ionization, with significant contribution of the direct process, while the two-photon sequential channel is partially open. Two-photon ionization induced by a single harmonic (27th) at photon energy 45 eV [23] has been reported in the past. At photon energies around 100 eV [30], multiple ionization has been reported in a work that was inconclusive with respect to the presence of a direct double-ionization process. Theoretical work on that experiment [46] has shown that a direct two-photon channel contributed to an inner shell fivefold ionization of Xe. To our knowledge the photon energies of this work are the highest of a harmonic comb, i.e., a superposition of discrete harmonics that have induced so far a hybrid direct and sequential twophoton double ionization of outer shell electrons. The present results establish the SYLOS GHHG-COMPACT beamline of ELI-ALPS as an intense attosecond [47] XUV beamline with which users can study or exploit nonlinear processes in the XUV spectral region. The work presented in this paper aims to disseminate the availability of such a user beamline and its capacity to the international community. While here the 10 Hz SYLOS system has been used, similar results will in the near future be produced with the 1 kHz SYLOS laser chain [48] enabling electron-electron and ion-electron coincidence XUV-pump-XUV-probe experiments with sub-fs temporal resolution.

### **II. EXPERIMENTAL METHODS**

In the present work the attosecond beamline is driven by the 10 Hz stage of the terawatt (TW) class SYLOS Laser system, delivering IR pulses with energy up to 40 mJ and 10 fs duration at a carrier wavelength of 850 nm [49]. Based on the concept of loose focusing of the driving field, the compressed IR radiation is steered towards the interaction region by means of a 10 m focal length spherical mirror. The long focusing configuration, as discussed above, allows the interaction with high laser pulse energies, increasing at the same time the number of emitters contributing to the total XUV emission [50-52]. As a consequence, the beamline generates XUV pulses in the  $\mu$ J energy range. In particular, when Ar is used as a generating medium, the total XUV pulse energy in the generation region is  $\sim 1 \ \mu J$  with the photon energies spanning the range of 16-50 eV. Although using Xe would have led to higher-XUV pulse energies, Ar gas was chosen due to its higher cutoff photon energies, which are more favorable for the excitation of the processes investigated in the present work. Based on recently developed arrangements under similar experimental conditions [31,32], the XUV radiation is generated by implementing a dual pulsed gas jet configuration placed near the focal area of the IR beam. Both gas jets are operated by piezoelectrically driven pulsed nozzles with the backing pressure optimized and set at 3.5 bars. The dual gas jet arrangement, exploiting a quasi-phase-matching strategy, leads to an enhancement compared to a single gas jet. Placing the first gas jet at the focusing plane of the driving field, the emitted XUV energy is optimized by adjusting the pressure. Then the second gas jet is switched on, and by moving it along the propagation axis, a relative enhancement of  $\sim 2$  is observed at a  $\sim 14$  cm distance between the two jets. The generated XUV radiation and the fundamental IR copropagate and impinge on a silicon plate (Si) placed at Brewster's angle ( $\sim$ 75°) for the IR radiation. The Si plate significantly reduces the amount of IR radiation and reflects 50%-60% of the XUV beam's energy [53]. Additionally, an aperture of 5 mm diameter is placed before the Si reflection, blocking the outer part of the residual IR beam. Furthermore, a mount hosting metallic filters is introduced in the beam path for the spectral selection of the XUV radiation, also eliminating any remaining amount of the fundamental frequency. For the experimental investigations in this work a 150 nm Al filter transmitting the harmonics with order  $q \ge 11$  was used. The XUV pulse energy was measured with a calibrated XUV photodiode, placed after the metallic filter. The photodiode was mounted on a translation stage that could move it in and out of the beam path. Moreover, the filtered XUV beam could be spatially characterized by means of an XUV beam profiler, consisting of a pair of multichannel plates (MCPs) and a phosphor screen followed by a CCD camera. Finally, the spectral components of the generated XUV radiation are recorded by a flat field spectrometer (FFS) which is attached to the beam line. After the XUV emission optimization and characterization, the beam is introduced into the detection chamber in which the interaction of the harmonic radiation with the Ne gas is studied. The XUV beam impinges at almost normal incidence onto a multilayer spherical mirror of 5 cm focal length mounted on a multiple-translation-rotation stage. The multilayer mirror has  $\sim 40\%$  reflectivity at 40 eV central photon energy with a bandwidth of  $\pm 2 \text{ eV}$  and focuses the radiation into the Ne gas target. The Ne gas is supplied into the interaction region by means of a piezo-based pulsed nozzle having its orifice very close to the XUV focus. The interaction products are recorded with a time-of-flight (TOF) ion mass spectrometer.

FIG. 1. (a) Two-XUV-photon double-ionization scheme of Ne. Ne<sup>2+</sup> is formed through either a direct or a sequential ionization process, induced by an XUV pulse with 40 eV central photon energy. (b) A typical XUV spectrum. The black filled curve depicts the measured harmonic radiation, the red-dashed curve the multilayer mirror reflectivity centered at 40 eV, while the blue curve filled with white color is the corrected spectrum after the reflection by the multilayer mirror.

Taking into account the measured XUV energy, the reflectivity of the Si plate, and the transmission of the Al filter as well as the reflectivity of the multilayer XUV focusing mirror, the energy of the harmonic radiation in the interaction region can be estimated. Furthermore, with an evaluation of the XUV focal spot, based on previous experimental investigations with similar XUV focusing geometries [28], as well as of the time duration of the attosecond pulse train (APT) envelope, the maximum peak intensity in the interaction region is estimated to be of the order of  $10^{12}$  W/cm<sup>2</sup>. Although the values reported in this work are expected to be improved as further optimization is still ongoing, already at such intensity levels nonlinear processes are expected to be observed upon interaction with atomic and molecular systems. In fact, excitation of Ne with XUV radiation of 40 eV photon energy leads to the observation of Ne<sup>2+</sup> ions via a nonlinear ionization process. In Fig. 1(a) the excitation scheme of Ne is presented, depicting the possible XUV-photon induced double-ionization channels for the harmonics transmitted by the Al filter and reflected by the multilayer spherical mirror. Under the influence of the XUV radiation used in the experiment, there are three possible channels producing Ne<sup>2+-</sup>ions. As depicted, these channels are either direct, through simultaneous absorption of two XUV photons of 40 eV energy, or sequential. In the

FIG. 2. (a) TOF ion mass spectrum produced by the interaction of the XUV radiation with Ne gas. *m* is the mass number and *Q* the charge state. (b) XUV intensity dependence of the <sup>20</sup>Ne<sup>2+</sup> yield (red-dotted circles). The slope of  $1.9 \pm 0.2$  evidences the second-order nonlinearity of the ionization process. In contrast, the He<sup>+</sup> ion yield (gray-dotted rhombus) has a linear dependence on the XUV intensity, with a slope of  $1.2 \pm 0.1$ , as expected for a single photon ionization process. In both cases the error bars correspond to one standard deviation of the integrated ion signals.

latter case, however, considering the 40 eV central photon energy of excitation, double ionization requires a three-photon absorption process. In particular, the first photon absorbed by Ne leads to the formation of an ionic Ne<sup>+</sup> state. Absorption of a second photon may then occur, leading to ionization of the Ne<sup>+</sup> ion. Finally, contribution of a sequential two-photon double-ionization process has to be considered since a small fraction of the ionizing spectrum has photon energies exceeding the ionization potential of Ne<sup>+</sup>. Indeed, as indicated in the theoretical part of this work, both the sequential and the direct processes contribute considerably to the double ionization under the present experimental conditions. In Fig. 1(a) the black field curve depicts a typical measured HHG spectrum produced in Ar, recorded by means of the FFS. The photon energies reach up to  $\sim$ 48 eV, corresponding to the 33rd harmonic of the frequency of the driving field. While the cutoff of the emitted spectrum is  $\sim 100 \text{ eV}$  [47], the  $\sim 50 \text{ eV}$  highest measured photon energy results from the Si reflectivity edge [53]. The red dashed curve is the reflectivity of the XUV multilayer spherical mirror, while the blue-white filled curve is the corrected spectrum introduced in the interaction region.

#### **III. EXPERIMENTAL RESULTS**

Figure 2(a) presents a characteristic TOF mass spectrum produced by the interaction of the focused 40 eV XUV radiation with Ne gas. In the recorded spectrum singly and doubly charged Ne are observable at m/Q = 20 and m/Q = 10, respectively, *m* being the mass number and *Q* the charge state of the ion. The other ionic mass peaks can be attributed to the additional species present in the residual gas in the interaction zone (coming from impurities in the gas and contamination in the chamber and gas valve). Those include He<sup>+</sup>, H<sup>+</sup>, N<sup>+</sup>, O<sup>+</sup>, OH<sup>+</sup>, and H<sub>2</sub>O<sup>+</sup>. It should be noted that these ions are produced by single-photon-ionization processes since the photoexcitation energy exceeds their ionization energies. The inset of Fig. 2(a) shows an expanded view of the portion of the TOF spectrum, for clarity reasons, in which <sup>20</sup>Ne<sup>2+</sup> is visible along with  ${}^{22}Ne^{2+}$ . The production of the doubly charged Ne species induced by a single-XUV-photon process would require photon energies larger than 62.5 eV. However, the spectrum reflected by the Si plate spans up to  $\sim 50$  eV. Moreover, as mentioned, after the generation the filtered XUV beam is focused by means of a multilayer mirror with its reflectivity centered at 40 eV. Thus the observation of <sup>20</sup>Ne<sup>2+</sup> is clear evidence of a nonlinear process induced by the intense XUV radiation. In order to confirm the nonlinear nature of the process, however, two additional measurements were conducted. According to lowest-order perturbation theory one expects the ion yield produced via a nonlinear process to scale proportionally with  $I^n$ , I being the intensity of radiation and n the minimum number of photons required by the ionization process [36]. The dependence of the  $Ne^{2+}$  yield on the XUV intensity has been measured and the results are presented in Fig. 2(b). The measured quadratic behavior is indicative of a dominant second-order process.

For the XUV intensity dependence of the double ionization of Ne, different TOF spectra were recorded and the  $^{20}$ Ne<sup>2+</sup> ion mass peak was integrated. The gas pressure in the interaction region was kept low, and adjusted and monitored, avoiding any unwanted space charge effects which affect the ionic distributions. The XUV pulse energy was varied by changing the delay between the opening of the HHG gas-jet nozzle and the arrival time of the driving IR pulse, thus changing the effective atomic density within the time interval of the interaction between the IR pulse and the gas medium. This controllable variation of the total XUV energy is illustrated by the variation of the yields of the single-photon-ionization products, such as the H<sub>2</sub>O<sup>+</sup> and He<sup>+</sup> ions. The measured yield of these products is proportional to the XUV intensity in the interaction region.

The measured <sup>20</sup>Ne<sup>2+</sup> ion signal is shown in log-log scale as a function of the XUV intensity in Fig. 2(b). The measured slope of  $1.9 \pm 0.2$  is within the experimental error, in full agreement with the value of 2 expected from theory, evidencing the pronounced two-photon character of the double-ionization process.

As further proof of the nonlinearity of the doubleionization process, the XUV focusing mirror was translated along the propagation axis in steps of 100  $\mu$ m. TOF spectra were recorded at various positions of the mirror by averaging 100 shots and the ion signal of the ionization volume was integrated. Taking into account the ion spectrometer's entrance diameter of 5 mm, for the displacement range of the measurement, the spectrometer essentially measures ions from the entire ionization volume. As demonstrated in Fig. 3(a)the  $^{20}\mathrm{Ne}^{2+}$  yield strongly varies when moving the focusing mirror, keeping the gas jet position and the spectrometer's entrance fixed. This is because for a two-photon process the measured ion signal scales quadratically with the intensity, i.e., inversely quadratically with the beam cross section, and increases linearly with the beam cross section because of the linear dependence of the number of ionizing atoms in the beam cross section. The net decrease of the ion signal with the beam cross section is thus linear. Hence, assuming a

FIG. 3. (a) Measured  ${}^{20}\text{Ne}^{2+}$  yield as a function of the position of the focus with respect to the TOF entrance. (b) He<sup>+</sup> signal as a function of the focusing position. The squares represent the measured data points with the corresponding error bars being a standard deviation of the integrated ion signal. The red lines represent a Lorentzian (a) and a constant (b) fit of the experimental data.

Gaussian XUV beam, the signal variation with the mirror position becomes Lorentzian. In contrast, as depicted in Fig. 3(b), the products of a single-photon-ionization process, such as the singly charged He, show an almost constant behavior. This is because the number of ions produced by a linear process depends only on the pulse energy which remains constant as the mirror is moved. The signal does not depend on the cross section because the intensity decreases linearly with it and the number of ionizing atoms increases linearly. The two variations cancel each other. Finally, an insignificant variation of the signal as the mirror moves is expected due to the gas pressure distribution in the interaction region considering the 0.5 mm gas jet orifice and the Lorentzian expansion of the gas density. The insignificance of the effect is evidenced by the negligible variation of the He<sup>+</sup> signal. These two intensitydependent measurements clearly evidence the nonlinearity of the phenomena involved in the production of doubly charged Ne species.

## **IV. THEORETICAL CALCULATIONS**

The interaction of the XUV radiation with Ne is treated via second-order time-dependent perturbation theory equations of motion (EOMs) which include the direct double ionization (DDI) and sequential double ionization (SDI) channels. In the present calculations the excitation path leading to the nearest autoionizing state (AIS) Ne  $\rightarrow$  Ne(2*s*<sup>-1</sup>3*p*) at ~45.1 eV

above the Ne ground state is also included. We have calculated its contribution to the populations and it is found to play an insignificant role in the doubly ionized signal relative to the direct and sequential ionization paths in accordance to similar findings in the case of helium [54]. This is due to its relatively long lifetime  $\sim 51$  fs as well as its large radial extension, resulting in a small electric transition amplitude for an excitation via further photon absorption. In practice this means that the relative phases of the field play no role in the results, and it is only the relative amplitudes of the individual harmonics that enter in the final equations via the pulse envelope.

Based on this observation we have omitted the AIS in the following discussion and the EOMs reduced to the below equation set:

$$\dot{\rho}_0(t) = -\left[\sum_q \gamma_{1q} I_q(t) + \sum_q \gamma_{2q} I_q^2(t)\right] \rho_0,$$
 (1a)

$$\dot{\rho}_{1}(t) = -\left[\sum_{q>27} \gamma_{1q}^{+} I_{q}(t)\right] \rho_{1}(t) + \left[\sum_{q} \gamma_{1q} I_{q}(t)\right] \rho_{0},$$
(1b)

$$\dot{\rho}_{2d}(t) = \left[\sum_{q} \gamma_{2q} I_q^2(t)\right] \rho_0, \qquad (1c)$$

$$\dot{\rho}_{2s}(\varepsilon,t) = \left[\sum_{q>27} L_q(\varepsilon)\gamma_{1q}^+ I_q(t)\right]\rho_1(t),\tag{1d}$$

$$L_{q}(\varepsilon) = \frac{\gamma_{1q}^{+}/2 \pi}{(E_{1} + \omega_{q} - \varepsilon)^{2} + (\gamma_{1q}^{+}/2)^{2}},$$
 (1e)

where  $I_q(t)$  represents the harmonic envelopes,  $I_q \sim E_q^2(t)$ . The  $\rho$ 's represent the populations of the different ionization stages of neon with initial conditions  $\rho_0(0) = 1$  and  $\rho_1(0) =$  $\rho_{2d}(0) = \rho_{2s}(0) = 0; \ \rho_{2d}(t)$  represents the Ne<sup>2+</sup> population due to the DDI while  $\rho_{2s}(t)$  represents the corresponding population to the SDI pathway. The DDI path from the Ne ground state to Ne<sup>2+</sup> is modeled via the two-photon ionization rates  $\gamma_{2q}^{(2)} = 2\pi |\mu_{2q}^{(0)}|^2$  with  $\mu_{2q}^{(d)}$  being a precalculated two-photon dipole matrix element for the DDI channel, evaluated at  $E_{2d;q} = E_0 + 2\omega_q$ . For the SDI pathway, that is, from the neutral Ne to the singly ionized neon, Ne<sup>+</sup>, and from there to the doubly ionized  $Ne^{2+}$  we have calculated for the first step the partial ionization widths  $\gamma_{1q} = 2\pi |\mu_{1q}^{(0)}|^2$  where  $\mu_{1q}^{(0)}$  are the dipole transition matrix element from the neutral Ne to Ne<sup>+</sup> calculated at the energies  $E_q = E_1 + \omega_q$ , where  $E_0$ ,  $E_1$  are the energies of the neutral, Ne, and the singly charged neon, Ne<sup>+</sup>, relative to the double-ionization threshold; so the energy of the Ne<sup>2+</sup> ground state is set to zero,  $E_2 = 0$ . For the second step the partial ionization rates are  $\gamma_{1q}^+ = 2\pi |\mu_{1q}^{(1)}|^2$ where  $\mu_{1q}^{(1)}$  are the dipole transition matrix element from Ne<sup>+</sup> to Ne<sup>2+</sup> evaluated at  $E_{2s;q} = E_1 + \omega_q$ . For sufficiently long pulses within a long pulse perturbation theory only the 29th and the 31st harmonics contribute to the second step as  $E_1$  +  $\omega_q < E_2 = 0$  for q = 23, 25, 27. However, the finite duration of the pulse allows contribution due to its frequency spectrum outside these sharp harmonic frequencies. This necessitated involving energy-resolved Ne<sup>2+</sup> states which include the

contribution of these closed channels at lower frequency via an effective Lorentzian factor  $L_q(\varepsilon)$  [55,56]. At the end of the pulse the SDI contribution is summed over all the respective Ne<sup>2+</sup> energies and the total DI signal is calculated as

$$\rho_2 = \rho_{2d}(t \gg \tau_p) + \int d\varepsilon \ \rho_{2s}(\varepsilon, t \gg \tau_p). \tag{2}$$

For our calculations we have used the single-ionization cross section from Ne to Ne<sup>+</sup> as  $\sigma_1 = 8 \times 10^{-18} \text{ cm}^2$  and from Ne<sup>+</sup> to Ne<sup>2+</sup> as  $\sigma_1^+ = 6.0 \times 10^{-18} \text{ cm}^2$ . Our calculations showed that the cross section are relatively constant in magnitude across the pulse's frequency range. The two-photon direct double-ionization cross section was calculated using uncorrelated final continuum states for the Ne<sup>2+</sup>; the estimated value used was  $\sim \sigma_{2d} = 1.4 \times 10^{-50} \text{ cm}^4 \text{ s} [57,58]$ . Unfortunately, we lack a more elaborate approach to calculate this cross section due to the neon's multielectron nature which makes it a nontrivial matter to calculate doubly ionized states; nevertheless, we believe that the uncorrelated assumption provides a good order of magnitude estimation for our purposes. From the above cross sections we calculated the corresponding dipole matrix elements,  $\mu_{nq}$ , using the well-known relation  $\sigma_n^{(j)} = 2\pi (2\pi/c)^n \omega_q^n |\mu_{nq}^{(j)}|^2$  (in a.u.) for n = 1, 2 and j = 0, 1 for ionization from the Ne and Ne<sup>+</sup>.

Because the duration of the XUV pulse has not been measured we investigate three distinct cases. These are (i) using an XUV pulse resulting from a Fourier transform (FT) of the measured XUV spectrum: Although it is well known that harmonic pulses are chirped (both the envelope of the train and the individual pulses) the calculation with a Fourier transform limited (FTL) pulse is performed for completeness, particularly because pulse compression possibilities have been previously demonstrated [59]. (ii) Using a 4 fs long Gaussian pulse: This duration is assumed as a result of findings of previous works [32,35] which indicate that the duration of the envelope of the XUV pulse train is  $\sim \sqrt{6}$ , suggesting that the generation of plateau harmonics can be essentially treated as a  $\sim$ sixth-order nonlinear process. For the 10 fs long driving laser field of the present work this corresponds to a  $\sim$ 4 fs long envelope. (iii) Using a 3 fs long Gaussian pulse: This is derived from case (i), where the pulse train is essentially reduced to a single pulse [inset of Fig. 4(a)] with negligibly small side pulses. From previous works [22,32] we anticipate that the duration of the pulses in an XUV pulse train, measured through 2second-order intensity volume autocorrelation, is typically about a factor of 2 larger than the FTL duration. For the present conditions this would result in an XUV duration of 3 fs.

As part of our investigation we solved the EOMs of Eq. (2) with pulses of peak intensity ranging from  $1 \times 10^{12}$  to  $1 \times 10^{13}$  W/cm<sup>2</sup> for all three cases. The calculated Ne<sup>2+</sup> ion yield (in arbitrary units) resulting from the sequential and/or direct channel as a function of the XUV intensity is shown in Fig. 4. The insets are the used XUV pulses. As presented in Fig. 4, both DDI and SDI yields scale with the slope of  $\approx 2$  over this intensity range, thus confirming the presence of a second-order nonlinearity, not affected by the presence of autotomizing states or by saturation of any of the steps involved.

FIG. 4. Log-log plot of the DDI and SDI yields (in arbitrary units) resulting using an FTL (a), a 3 fs long Gaussian (b), and a 4 fs long Gaussian XUV pulse (c). The slope of all lines is 2, indicative of a second-order process. The ratio of the DDI to the SDI yield scales essentially linearly with the XUV pulse duration.

As depicted in Fig. 4, for the excitation pulses with the given properties (peak intensity, duration) both the SDI and the DDI pathways contribute significantly to the production of doubly charged Ne, in all three cases. While for the FTL pulse the yield of the direct process is slightly higher than that of the sequential one, in the other two cases the sequential process becomes more probable than the direct one. Since the sequential process scales with the square of the XUV pulse duration, while the direct process scales linearly with it, it is expected that the ratio of the direct to the sequential process yield scales linearly with the XUV pulse duration [38]. This conclusion is in agreement with the results of our calculations.

Finally, it should be noted that the dominance of the DDI may also occur for longer pulses at higher intensities, at which the first step of the SDI is saturated and thus the SDI becomes linear with the intensity while the DDI is quadratic. However, such XUV intensities are not reached in the present work.

#### V. CONCLUSIONS AND PERSPECTIVES

In conclusion, in this work two-XUV-photon double ionization of Ne induced by intense coherent XUV radiation at ELI-ALPS is demonstrated. We compared the experimental data to theoretical calculations performed using three different pulse durations. The theoretical calculations indicate that both the direct and the sequential processes contribute to this two-XUV-photon double ionization, with their relative strength, as expected, varying linearly with the XUV pulse duration. In the present studies, the harmonic radiation is generated in Ar spanning the range of 16–50 eV with total pulse energy of  $\sim 1 \mu$ J. Using high-reflectivity XUV optics, a narrowband XUV spectrum with central photon energy at 40 eV and a total bandwidth of 4 eV is selected for the excitation of Ne with intensities of the order of  $10^{12}$  W/cm<sup>2</sup> in the interaction region. The measurements of the Ne<sup>2+</sup> yield as a function of the XUV intensity revealed a nonlinear behavior with a slope, in log-log scale, of nearly 2, indicating the secondorder nonlinearity underlying the double-ionization process. The calculated ion yields scale over the intensity range of  $1 \times 10^{12}$ -1  $\times 10^{13}$  W/cm<sup>2</sup> with the slope of 2, in agreement with the second-order nonlinearity measured experimentally. The presented results establish the recently constructed SY-LOS GHHG-COMPACT beamline at ELI-ALPS as an intense attosecond beamline with which nonlinear XUV processes can be studied and/or used. A potential step forward in the near future is to drive the beamline with the now operational 1 kHz repetition rate laser chain at ELI-ALPS. Two-XUV-photon direct double ionization at 1 kHz repetition rate enables electron-electron and electron-ion coincidence experiments which will shed light onto several open questions in electron-electron correlation and other ultrafast processes. The 1 kHz SYLOS GHHG-COMPACT beamline will host an advanced reaction microscope end station dedicated to such investigations.

#### ACKNOWLEDGMENTS

We acknowledge support of this work by the Hellenic Foundation for Research and Innovation (HFRI) and the General Secretariat for Research and Technology (GSRT) under the following grant agreements: GAICPEU (Grant No. 645) and Grant No. NEA-APS HFRI-FM17-3173, and the H2020 project IMPULSE (Grant No. GA 871161). The ELI-ALPS Project (Grant No.GINOP-2.3.6-15-2015-00001) is supported by the European Union and it is cofinanced by the European Regional Development Fund. S.K. acknowledges Project No. 2020-1.2.4-TÉT-IPARI-2021-00018, which has been implemented with support provided by the National Research, Development and Innovation Office of Hungary, and financed under the 2020-1.2.4-TET-IPARI-CN funding scheme. H.S., B.B., and M.F.K. are grateful for support by the Max Planck Society within the framework of the Max Planck Fellow program. M.F.K.'s work at SLAC is supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Scientific User Facilities Division. G.S. acknowledges financial support by the Deutsche Forschungsgemeinschaft Grant No. 429805582 and by the Bundesministerium für Bildung und Forschung (Project No. 05K19VF1). L.A.A.N.

GOIPG/2018/1070). I.O. and E.S. acknowledge support by the ELI-ALPS team during the experimental runs.
