(Received 1 August 2023; revised 21 May 2024; accepted 23 May 2024; published 17 June 2024)

Synthetic-dimension platforms offer unique pathways for engineering quantum matter. We compute the phase diagram of a many-body system of ultracold atoms (or polar molecules) with a set of Rydberg states (or rotational states) as a synthetic dimension, where the particles are arranged in real space in optical microtrap arrays and interact via dipole-dipole exchange interaction. Using mean-field theory, we find three ordered phases—two are localized in the synthetic dimension, predicted as zero-temperature ground states by Sundar *et al.* [Sci. Rep. **8**, 3422 (2018); Phys. Rev. A **99**, 013624 (2019)], and one is a delocalized phase. We characterize them by identifying the spontaneously broken discrete symmetries of the Hamiltonian. We also compute the phase diagram as a function of temperature and interactions, we find that the thermal phase transitions can be first or second order, which leads to a tricritical point on the phase boundary. By examining the dependence of the tricritical point and other special points of the phase boundary on the synthetic dimension size, we shed light on the physics for thermodynamically large synthetic dimension.

### I. INTRODUCTION

Synthetic-dimension platforms are more than a powerful tool for investigating interesting physics from broad fields; they are also a pathway for simulating interacting quantum matter that has no analog in other systems. A synthetic dimension is built using the internal or motional states of quantum particles such as ultracold atoms, molecules, and photons. When the levels are coupled with electromagnetic radiation, these platforms can be used to engineer Hamiltonians that are identical to a wide variety of Hamiltonians describing motion in real space. They are highly tunable, allowing independent control of the system parameters, including tunneling amplitudes and phases, and the on-site synthetic potentials.

Since the first proposal [1], several platforms have been experimentally realized. Examples include synthetic dimensions based on nuclear spin states [2–4], momentum states [5–13], optical clock states [14], harmonic trap states [15,16], Floquet states [17], and Rydberg states [18–20] of ultracold atoms and time and frequency states of photons [21–25]. There are also proposals to build synthetic dimensions using rotational states of polar molecules [26]. Observation of topological edge states [3,6,11,19,27–34], Anderson localization [7,12],

nonlinear physics [10], and the non-Hermitian skin effect [13], and the realization of synthetic gauge fields [2,3,35] and hyperbolic lattices [36,37] are some of the highlights. Proposals to engineer topological quantum field theory models [38] and other topological physics [39] further the versatility of these platforms.

Synthetic-dimension platforms have been utilized to observe not only single-particle phenomena but also unique interacting physics. Alkaline-earth atoms with nuclear spin states interact via SU(N) symmetric interactions that are non-local in the synthetic space [3,40–43], photonic states interact via synthetic-site-preserving interactions [23], momentum-space lattices have local (on-site) attractive interactions [44,45], and Rydberg atoms interact via dipolar exchange interactions [20] that are local (roughly nearest neighbor) in synthetic space.

In this work, we focus on a model of dipolar interacting quantum many-body systems first proposed to be built with rotational states of ultracold polar molecules trapped in optical microtraps [26]. The same model can also be realized with Rydberg states of ultracold atoms [19,20,27].

One of the intriguing features of this system is that for strong interactions compared to the synthetic-tunneling rates, the ground states are localized to finitely many sites in the synthetic dimension. They resemble thick strings (membranes) in one- (two-) dimensional real-space arrays of molecules or Rydberg atoms fluctuating in a two- (three-) dimensional real + synthetic space and hence are named the string or membrane phases. The essential features of these phases have been studied for some special cases. In Ref. [46], the

FIG. 1. Two real-space sites of a Rydberg atom  $(n \gg 1)$  array with  $N_s$  synthetic sites. The synthetic sites are indexed by  $\nu$  (1 to  $N_s$ ). Resonant microwaves couple alternating s (odd  $\nu$ ) and p (even  $\nu$ ) angular momentum states. Atoms interact via dipolar exchange. Deep traps prevent real-space tunneling

wave function for the string phase was exactly solved for one real dimension and one synthetic dimension when the synthetic-tunneling rates vanished. Mean-field theory [26] and the density-matrix renormalization group (DMRG) [46] predict that the string or membrane phase persists to infinitely large synthetic dimensions for any synthetic tunnelings for attractive interactions, while for repulsive interactions there is a critical synthetic tunneling at which the system transitions from a string or membrane to a disordered phase. Recently, stochastic Green's-function quantum Monte Carlo studies [47] showed that in two-dimensional real-space arrays, the membranes survive to finite temperatures in systems with a finite number of synthetic lattice sites and undergo a thermal phase transition into the disordered phase as temperature is raised.

However, fundamental questions remain unanswered: (1) Are these the only phases of this model? (2) Is there a simple physical understanding of the phases? (3) Do they persist at finite temperature for repulsive interactions? (4) How does the size of the synthetic dimension affect the phases and the critical temperature?

In this paper, we make progress on these questions. We identify three symmetry-broken phases, accessible to experiments by tuning a single system parameter. Two of the phases are localized in the synthetic dimension and were predicted in Ref. [26] and studied in [46,47], while our calculations reveal an additional ordered delocalized phase. By identifying the symmetry groups and a mean-field theory, we classify them by the discrete symmetries that they break and show that all of the nontrivial phases persist to finite temperature. We characterize the dependence on the synthetic-dimension size of all the phases and the transitions between them.

We also find a tricritical point on the thermal phase boundary for attractive interactions when there are more than six synthetic sites. In this case, the thermal transition is first order for weak synthetic tunnelings and second order for strong synthetic tunnelings with a tricritical point in between. We discuss the analogy of this phenomenon with the classical Potts and *p*-state clock model later.

We remark that one could alternatively view the system as a large spin model in lieu of using the synthetic-dimension perspective. However, the synthetic-dimension language and concepts emphasize the analogy of single particles with internal couplings to a particle hopping in a periodic lattice, which makes the powerful tools associated with Bloch wavefunction description natural. This also is the natural language for experiments that realize different coupling schemes such as topological Su-Schrieffer-Heeger chains [19,48,49] and the artificial gauge field on a ring [20] in one dimension and Aharonov-Bohm caging in two dimensions [50]. Moreover, the internal symmetries are naturally those associated with a synthetic dimension (i.e., translation in the synthetic dimension) that are awkward to describe in the spin language, where the natural symmetries are usually SU(N) or its various subgroups, such as SU(2), U(1), and  $\mathbb{Z}_2$ .

This paper is organized as follows: Sec. II discusses the platform and the Hamiltonian, Secs. III and IV describe the mean-field theory and the resulting phase diagram, and we conclude in Sec. V and suggest interesting open questions.

### II. RYDBERG ATOM AND MOLECULE SYNTHETIC DIMENSIONS

We consider a system of ultracold Rydberg atoms or polar molecules, trapped individually in optical microtraps or sites of an optical lattice in a one- or two-dimensional bipartite realspace geometry (Fig. 1). (Results for attractive interactions also apply to nonbipartite lattices.) Rydberg levels of atoms or rotational states of molecule are separated by microwave frequencies, allowing coherent control of several levels. The lattice is sufficiently deep to prevent real-space tunneling. Throughout the rest of this paper, we describe the system in terms of Rydberg states of ultracold atoms, but equivalent physics exists in polar molecules as well.

A set of Rydberg states, alternating between s and p angular momentum levels, is resonantly coupled with microwaves to form a linear synthetic dimension, as depicted in Fig. 1. This forms an open boundary condition, or the last state can be coupled to the first to have a periodic boundary condition. The power of the microwaves coupling pairs of synthetic sites sets the corresponding tunneling amplitude. The detuning of the microwaves from the resonant frequency sets the on-site potential energy. In our model, we fix all the synthetic tunnelings to be equal to each other and all the detunings to be zero, which is easy to achieve experimentally.

Pairs of Rydberg atoms interact strongly via the dipoledipole interaction [51]. In general, interactions depend on the synthetic sites of the two atoms. But our choice of alternating s and p angular momentum states implies that the interaction can be nonzero only between sites of different parities with the pairs of states next to each other being the strongest. For most scenarios, the interaction strength between sites separated by three synthetic sites is small and is ignored in our calculations. The interaction strength does not vary significantly with the principal quantum numbers n of the Rydberg states for large n. Hence, we approximate to having nonzero interaction strengths only when two atoms are separated by exactly one synthetic site and assume they are equal. The Hamiltonian describing the situation is

$$H = -J \sum_{\nu=1}^{N_s} \sum_{i} |\nu, i\rangle \langle \nu - 1, i| + \text{H.c.}$$

$$+ V \sum_{\nu=1}^{N_s} \sum_{\langle i, j \rangle} |\nu, i; \nu - 1, j\rangle \langle \nu - 1, i; \nu, j| + \text{H.c.},$$
(1)

where  $N_s$  is the total number of synthetic sites; J is the tunneling amplitude between a pair of synthetic sites, which we assume throughout is positive; V is the interaction energy between two atoms; and  $|v, i\rangle$  represents an atom at real (synthetic) site i (v), with v = 0 and  $v = N_s$  identified to induce the periodic boundary condition. We have assumed the quantization axis is perpendicular to the array (or otherwise oriented so that the dipolar interaction is isotropic) and have truncated the  $1/r^3$  interaction to nearest neighbors. In one dimension we expect this truncation to have only relatively small effects on the phase diagram, and that is likely also true in two dimensions. In three dimensions the  $1/r^3$  interaction and anisotropy are likely to play major roles, a question we leave to future work. Some further discussion on these points can be found in the conclusions.

Considering an infinitely large lattice in real space and the periodic boundary condition in the synthetic dimension, the Hamiltonian in Eq. (1) has a  $\mathcal{D}_{2N_s} \times \mathcal{T}$  symmetry;  $\mathcal{D}_{2N_s}$ is the symmetry group of a regular polygon of  $N_s$  sides, and  $\mathcal{T}$ is the discrete symmetry group of the real-space lattice.

### **III. MEAN-FIELD THEORY**

To calculate the phase diagram of the Hamiltonian in Eq. (1), we employ a mean-field approximation to decouple the interaction terms, giving

$$\mathcal{H} = \sum_{\nu=1}^{N_s} \sum_{s=\pm 1} \left( -\frac{J}{2} + \tilde{V} \phi_{\nu,\bar{s}}^* \right) |\nu, s\rangle \langle \nu - 1, s| + \text{H.c.}, \quad (2)$$

where  $s = \pm 1$  label the two sublattices of the bipartite lattice,  $\bar{s} = -s$ ;  $\tilde{V} = \frac{Vz}{2}$ , with z being the number of nearest-neighbor atoms; and

$$\phi_{\nu,s} = \langle |\nu, s\rangle \, \langle \nu - 1, s | \rangle \tag{3}$$

are the mean fields. As mentioned above, the periodic boundary condition is imposed by identifying v = 0 and  $v = N_s$ . We allow the mean fields to differ on the two different sublattices in the real dimension. This will be necessary to describe the phases for V > 0. Expanding the expectation value on the right-hand side of Eq. (3), we see that the mean fields satisfy the self-consistent equation

$$\phi_{\nu,s} = \frac{1}{\mathcal{Z}} \sum_{\alpha} \langle \alpha | \nu, s \rangle \langle \nu - 1, s | \alpha \rangle e^{-E_{\alpha}/T}, \qquad (4)$$

where  $\mathcal{Z} = \sum_{\alpha} e^{-E_{\alpha}/T}$  is the mean-field partition function and  $|\alpha\rangle$  and  $E_{\alpha}$  are the  $\alpha$ th eigenstate and eigenenergy of the mean-field Hamiltonian in Eq. (2), respectively. Note that  $|\alpha\rangle$  and  $E_{\alpha}$  are functions of the mean fields,  $\{\phi_{\nu,s}\}_{\nu=1,\dots,N_s;s=\pm 1}$ . We have set the Boltzmann constant  $k_B = 1$ .

The mean-field approximation identifies all real lattice points in a sublattice, thus reducing the symmetry group T

to  $\mathbb{Z}_2$ . Therefore, the mean-field Hamiltonian [Eq. (2)] has  $\mathcal{D}_{2N_s} \times \mathbb{Z}_2$  symmetry when all the mean fields are equal, which corresponds to the disordered phase.

We iteratively solve for the mean fields using Eq. (4). We start with a random initial seed for each mean field in (-1, 1). The results are considered converged when  $|\phi_{\nu,s}^k - \phi_{\nu,s}^{k-1}| < 10^{-6} \forall \nu, s$ ; *k* labels the iteration step. We estimate a relative error of less than 2%, where the relative error is defined as  $|(\phi_{\nu,s}^{k_{\text{max}}} - \phi_{\nu,s}^{k_{\text{max}}/2})/\phi_{\nu,s}^{k_{\text{max}}}|$ , where  $k_{\text{max}}$  is the number of iterations needed for the mean fields to be considered converged.

### **IV. PHASE DIAGRAM**

Mean-field theory predicts a phase diagram with four phases (Fig. 2). They are characterized by the subgroups of  $\mathcal{D}_{2N_s} \times \mathbb{Z}_2$ , the symmetries of the Hamiltonian in Eq. (2). The localized I phase (green) breaks the  $\mathcal{D}_{2N_s}$  symmetry but retains the  $\mathbb{Z}_2$  symmetry, while the localized II (blue) phase breaks both. The delocalized II (red) phase preserves only the symmetry of simultaneous rotation by half the syntheticdimension size and real-space exchange. The delocalized I (white) phase is the trivial or disordered phase where all the mean fields are equal and the system has the full  $\mathcal{D}_{2N_s} \times \mathbb{Z}_2$ symmetry. Insets (iv)–(vii) of Fig. 2 depict the ground-state wave functions  $|\Psi^g\rangle$  in different phases, corresponding to the white semicircles in the main plot.

The phases are diagnosed with three order parameters,

$$\int_{s}^{\text{rot}} = \left| \sum_{\nu=1}^{N_{s}} \phi_{\nu,s} e^{-i2\pi\nu/N_{s}} \right|,$$
(5)

$$\varphi^{\mathbb{Z}_2} = \sum_{\nu=1}^{N_s} |\phi_{\nu,1} - \phi_{\nu,-1}|^2, \tag{6}$$

$$\varphi^{r_{N_s/2} \times \mathbb{Z}_2} = \sum_{\nu=1}^{N_s} \left| \phi_{(\nu+N_s/2),1} - \phi_{\nu,-1} \right|^2 \tag{7}$$

for even  $N_s$ . Each vanishes if and only if the corresponding symmetry is preserved.  $\varphi_s^{\text{rot}}$  distinguishes phases with from those without all the rotation symmetries of the dihedral group  $\mathcal{D}_{2N_s}$ . The value of s is irrelevant for the phases in the mean-field theory. From panel 3 in Fig. 2, it is evident  $\varphi^{\rm rot}$  separates the trivial phase, delocalized I, from the rest of the phases.  $\varphi^{\mathbb{Z}_2}$  distinguishes phases with sublattice exchange symmetry. The sublattice exchange symmetry, characterized by  $\varphi^{\mathbb{Z}_2}$ , is never broken for attractive interactions, as seen in panel 2 in Fig. 2, but is broken in all the nontrivial phases for repulsive interactions. For even  $N_s$ , the delocalized II phase (red region in Fig. 2) is the only nontrivial phase preserving the  $r_{N_s/2} \times \mathbb{Z}_2$  symmetry. For odd  $N_s$ , rotation by  $N_s/2$  is not well defined. Instead, if we perform rotation by  $(N_s \pm 1)/2$ sites, then  $r_{(N_s \pm 1)/2} \times \mathbb{Z}_2$  is "almost" a symmetry. The order parameter in the delocalized II phase is small (<0.1) compared to localized I and II phases (0.3-1) but not exactly zero. The phase diagram of Fig. 2 is sketched by adding the three different colors (in an RGB sense) of panels 1-3 at individual points.

In addition to their symmetry-breaking features, an intriguing feature of the localized I and II phases is that they are localized along finitely many synthetic sites (i.e., the

FIG. 2. Phase diagram for  $N_s = 12$  in the  $T/|\tilde{V}|-J/\tilde{V}$  plane. The green, blue, and red regions correspond to the 'localized I,'' "localized I,'' and "delocalized II" phases, respectively, and the white area corresponds to the disordered phase, "delocalized I.'' On the right, panels 1, 2, and 3 show the density plots of the three order parameters,  $\varphi^{r_{N_s/2} \times \mathbb{Z}_2}$ ,  $\varphi^{\mathbb{Z}_2}$ , and  $\varphi^{\text{rot}}$ . The *x* and *y* axes in panels 1, 2, and 3 are identical to those in the main plot. The phase diagram is obtained by superposing the three order parameters, colored as in panels 1, 2, and 3, so that each phase is uniquely identified. The black solid (dashed) line demarcates the phase boundaries corresponding to first- (second-) order transitions between the ordered and disordered phases. The black circle (magenta square) on the phase boundary denotes the tricritical point (meeting point of the localized II, delocalized II, and localized I phases). Insets (i) and (ii): The average of the three order parameters,  $\varphi_{av} = \frac{1}{3}(\varphi^{r_{N_s/2} \times \mathbb{Z}_2} + \varphi^{\mathbb{Z}_2} + \varphi^{\mathbb{Z}_2} + \varphi^{\text{rot}})$  versus  $T/|\tilde{V}|$ ; blue squares (red dots) correspond to the blue dotted (red solid) vertical cut. Inset (iii): The average of the order parameters plotted versus  $J/\tilde{V}$  for the dark blue dash-dotted horizontal cut. Insets (iv)–(vii): The ground-state wave function  $|\psi^g\rangle$  of the mean-field Hamiltonian at T = 0 corresponding to  $J/\tilde{V}$  at the white semicircles. The *y* axis corresponds to the  $N_s$  discrete synthetic sites, labeled by *n*. The columns correspond to the two sublattices,  $s = \pm 1$ . Both the color intensity and marker size vary proportionally with the absolute value of the wave function.

probability decays exponentially outside of a finite number of synthetic sites), as seen for the ground states shown in insets (v) and (vi) in Fig. 2. The existence of two localized ground states was already predicted in Ref. [26] using mean-field theory. For J = 0, Ref. [46] analytically proved that one-dimensional real-space arrays have ground states confined to two or three adjacent synthetic sites. Similar behavior is observed in our J = 0 mean-field theory: width-2 and width-3 states are degenerate and lower in energy than the disordered phase when  $N_s > 4$ , as shown in Appendix A.

The delocalized II phase, not reported in Refs. [26,46], is spread over a large fraction of the synthetic dimension, but the atoms are spread over opposite sets of synthetic sites on each sublattice. The system, however, remains invariant under simultaneous rotation by half of the synthetic sites and realspace sublattice exchange for an even number of synthetic sites.

We expect the localized I-delocalized I and delocalized I-delocalized II quantum critical points  $(J/V)_c$  to scale as  $O(N_s)$ , whereas the localized II-delocalized II one scales as O(1). Transitions from the disordered phase to any ordered phase suppress the kinetic energy by  $O(1/N_s)$  while enhancing the interaction energy by O(1). However, transitions between the two ordered phases enhance the interaction energy only by O(1). The scaling of the quantum critical points with  $N_s$  is further discussed and shown in Appendix B and Fig. 4.

All three nontrivial phases extend to nonzero temperatures for finite  $N_s \ge 5$ . However, the transition temperatures tend to zero as  $N_s \to \infty$ . A Peierls-like argument comparing the free energies,  $\Delta \mathcal{F} = \mathcal{F}_{ordered} - \mathcal{F}_{Delocalized I}$ , of the ordered phases and the delocalized I phase suggests this, and it is consistent with our analysis of the critical temperatures' dependence on  $N_s$ . We plot the highest critical temperature in each of the three ordered phases as a function of  $N_s$  in Fig. 3(a).

The orders of the thermal phase transitions depend on  $N_s$ and the ratio  $J/\tilde{V}$ . The phase boundary between the localized I and delocalized I phases hosts a tricritical point for  $N_s > 6$ . We observe that the phase transition changes from being first order at small  $J/|\tilde{V}|$  to being second order at large  $J/|\tilde{V}|$ with a tricritical point in between (black circle in Fig. 2). The value of  $T/|\tilde{V}|$  ( $J/|\tilde{V}|$ ) at the tricritical point decreases (increases) with  $N_s$  [Fig. 3(b)]. The inset in Fig. 3(b) strongly suggests that in the limit  $N_s \to \infty$ , the tricritical point is at  $T/|\tilde{V}| = 0, J/\tilde{V} = -\infty$ . This is consistent with the arguments of Ref. [26] that the V < 0 ground state for  $N_s \to \infty$  is always a string.

We understand the qualitative behavior of the tricritical point in two ways: an analytic argument for J = 0 and analogies to previously studied classical models. In Appendix A, we analytically show that the thermal phase transition is first (second) order at J = 0 for  $N_s > 6$  ( $N_s \le 6$ ). Furthermore, we note that the  $N_s$  dependence of the order of the phase

FIG. 3. Trends of the phase diagram with  $N_s$ . (a) Scaling of the highest critical temperature in each of the three phases with  $N_s$ . It appears that all three  $T_c^{\max}$  scale to zero with  $N_s$ , but at different rates. (b) Scaling of the tricritical point with  $N_s$ . The plot suggests that the tricritical point scales to  $J^{N_s=\infty}$ ,  $T^{N_s=\infty} = -\infty$ , 0. This is even more prominent in the inset, where the *x* axis is inverted to  $\tilde{V}/J$ . (c) Scaling of the meeting of the localized II, delocalized I, and delocalized II phases with  $N_s$ . The plot suggests that it scales to zero temperature but a finite tunneling as  $N_s \to \infty$ .

transition resembles that of the classical Potts model [52], if the synthetic sites are considered to be spin indices of a large spin  $[S = (N_s - 1)/2]$  system. For example, for the two-dimensional Potts model, the thermal phase transition is second (first) order when  $N_s \leq 4$  ( $N_s > 4$ ). For another large-spin model, the clock model, the analogy is less direct: the system undergoes a second-order thermal phase transition when  $N_s \leq 4$  and has a Berezinskii-Kosterlitz-Thouless phase intermediate to ordered and disordered phases for  $N_s > 4$ .

In making the analogy to classical models, it is worth noting that the synthetic-dimension Hamiltonian (1) has qualitative differences from both the Potts and clock models. The Potts model has a different symmetry—a full spinpermutation symmetry—whereas the clock model has the same  $D_{2N_s}$  symmetry but has nonlocal interactions between all synthetic sites.

A model that captures both the symmetry and the locality of the interactions in synthetic space was introduced and studied in Ref. [53]. It includes same-synthetic-site ( $J_0$ ) and nearest-synthetic-site ( $J_1$ ) interactions. When  $J_1 \gg J_0$ , the naive case corresponding to the quantum model, a direct phase transition from a narrow sheet (dubbed "ferromagnetic" there) to the disordered phase is found. For large  $N_s$  this is clearly first order, while for smaller  $N_s$ , the order is less clear—it is either a less drastic first-order or second-order transition (e.g., Fig. 3 of Ref. [53]). This classical analogy also suggests other interesting phenomena. For example, when  $J_1$  is sufficiently

FIG. 4. Zero-temperature phase boundaries between (a) the localized I and Delocalized I phases and (b) the localized II and Delocalized II phases as a function of  $1/N_s$ . Black dashed lines are guides to the eye for the mean-field extrapolation to  $N_s \rightarrow \infty$ (using cubic polynomials). DMRG results (green band) are for one real dimension plus one synthetic dimension with six real sites [46]. The QMC phase transition point [red circle in (a)] is for two real dimensions plus one synthetic dimension and  $N_s = 10$  [47].

larger than  $J_0$ , the transition becomes second order and may involve a second crossover or Berezinskii-Kosterlitz-Thouless transition, an interesting possibility in the quantum model.

The  $N_s$  dependence of the meeting point of the localized II, delocalized II, and delocalized I phases for repulsive interactions shows that the localized II phase extends only to finite  $J/\tilde{V}$  even as  $N_s \rightarrow \infty$ , in contrast to the localized I phase [Fig. 3(c)]. From Fig. 3(c), it seems that  $T/\tilde{V}$  goes to zero, but  $J/\tilde{V}$  tends to a finite value as  $N_s \rightarrow \infty$ . This qualitatively agrees with the findings of Ref. [26] and DMRG calculations of Ref. [46] that for  $N_s \rightarrow \infty$  and repulsive interactions, the system undergoes a quantum phase transition. For a more quantitative comparison between our mean-field theory and DMRG, see Appendix B.

Our phase boundary for attractive interactions is also qualitatively consistent with that computed with stochastic-Green's-function (SGF) quantum Monte Carlo (QMC) [47]. The SGF-QMC method is sign problem free for attractive interactions (only) and thus can calculate observables to high precision. Figure 9 of Ref. [47] shows the phase diagram for  $N_s = 10$  for a two-dimensional square lattice, finding a finitetemperature phase transition between the quantum membrane (localized I) and disordered (delocalized I) phases, as we predict from mean-field theory. The SGF-QMC transition temperature is similar to, although shifted from, the meanfield predictions, and the trends with  $N_s$  and  $J/\tilde{V}$  are similar. For example, both the QMC and the mean-field theory predict that the system undergoes a T = 0 quantum phase transition at finite  $J/\tilde{V}$ ; for  $N_s = 10$ , QMC finds this transition to be at  $J/\tilde{V} \approx -1.2$ , whereas our mean-field results determine it is at  $J/\tilde{V} \approx -1.7$ . Mean-field theory predicting the quantum critical point at a larger  $J/\tilde{V}$  is unsurprising since it ignores all fluctuations. For a more detailed comparison of the two methods see Appendix B.

Additionally, QMC observes only second-order phase transitions for  $N_s = 10$ . This could be because the tricritical point for  $N_s = 10$  is very weakly first order or because it occurs at a much lower value of  $J/\tilde{V}$  than shown in the QMC studies, or it could be that the transitions at all  $J/\tilde{V}$  for  $N_s = 10$  are second order. In the latter case, it is possible that the critical  $N_s$  above which the tricritical point first appears has been shifted from the  $N_s = 6$  value predicted by mean-field theory to  $N_s > 10$ . We believe this is likely, as the QMC results for  $N_s = 14$  and V = -5J (Fig. 7 of Ref. [47]) show a step feature suggestive of a first-order transition.

## V. CONCLUSION AND OUTLOOK

We calculated the phase diagram of a dipolar interacting quantum system with real and synthetic dimensions and analyzed the features of the phase diagram as a function of interaction, temperature, synthetic tunnelings, and syntheticdimension size. This model can be engineered with ultracold Rydberg atoms or polar molecules arranged in optical microtraps or optical lattices and external microwave couplings, with a recent study of its dynamics given in Ref. [20]. Tuning a single parameter,  $J/\tilde{V}$ , realizes a rich phase diagram with four distinct phases and both thermal and quantum phase transitions, which may be either first or second order.

Using mean-field theory and analyzing the results according to order parameters constructed based on the symmetry group, we classified the string or membrane phases predicted in Refs. [26,46]. Both these phases spontaneously break the  $D_{2N_s}$  symmetry of the model, with some remnant symmetries depending on the sign of V and whether  $N_s$  is even or odd. For V > 0, this phase breaks the real-space sublattice-exchange  $\mathbb{Z}_2$  symmetry.

In addition, we predict the existence of another symmetrybroken phase that is not string or membrane-like. This phase occurs for V > 0 over an intermediate range of  $J/\tilde{V}$ , and it enjoys a remnant symmetry under a simultaneous rotation by half the synthetic sites and sublattice exchange (for even  $N_s$ ). Moreover, the system is delocalized over a finite fraction of the synthetic space. It is an open question to what extent the localization plays a role beyond symmetry breaking—are the universal properties of the low-energy excitations of the ordered phases solely determined by the symmetry, or does the stringiness also play some additional role?

We observed the presence of both first- and second-order transitions with a tricritical point in between for  $N_s > 6$  and V < 0. The thermal phase transitions are second order for  $N_s \leq 6$ . The dependence of the order of the transition on  $N_s$  resembles Potts-model physics.

The scaling of the phase boundaries with  $N_s$  is consistent with earlier T = 0 mean-field calculations and the special cases that have been treated numerically. We showed that the tricritical point scales to  $(J/\tilde{V} \rightarrow -\infty, T \rightarrow 0)$  as  $N_s \rightarrow \infty$ ; hence, the localized I phase persists to arbitrarily large  $|J/\tilde{V}|$ at T = 0 for  $N_s \rightarrow \infty$ . Similarly, we showed that the meeting point of the localized II, delocalized II, and delocalized I phases scales to a finite  $J/\tilde{V}$  and zero T with  $N_s \rightarrow \infty$ . These results are qualitatively consistent with previous predictions [26,46] that the string phase for V > 0 (V < 0) persists to finite (arbitrarily large)  $J/\tilde{V}$ .

The physical realization of the different phases and observation of the phase transitions appear within reach of current experiments, for example, using the Rydberg tweezer platform of Ref. [20]. Usually, in experiments it is convenient to start with a product state, e.g.,  $|\psi\rangle = |1111\cdots\rangle$ . The T = 0 ground state for different  $J/\tilde{V}$  values can be adiabatically prepared by slow variations of the microwave parameters (detunings and amplitudes). Importantly, to capture features of the (de)localized II phase one also needs to break the spatial translation and reflection symmetries during state preparation, as demonstrated in Ref. [54] for a special  $N_s = 2$  case. Following adiabatic preparation, the properties of the ground state can then be explored to identify the different phases discussed. For example, measurements of the counting statistics-measuring the number of Rydberg atoms in a chosen level in a given shot and then taking a histogram of this quantity-can provide a means to distinguish between the localized and the delocalized phases. Delocalized phases would have broad, roughly Poissonian fluctuations around a mean value, whereas localized phases would have a bimodal character: a peak with  $O(1/N_s)$  probability of seeing around  $O(N_s)$  Rydberg atoms in a given level and an O(1) peak for seeing no particles in the level. Alternatively, by attempting to ramp from and then back to the state  $|1111\cdots\rangle$ , one can identify accessible phase transitions by finding breakdowns in adiabaticity at particular  $J/\tilde{V}$  values.

The effects of long-range interactions and interactions that vary with the synthetic site on the phases are left for future investigations. For the dipolar real-space interactions, states that preserve sublattice symmetry will remain meanfield eigenstates with the same eigenenergy, where their only consequence is to change the effective z factor in  $\tilde{V}$ . For states breaking the sublattice symmetry, the intrasublattice (A-A) versus intersublattice (A-B) interactions will couple to different mean fields. Although a weak dependence of the interactions on the synthetic site index itself should not drastically change the phase diagram (localized-delocalized phase transitions change to sharp crossovers), having interactions nonlocal in the synthetic space could have nontrivial effects.

In the future, we expect the dipolar synthetic-dimension platform to be a powerful tool for studying the interplay of interactions, topology, and synthetic gauge fields. Incorporating different synthetic-tunneling schemes or geometries along the synthetic dimension is experimentally feasible, so the already rich physics observed here is likely to be the tip of an iceberg. Different tunneling schemes can be implemented by simply adjusting the power of the microwaves similar to the schemes in Ref. [55]. The Su-Schrieffer-Heeger model, which hosts topological edge states, was already realized in a single Rydberg atom [19], and systems with gauge fields were realized in the platform of Rydberg atom tweezer arrays [20].

#### ACKNOWLEDGMENTS

This work was supported in part by the Big-Data Private-Cloud Research Cyberinfrastructure MRI-award funded by NSF under Grant No. CNS-1338099 and by Rice University's Center for Research Computing (CRC).

K.R.A.H., R.T.S., and B.G. planned the research. S.D. and K.R.A.H. performed the mean-field theory calculations. All authors interpreted results, compared them with prior results (SGF-QMC, classical models, and similar), and evaluated experimental feasibility. S.D. primarily wrote the initial draft, and all the authors helped in writing the manuscript.

## APPENDIX A: J = 0 ANALYTIC SOLUTION

When J = 0, we can derive a set of simplified equations for the mean-fields and infer that the thermal phase transition is first order for  $N_s > 6$  and second order otherwise. In this limit, the mean-field Hamiltonian is

$$\mathcal{H} = \sum_{\nu} \sum_{s=\pm 1} \tilde{V} \phi^*_{\nu,\bar{s}} |\nu, s\rangle \langle \nu - 1, s| + \text{H.c.}$$
(A1)

Numerically solving the mean-field equations, we find two solutions, a disordered phase in which all mean fields are equal and a string or membrane phase in which one or two adjacent mean fields are nonzero. Using this information as an ansatz, an analytic understanding of the phases and phase transitions can be obtained. For  $N_s > 4$ , the mean-field ground state is the string or membrane state. For  $N_s = 4$ , they are equal in energy, and our mean-field theory cannot distinguish the two.

We can predict the critical temperature and the order of the phase transition of the system at J = 0 by considering the self-consistency equation for the mean fields,

$$\tilde{\phi}_s = \frac{1}{2} \left( \frac{e^{-\beta \tilde{V} \tilde{\phi}_{\tilde{s}}} - e^{\beta \tilde{V} \tilde{\phi}_{\tilde{s}}}}{N_s - 2 + e^{-\beta \tilde{V} \tilde{\phi}_{\tilde{s}}} + e^{\beta \tilde{V} \tilde{\phi}_{\tilde{s}}}} \right), \tag{A2}$$

where  $\tilde{\phi}_s = \sum_{\nu=1,2} |\phi_{\nu,s}|^2$ , *s* labels the sublattice,  $\bar{s} = -s$ , and *m* sums over the two potentially nonzero mean fields, which we have labeled 1 and 2. For small  $\tilde{\phi}_s$ ,

$$\tilde{\phi}_{s} = \left(\frac{\tilde{V}}{N_{s}T}\right)^{2} \tilde{\phi}_{s} + (N_{s} - 6)\tilde{V}^{4} \frac{[(N_{s}T)^{2} + \tilde{V}^{2}]}{6N_{s}^{5}T^{6}} \tilde{\phi}_{s}^{3} + O(\tilde{\phi}_{s}^{5}).$$
(A3)

A phase transition occurs when the coefficient of the linear term,  $1 - (\frac{\tilde{V}}{N_s T})^2$ , vanishes and the order of the phase transition is determined by the sign of the  $\tilde{\phi}_s^3$  term. This is equivalent to the standard Landau theory analysis of phase transitions with U(1) symmetry associated with the phase of  $\tilde{\phi}_s$ , with the coefficients determined using the mean-field theory. Thus, the critical temperature is  $T_c = \tilde{V}/N_s$  when the

FIG. 5. Comparison of the phase boundary between the localized I and delocalized I phases for  $N_s = 10$  between MFT and QMC. The blue solid (dashed) lines depicts the first- (second-) order transition in the mean-field theory, and the blue circle corresponds to the tricritical point.

transition is second order. In Eq. (A3), the coefficient of the  $\tilde{\phi}_s^3$  term on the right-hand side is positive for  $N_s > 6$  and thus has a first-order transition, and it is negative for  $N_s < 6$  and thus has a second-order transition.

#### APPENDIX B: COMPARISON WITH DMRG AND QMC

Mean-field theory predicts the  $N_s \rightarrow \infty$  quantum critical points for one real dimension plus one synthetic dimension (Fig. 4) to a reasonable accuracy when compared against DMRG [46] (green band). The DMRG calculation could only distinguish localized from delocalized phases. Thus, the two phase transitions it could capture would correspond to the those between the localized I and delocalized I phases [Fig. 4(a)] and between the localized II and delocalized II phases [Fig. 4(b)]. In either case, we see weak  $N_s$  dependence compared to the mean-field theory. As mentioned in Sec. IV, we expect the mean-field critical  $\tilde{V}/J$  to scale as a  $O(1/N_s)$  for transitions from an ordered state to the disordered delocalized I phase and to scale as O(1) for the localized II to delocalized II transition. For the former, our expectation agrees with both the DMRG and the mean-field extrapolation [black dashed lines in Fig. 4(a)] in the asymptotic limit  $N_s \to \infty$ . However for the latter, although a finite critical value is predicted by both the DMRG and mean-field theory in the large- $N_s$  limit [Fig. 4(b)], the mean-field extrapolated value [black dashed lines in Fig. 4(b) is 1.5–2 times larger than the corresponding DMRG value. This discrepancy could, perhaps, be attributed to the fact that the mean field is capturing a first-order transition between two ordered phases.

Mean-field theory also predicts the finite- $N_s$  quantum phase transition between the localized I and delocalized I phases reasonably well for two real dimensions plus one synthetic dimension when compared against QMC [red circle in Fig. 4(a)]. The transition temperature was determined with QMC by the jumps in specific heat, Binder ratio, and average synthetic-site separation [47].

The critical temperature of the mean-field theory is typically less than but within about 30% of the QMC values (Fig. 5). This is unusual because one generally expects meanfield theory to have a higher transition temperature. One hypothesis is that this model at strong interactions has two transitions upon lowering temperature, similar to the classical *p*-state clock model [52] and the *p*-state Potts model with an additional nearest-neighbor spin interaction [53]. The first would be from a disordered to a quasi-long-range ordered phase, and the second would be from this to a fully ordered phase. It is possible that the transition point obtained using the QMC is the higher critical point. In Ref. [56] the crossing of the Binder ratio provided the higher critical temperature of the p-state clock model. To obtain the lower critical point, very large system sizes and computing the temperature derivative of the Binder ratio were necessary. It is therefore plausible

this would be difficult to detect in the QMC in [47]. The mean-field theory locates the critical temperature where the  $D_{2N_s}$  symmetry is broken, which corresponds to the lower critical temperature. Interestingly, this would imply a critical region of temperatures between the ordered and disordered phases. We leave the investigation of this hypothesis and any resulting critical region for future studies.
