V. Kaufman and J. Sugar National Bureau of Standards, Gaithersburg, Maryland 20899 (Received 7 August 1986)

Spectra from laser-produced plasmas of Ca, Sc, Ti, V, Cr, and Mn have been recorded in the grazing-incidence region, and the transition arrays 3s-4p, 3p-4s, 3p-4d, and 3d-4f of the neonlike ions have been identified. The measured wavelengths together with the previously observed 3-3 transitions have been used for deriving energy levels of the $2s^22p^{5}3l$ and $2s^22p^{5}4l$ configurations. The term structure has been analyzed by means of *ab initio* and parametric calculations and isoelectronic relations. Coupling conditions have been studied and eigenvectors have been derived. Significant perturbations caused by the $2s2p^{6}nl$ configurations have been investigated.

I. INTRODUCTION

The $2p^{5}3s$, 3p, and 3d configurations of highly charged ions in the neonlike isoelectronic sequence have been the object of several investigations during recent years. The interest in these ions has to a great extent been stimulated by the possibility of obtaining laser action in certain 3s-3plines in the extreme ultraviolet region^{1,2} and by the identifications of 3s-3p and 3p-3d lines of Fe XVII in solar-flare spectra.^{3,4} Thus 3s-3p and 3p-3d transitions in the region 200-700 Å have been identified in Ca XI-Mn XVI in spectra emitted from laser-produced plasmas,⁵⁻⁷ and in Ti XIII, Cr XV, and Fe XVII in beam-foil experiments.⁸⁻¹⁰ The level structure of these configurations was analyzed by means of Slater-Condon theory in Ca XI, Ti XIII, and Fe XVII,^{5,6} and the derived scaling factors for the Slater parameters could be used for predictions of the level structure and transition wavelengths. Several *ab initio* studies of these configurations have also been published.¹¹⁻¹⁴

In the present work transitions between the $2p^{5}3l$ and $2p^{5}4l$ configurations in neonlike Ca XI—Mn XVI have been identified in spectra from laser-produced plasmas. Identifications of the strongest lines of 3-4 transition arrays have previously been reported by Fawcett *et al.*,¹⁵ but that investigation appears to have been hampered by a low spectral resolution and by the lack of information on the $2p^{5}3l$ structure. The strongest 3p-4d lines were also observed by Kastner *et al.*¹⁶ All observed 3-3 and 3-4 transitions have now been used for deriving energy levels of the $2p^{5}3l$ and $2p^{5}4l$ configurations. As a result all the levels of 3s, 3p, 3d, 4d, and 4f in Ca XI—Mn XVI are now

known, or predictable with high accuracy. Concerning 4s and 4p, a number of levels are still missing in certain ions. This is due to the low intensity of the 3s-4p and 3p-4s transitions, and the irregularities in the isoelectronic trends of wave numbers and energy levels caused by perturbations from the core-excited $2s2p^{6}3l$ configurations.

II. EXPERIMENT

The spectra of highly ionized calcium, scandium, titanium, vanadium, chromium, and manganese were emitted from plasmas produced by focusing a Nd-glass pulsed laser beam with a power of 1 GW and pulse width of 15 ns onto solid metal targets. The spectra were recorded on Kodak 101-05 plates with the 10.7-m grazing-incidence spectrograph at the National Bureau of Standards, Washington, D.C. A slit width of 50 μ m was used, and about 20 laser pulses were needed to produce satisfactory exposures. For plate calibration we used laser-generated spectra of YXI-XIV and MoXIV-XVII with the wavelengths reported in Refs. 17-21 with an uncertainty of ± 0.005 Å. We estimate our wavelength uncertainty to be at most $\pm 0.005-0.01$ Å.

III. SPECTRAL LINES

All the lines included in the present work are given in Tables I–IV, containing the transition arrays 3s-4p, 3p-4s, 3p-4d, and 3d-4f. The strongest spectrum and consequently the most complete transition arrays were obtained in chromium, where furthermore the structure of the neonlike n=4 configurations is essentially unaffected by the perturbations to be discussed below. For these reasons the identification work was started in chromium. We

made use of the regular isoelectronic trends of the wave numbers shown in Figs. 1 and 2 and the derived scaling of the Slater parameters.

The level designations in Tables I–IV are given in jj and jl notation, and will be further discussed below.

IV. ENERGY LEVELS

The neonlike ions are characterized by the large energy gap between the ground state $2p^{61}S_0$ (see Fig. 3) and the first excited configuration $2p^{5}3s$. Thus the absolute energy scale of the term system is established through lines in the soft-x-ray region. In the present work the excited levels were connected to the ground state by means of the transitions from $3s(\frac{1}{2},\frac{1}{2})_1$ and $3s(\frac{3}{2},\frac{1}{2})_1$ measured by Edlén and Tyrén²² and Tyrén,²³ and quoted in the NBS compilations of iron-group energy levels.²⁴

The 3-4 transitions from the present work and 3-3 transitions from previous investigations have been used for deriving the $2p^53l$ and $2p^54l$ levels of Ca XI-Mn XVI. With a few exceptions, the 3-3 lines were taken from the recordings of laser-produced plasmas in Refs. 5-7. The lines of the neonlike ions are obviously much more prominent in the beam-foil recordings in Refs. 8-10 than in the laser-produced plasmas of Refs. 5–7, but the wavelength accuracy is higher in the latter case. For this reason, only wavelengths of lines that were not observed in the plasma investigations have been taken from the beam-foil work. In particular it should be noted that the beam-foil wavelength for $3s(\frac{3}{2},\frac{1}{2})_2 \cdot 3p(\frac{3}{2})[\frac{1}{2}]_1$, 551.60 Å,⁸ has replaced the erroneous wavelength for this line in Ref. 5. Furthermore, the analysis of the n=3 configurations has shown that two lines reported in Ref. 7 have to be discarded, viz., 342.202 Å in V XIV and 377.414 Å in Mn XVI.

The derived $2p^{5}3l$ and $2p^{5}4l$ energy levels are given in Tables V, VI, and VII. Predicted values, obtained from parametric calculations to be discussed below, are inserted in parentheses in cases were no level values could be derived from the observations. In 4s and 4p, the small number of observed levels make the parametric calculations rather uncertain, and therefore predicted values are not given.

It has not been possible to find $3s \cdot 3p$ or $3s \cdot 4p$ lines that can be used for establishing the position of $3s(\frac{1}{2}, \frac{1}{2})_0$ relative to the rest of the 3s levels in V XIV and Mn XVI. This level is, however, crucial for the derivation of certain level values of the higher configurations, and its position has therefore been determined through isoelectronic interpolation of the $3s(\frac{1}{2}, \frac{1}{2})_1 \cdot (\frac{1}{2}, \frac{1}{2})_0$ interval. The regular trend of this interval and the $3s(\frac{3}{2}, \frac{1}{2})_1 \cdot (\frac{3}{2}, \frac{1}{2})_2$ interval is shown in Fig. 4, where the FeXVII data were taken from Ref. 4. The values for the J=0 level of 3s in V XIV and Mn XVI obtained from a least-squares fit of a straight line to the $3s(\frac{1}{2}, \frac{1}{2})_1 \cdot (\frac{1}{2}, \frac{1}{2})_0$ interval for Ca XI—FeXVII are given in Table V. They are believed to be more accurate than the values from parametric calculations.

The high probabilities for transitions from the odd J=1 levels to the ground state lead to unfavorable branching ratios for transitions to other excited levels, and with the exception of 3s, many of the odd J=1 levels are therefore badly or not at all connected to the rest of the excited system. In such cases the level values derived from x-ray transitions to the ground state as quoted in Ref. 24 are given in Tables V, VI, and VII. For 3d and 4d the values from the parametric calculations are also shown for these levels. In 3d the agreement is in most cases good, while some serious deviations are found in 4d. Relative to the rest of the excited levels, the calculated level values are believed to be better than the x-ray values.

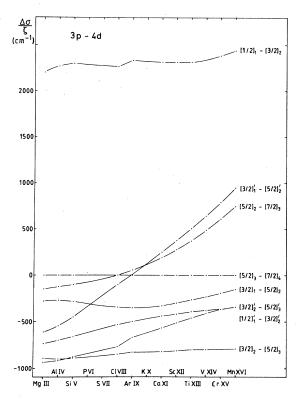

FIG. 1. Wave-number differences divided by the core charge ζ plotted versus ζ for the strongest 3p-4d lines in MgIII-Mn XVI. The abbreviated notation [K] is used for $(\frac{3}{2})[K]$ and [K]' for $(\frac{1}{2})[K]$. $\Delta \sigma$ is the distance from the $3p[\frac{5}{2}]_3-4d[\frac{7}{2}]_4$ line. The deviations from the smooth behavior of some of the curves at Cl VIII and Ar IX are due to interaction between $2s^22p^54d$ and $2s2p^63p$; cf. the text and Fig. 6.

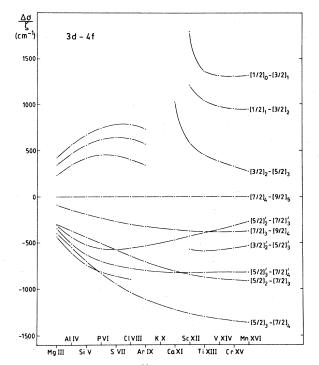

FIG. 2. Wave-number differences divided by the core charge for the strongest 3d-4f lines in Mg III-Mn XVI. The abbreviated designations are explained in the text of Fig. 1. The strong irregularities in some of the curves are due to perturbations of certain 4f levels, evident in Fig. 7.

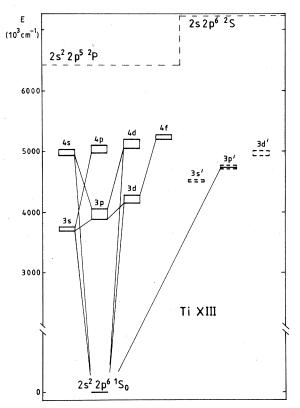

FIG. 3. Survey term diagram of Ti XIII showing the n=3 and n=4 configurations.

TABLE VI. Energy levels (cm^{-1}) of the $2p^{5}4s$ and 4p configurations

^aLevel value determined from transition to the ground state (Ref. 24).

No lines have been found that connect levels having different parent states $({}^{2}P_{1/2} \text{ and } {}^{2}P_{3/2})$. A direct connection would be given by the magnetic dipole transition within the 3s configuration, viz., from the metastable $(\frac{1}{2},\frac{1}{2})_0$ level to $(\frac{3}{2},\frac{1}{2})_1$, and in fact a line in a solar flare spectrum has been identified as this transition in Fe XVII.⁴ Another line connecting the two parent systems has been reported in Ti XIII,²⁵ and it might be possible to use these observations for interpolating the ${}^{2}P_{1/2} - {}^{2}P_{3/2}$ interval.²⁶ Pending more accurate observations, e.g., of the magnetic dipole transition in tokamak plasmas, the relative positions of the two sets of levels are determined in the present work by the x-ray transitions to the ground state. Predicted wavelengths for the magnetic dipole transition derived from the energy levels of Table V are given in Table VIII. The table also contains predicted wavelengths for the magnetic quadrupole transition from the metastable $3s(\frac{3}{2},\frac{1}{2})_2$ level to the ground state. This transition has been observed in Cr XV in a tokamak plasma.²⁷

V. TERM STRUCTURE

The structure of the $2p^5nl$ configurations in highly charged neonlike ions is dominated by the large spin-orbit interaction within the $2p^5$ core. The levels are thus split in two separate groups, correlated to the ${}^2P_{3/2}$ and ${}^2P_{1/2}$ states of the inverted parent term. Representations other than the *LS* scheme that give the most appropriate descriptions of the level structure will be discussed for each configuration below.

As Z increases, the $2s2p^{6}3l$ configurations move downwards through the term system to positions close to $2s^{2}2p^{5}3l$. These two groups of configurations have the same set of principal quantum numbers, which gives large interaction integrals. This means that the resulting perturbations may be significant even at large distances between the interacting configurations,^{11,28} but they vary smoothly along the isoelectronic sequence. Perturbations may also occur where the $2s2p^{6}3l$ configurations cross the $2s^{2}2p^{5}4l$ configurations of the same parity, but in these cases the interaction integrals are small and the perturbations are large only at small distances between the interacting states. The possible positions for such local perturbations can be found in Fig. 5, where the configuration average energies predicted by Hartree-Fock wave functions are shown for AlIV-FeXVII. The perturbations of 4d in Cl VIII and 4s in K x caused by $2s2p^{6}3p$ were found and discussed already by Edlén and Tyrén.²² Drastic perturbations of this kind have been observed in the present work and will be discussed in connection with the n=4configurations.

The *ab initio* wave functions and Slater intervals were obtained from the Froese Fischer MCHF72 computer program²⁹ used in the single-configuration mode. These integrals were used as input to the matrix program of Cowan,³⁰ which calculates the angular matrices, diagonalizes them, and provides eigenvectors in various coupling schemes. The integral values were adjusted by a least-squares program of Cowan to fit the observed levels.

A. The $2p^{5}3l$ configurations

The fitted energy parameters and the Hartree-Fock energy integrals for the 3s, 3p, and 3d configurations are shown in Tables IX-XI. The structure of the n=3 configurations has been analyzed previously in Ca XI (Ref. 6) and Ti XIII (Ref. 5), and the predicted isoelectronic trends of the scaling factors for the *ab initio* integrals are fully confirmed in the present work. In particular the ratios between the fitted and the *ab initio* values of the configuration average energies are seen to approach a minimum close to unity and then increase again. This behavior, caused by decreasing correlation and increasing relativistic effects as Z increases, is discussed in detail in Ref. 11. It

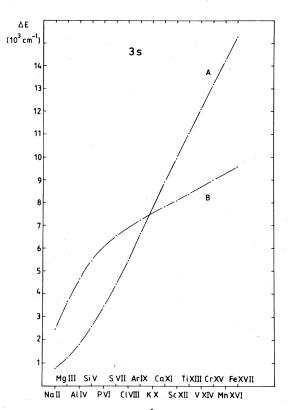

FIG. 4. Intervals in the $2p^{5}3s$ configuration. Curve A: $(\frac{3}{2}, \frac{1}{2})_{1}-(\frac{3}{2}, \frac{1}{2})_{2}$. Curve B: $(\frac{1}{2}, \frac{1}{2})_{1}-(\frac{1}{2}, \frac{1}{2})_{0}$. The missing intervals in V XIV and Mn XVI have been determined through interpolation along a least-squares-fitted straight line from Ca XI to Fe XVII.

should be noted that the parameters for Ti XIII have been changed somewhat from Ref. 5 due to the addition of levels derived from beam-foil data.

As can be seen in Table V, the 3s levels are given jj designations. The eigenvector components, shown in the table for Ca XI and Mn XVII, reveal that the purity in jj coupling is high, and that it increases with increasing Z as expected. The average purity for 3s in jj coupling is 98% in Mn XVI. The LS designations shown at the right-hand part of the table correspond to the appropriate level designations in the beginning of the sequence, but they are not

^aObserved wavelength 21.213 Å (Ref. 27).

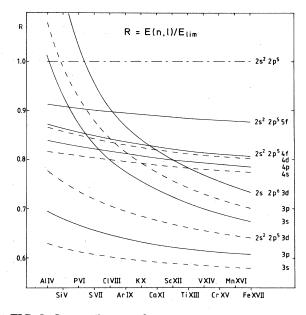

FIG. 5. Survey diagram of some excited configurations in the neonlike isoelectronic sequence. The average energy of each configuration, calculated from Hartree-Fock wave functions, is plotted as a function of the nuclear charge. The energy is scaled by the distance between the $2s^22p^6$ ground state and the ionization limit $2s^22p^5$. Even and odd configurations are represented by solid and dashed curves, respectively. It is seen that strong local perturbations due to interaction between $2s^22p^54l$ and $2s2p^63l$ may occur in the ions S VII—Sc XII.

applicable to the ions discussed here (except for J=0 and 2, which are pure in both schemes).

As in 3s, LS designations do not describe the 3p and 3dlevels properly. Here the coupling is, however, still intermediate, and no representation gives eigenvectors of high purity for all the levels. It could be discussed whether the er the ultimate coupling asymptotically approached at high Z will be jj or jl, ³¹ and, in fact, jj designations have been used in the relativistic calculations by Cogordan and Lunell.¹³ We have, however, chosen *jl* designations in the present work for different reasons: (i) the average purity is higher in *jl* than in *jj* representation for the ions treated here, (ii) jl notation is generally used in the compilations of previous work,²⁴ and (iii) the 4d and 4f configurations show high purity in the jl representation, and the 3p-4dand 3d-4f transition arrays have the pronounced diagonal character typical for *jl* coupling (strongest lines where $\Delta J = \Delta K$). The *jl* eigenvector components are shown in Table V, and in most cases the purity is seen to be high. The average purities in *jl* coupling in Mn XVI are 82 and 86% for 3p and 3d. For convenience the LS designations corresponding to the maximum eigenvector components in the beginning of the sequence and used in Refs. 5-7are shown in Table IV. In several cases these designations do not agree with the low purity maximum LS components for the ions treated here. It should be noted that even in *jl* representation, the purity of the 3p J=0 levels is low, and that the designations in Ca XI are chosen ac-

TABLE IX. Energy parameters (cm^{-1}) for $2s^2 2p^5 3s$. The first row for each parameter gives the fitted value. The second row

cording to the isoelectronic trend and do not correspond to the maximum eigenvector components.

The level designations used here are an abbreviated form of the jK notation. Thus $2p^{5}({}^{2}P_{J1})nl[K]_{J}$ is written $nl(J1)[K]_J$. In the figures the parent state is further abbreviated, so that [K] stands for $(\frac{3}{2})[K]$ and [K]' for $(\frac{1}{2})[K].$

As mentioned previously, both 3p and 3d are affected by long-range perturbations from $2s2p^{6}3l$. Due to the lack of information on these configurations and the slowly changing magnitude of the perturbations along the sequence, it has not been possible to treat the interaction in detail. The perturbations are instead taken care of by the effective parameter D^1 in the fitting procedure. The introduction of this parameter significantly reduces the standard deviation of the fitted levels shown in the last row of Tables X and XI, but the derived values of the parameter are uncertain and show a somewhat irregular behavior. A more exact treatment will be possible when accurate data on $2s2p^{6}3l$ become available.

Due to the difficulty mentioned above to establish two of the J=1 levels of 3d, it was necessary to fix the value of $G^{1}(2p, 3d)$ at a scaled Hartree-Fock value in the parametric fit. The scaling factor was obtained through

TABLE X. Energy parameters (cm⁻¹) for $2s^22p^53p$. The first row for each parameter gives the fitted value. The second row contains the Hartree-Fock value for the corresponding energy integral, while the ratio between these two quantities is given in the third row. Parentheses mean that the parameter was fixed during the fitting procedure. N is the number of fitted levels; σ is the rms deviation of the calculated levels.

isoelectronic extrapolation.⁵ In the same way, $G^{0}(2p,3p)$ had to be fixed for 3p in Ca XI, Ti XIII, and Mn XVI. Level values derived from the fitted and extrapolated parameters are given in parentheses in Table V for levels that could not be established experimentally.

B. 4*d*

The energy levels of the $2p^{5}4l$ configurations are shown in Tables VI and VII, and the energy integrals of 4d and 4f in Tables XII and XIII. The discussion will start with 4d as it is the most completely known n=4 configuration, essentially unaffected by perturbations.

The regular behavior of the 3p-4d transitions and the 4d-level structure can be seen in Figs. 1 and 6. The figures also reveal the slight perturbations of certain levels in Cl VIII and Ar IX, caused by $2s2p^{6}3p$ as expected from Fig. 5. No perturbations are, however, evident in Ca XI-Mn XVI, and no interaction or effective parameters had to be introduced in the parametric fit. The derived parameters and the *ab initio* integrals are shown in Table XII. The level purities are seen in Table VII to be generally high in *jl* coupling, the only significant exception

being the mixing of the J=1 levels of the $J=\frac{3}{2}$ parent. However, Fig. 6 shows that the pair structure is not particularly prominent. The average *jl* purity in Mn XVI is 89%.

As for 3*d*, two of the 4*d* J=1 levels decay most readily to the ground state, and they are therefore difficult to establish relative to the rest of the configuration. For this reason, $G^{1}(pd)$ was fixed during the parametric fit at a scaled Hartree-Fock value in CaXI to VXIV, with the scaling factor derived through isoelectronic interpolation.

C. 4f

The 3d-4f transitions form an easily recognizable group of lines, but the positions of certain lines are severly affected by perturbations as shown in Fig. 2. Perturbations of the 4f structure had been noticed at lower ionization stages as large deviations of the fitted G^2 and G^4 parameters from Hartree-Fock values.^{32–34} Preliminary calculations showed that the small perturbations in these ions could be absorbed by effective parameters, but in the present work the actual perturber, $2s2p^{6}3d$, has been included in the calculations.

TABLE XIII. Energy parameters (cm^{-1}) for $2s^22p^54f + 2s2p^63d$. The first row for each parameter gives the fitted value. The second row contains the corresponding energy integral calculated from Hartree-Fock wave functions. The value in the third row is the ratio between the fitted parameter and the HF integral. Values fixed in the fit are given in parentheses. N is the number of fitted levels; σ is the rms deviation of the calculated levels.

FIG. 6. Energy level structure of $2s^22p^{5}4d$. The circles represent level values derived from fitted energy parameters in Ca XI-Mn XVI in cases where it was not possible to establish the levels from the present observations. A number of the levels are seen to be depressed in Cl VIII and pushed up in Ar IX due to interaction with $2s2p^{6}3p$.

SiV

The 4*f*-level structure is shown in Fig. 7, where the two groups of levels based on the parent states with $J = \frac{1}{2}$ and $J = \frac{3}{2}$ are shown separately. In each case the positions are relative to the level with maximum J, which is unperturbed. The *jl* pair structure is evident, with the $(\frac{3}{2})[\frac{9}{2}]$ pair unresolved in the scale of the figure. For the $(\frac{1}{2})[\frac{5}{2}]$ and $(\frac{3}{2})[\frac{5}{2}]$ pairs only the predicted centers of gravity are shown, as the J=2 levels of these pairs could not be established. This is caused by the difficulty to establish the J=1 levels of 3*d*.

The energy parameters and the *ab initio* integrals for 4f and $2s2p^{6}3d$ are shown in Table XIII. The latter configuration has not been observed, and therefore its internal parameters and the interaction parameters were fixed at the Hartree-Fock values during the fit. The magnitude of the perturbation was allowed to vary by changing the average energy of the perturbing configuration. The small pair intervals and the fact that certain levels were missing for most or all of the ions made it difficult to obtain significant values for the small G^2 , G^4 , and ζ_{4f} parameters. For this reason they were fixed at scaled Hartree-Fock values, the scaling factors being chosen at the commonly

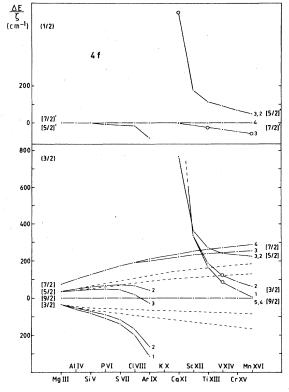

FIG. 7. Level structure of $2s^22p^{5}4f$. As in Fig. 6, the circles represent predicted values for levels that could not be derived from the observed lines. As expected from the curves in Fig. 5, the structure is perturbed by $2s2p^{6}3d$, which crosses 4f near KX. The dashed curves for the $(\frac{3}{2})[\frac{3}{2}]$ and $(\frac{3}{2})[\frac{5}{2}]$ levels represent Hartree-Fock predictions without configuration mixing.

found values of 0.8 for G^k and 1.0 for ζ . Thus the fits were made with only four free parameters.

The *jl* eigenvector components are shown in Table VII for Ca XI and Mn XVI. It is seen that the level purities are very high in Mn XVI, but the mixing with the $2s2p^{6}3d$ levels, given in LS notation, is evident in Ca XI. It is significant also in Sc XII. The large perturbation in Ca XI made both the *ab initio* predictions and the isoelectronic extrapolations uncertain, and it was only possible to establish eight of the 12 4*f* levels. The average *jl* purity in Mn XVI is 92%.

As can be seen in Fig. 7, the perturbation brings the $(\frac{3}{2})[\frac{7}{2}]_3$ and $(\frac{3}{2})[\frac{5}{2}]_3$ levels very close together in V XIV. This causes a strong mixing of the states, making the designation based on the eigenvector composition arbitrary. However, the combinations with 3*d* unambiguously point at the designations shown in Table VII.

For strict jl coupling³⁰ the higher energy level of a pair is that having even J when l_1+l_2 is even. A necessary condition is, however, that the pair splitting is mainly caused by the exchange interaction, and not by the spinorbit interaction of the outer electron. The rule is not obeyed by the $4f(\frac{3}{2})[\frac{9}{2}]$ pair in the ions analyzed in this work, where the levels have the expected order in Ca XI and Sc XII, but the interval decreases to zero in Ti XIII and then increases again with the opposite order. The trend seems to be broken in V XIV, but this is caused by a blended line establishing the J=4 level. The explanation to the changed order can be found in the approximate formulas for the pair splittings in $p^5 f$ given by Humphreys *et al.*³⁵ Here it is seen that the interval of one pair, viz., $(\frac{3}{2})[\frac{9}{2}]$, is given by the difference of two terms in G^4 and ζ_{4f} . As the spin-orbit integral increases more rapidly than the exchange interaction along the sequence, the difference changes sign and the order of these two levels is reversed, just as observed here.

D. 4s

The 3p-4s lines are quite weak in the observed spectra, and it was possible to establish all the 4s levels only in Cr XV. No 3p-4s were found in V XIV, and in Ca, Sc, Ti, and Mn only transitions from the J=2 level of 4s could be identified with reasonable certainty. A reason for this is the fact that the J=1 levels as in 3d and 4d are mainly depopulated through transitions to the ground state. The J=1 level values derived from these transitions in the soft x-ray regions are shown in Table VI together with the levels derived in the present work.

No general parametric calculations have been made due to the small number of levels. A comparison between the observations and *ab initio* predictions show an improved agreement for the lower charge states when the interaction with $2s2p^{6}3p$ is included in the calculations.

E. 4p

The 3s-4p lines are also weak, and it is difficult to identify more than a few lines unambiguously. Here the situation is complicated by the perturbation from $2s2p^63d$, which passes through 4p close to Sc XII. The perturbation effects the structure more severely in 4p than in 4f, as all J values of 4p except J=0 occur in the perturbater. In fact also the J=0 levels may be perturbed, viz., by $2s2p^63s$.

Predictions with scaled Hartree-Fock parameters including the perturbation made it possible to identify a number of lines in Cr XV, and the stronger of them were found also in Mn XVI. The predictions and the observed intensities indicate that the lines $(\frac{3}{2}, \frac{1}{2})_1 - (\frac{3}{2})[\frac{3}{2}]_1$ and $(\frac{3}{2})(\frac{1}{2})_2 - (\frac{3}{2})[\frac{1}{2}]_1$ coincide in these ions. In the lower charge states it has only been possible to identify the two strongest lines of the array except in Ti XIII, where only one line was found. No significant parametric calculations could of course be made at the small number of established levels. The isoelectronic trend of the two strongest lines is shown in Fig. 8.

VI. CONCLUSIONS

The present work greatly extends the knowledge of the n=3 and 4 configurations in the neonlike isoelectronic se-

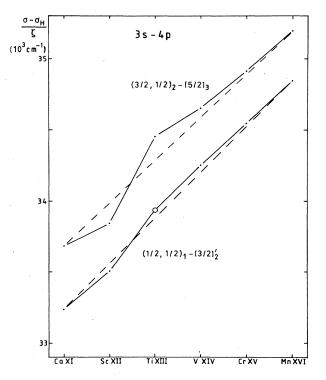

FIG. 8. The two strongest lines of the 3s-4p transition array. The quantity plotted is $(\sigma - \sigma_H)/\zeta$, where $\sigma_H = R\zeta^2(\frac{1}{9} - \frac{1}{16})$. In Ti XIII a predicted value from an *ab initio* calculation of the 4pstructure is given for one of the lines, which was not observed. Dashed straight lines are drawn between Ca XI and Mn XVI to make visible the perturbation from $2s2p^63d$, which crosses 4pbetween Sc XII and Ti XIII.

quence. In particular it has demonstrated the influence from configuration crossings. The n=3 levels and the 3-3 transitions can be safely extrapolated to high values of Z, most accurately by using differences between the observations and relativistic calculations.^{11,13} Concerning the n=4 levels and the 3-4 transitions, all the possible local perturbations caused by the crossings with $2s2p^{6}3l$ appear before Ti XIII, and the structure at higher Z can be predicted, e.g., by extrapolating the scaling factors for the Hartree-Fock integrals. Even for 4s and 4p, where it has been impossible to make complete analyses in most of the ions, the data for Cr XV form a good basis for further work.
