We perform a mean-field study of the binary Bose-Einstein condensate mixtures as a function of the mutual repulsive interaction strength. In the phase segregated regime, we find that there are two distinct phases: the weakly segregated phase characterized by a ''penetration depth'' and the strongly segregated phase characterized by a healing length. In the weakly segregated phase the symmetry of the shape of each condensate will not take that of the trap because of the finite surface tension, but its total density profile still does. In the strongly segregated phase even the total density profile takes a different symmetry from that of the trap because of the mutual exclusion of the condensates. The lower critical condensate-atom number to observe the complete phase segregation is discussed. A comparison to recent experimental data suggests that the weakly segregated phase has been observed. I. INTRODUCTION

Shortly after its first theoretical study [1], the binary mixture of Bose-Einstein condensates (BEC's) of alkali-metal atoms in a trap has been realized experimentally [2] and the development of this field is now blooming [3–7]. The binary mixture idea has been extended to trapped boson-fermion and fermion-fermion systems [4]. This opens the door to studying the rich physics in new parameter regimes. There have been several theoretical studies [5–7]; most of them are numerical in nature or are from the atomic physics point of view. In the present paper, we perform a mean-field-type study based on the nonlinear Schrödinger equation, and obtain a qualitative and in many cases a quantitative analytical understanding of a variety of properties of the binary BEC mixtures. Along with results from the competition between the healing length and the ''penetration depth,'' as well as from the finite trap effect, we have summarized previously known results in the manner of simplified mean-field solutions. In this way, we provide a convenient framework for classifying various excitations in the system, and pave the way for further study of the properties of binary BEC's, such as the time evolution of the two condensates during a phase segregating process.

We start from the Hamiltonian formulation of the binary BEC's at zero temperature:

$$H = \int d^3x \left[\psi_1^*(x) \left(\frac{-\hbar^2 \nabla^2}{2m_1} \right) \psi_1(x) + \psi_1^*(x) U_1(x) \psi_1(x) \right]$$

$$+ \int d^3x \left[\psi_2^*(x) \left(\frac{-\hbar^2 \nabla^2}{2m_2} \right) \psi_2(x) + \psi_2^*(x) U_2(x) \psi_2(x) \right]$$

$$+ \frac{G_{11}}{2} \int d^3x \, \psi_1^*(x) \psi_1(x) \psi_1^*(x) \psi_1(x)$$

$$+ \frac{G_{22}}{2} \int d^3x \, \psi_2^*(x) \psi_2(x) \psi_2^*(x) \psi_2(x)$$

$$+ G_{12} \int d^3x \, \psi_1^*(x) \psi_1(x) \psi_2^*(x) \psi_2(x). \tag{1}$$

Here ψ_i, with $i=1,2$, is the effective wave function of the ith condensate, with the mass m_i and the trapping potential U_i. The interaction between the ith condensate atoms is specified by G_{ii}, and that between 1 and 2 by G_{12}. In the present paper all G's will be taken to be positive. The corresponding time-independent equation of motion is the well-known nonlinear Schrödinger equation [8], obtained here by minimization of the energy, Eq. (1), with fixed condensate-atom numbers:

$$-\frac{\hbar^2}{2m_1} \nabla^2 \psi_1(x) + [U_1(x) - \mu_1] \psi_1(x) + G_{11} |\psi_1(x)|^2 \psi_1(x)$$

$$+ G_{12} |\psi_2(x)|^2 \psi_1(x) = 0, \tag{2}$$

$$-\frac{\hbar^2}{2m_2} \nabla^2 \psi_2(x) + [U_2(x) - \mu_2] \psi_2(x) + G_{22} |\psi_2(x)|^2 \psi_2(x)$$

$$+ G_{12} |\psi_1(x)|^2 \psi_2(x) = 0. \tag{3}$$

The Lagrangian multipliers, the chemical potentials μ_1 and μ_2, are determined by the relations $\int d^3x |\psi_i(x)|^2 = N_i$, $i=1,2$, with N_i the number of the ith condensate atoms.

Experimentally, the trapping potentials $\{U_i\}$ are simple harmonic in nature. For the sake of simplicity and to illustrate the physics we shall consider a square-well trapping potential $U_i = U$: zero inside and large (infinite) outside, unless otherwise explicitly specified.

II. CRITERIA AND SYMMETRIES IN SEGREGATED PHASES

A. Simplified mean-field solutions

With the square-well trapping potential specified in Sec. I, the coupled nonlinear Schrödinger equations have an obvious homogeneous solution: inside the trap the condensate densities $\rho_i = |\psi_i|^2$, $\rho_i = N_i/V$, with V the volume of the square-well potential trap, and the chemical potentials $\mu_1 = G_{11}\rho_1 + G_{12}\rho_2$ and $\mu_2 = G_{22}\rho_2 + G_{12}\rho_1$. The corresponding total energy of the system is

$$E_{ho} = \frac{1}{2} \left[G_{11} \frac{N_1^2}{V} + G_{22} \frac{N_2^2}{V} + 2G_{12} \frac{N_1 N_2}{V} \right]. \tag{4}$$

*Permanent address: Department of Theoretical Physics, Umeå University, 901 87, Umeå, Sweden.

For a small enough G_{12}, any variation on top of this solution will increase the system energy. This implies that the excitations are stable. Therefore in this parameter regime the homogeneous state is the ground state. If the mutual repulsive interaction G_{12} is strong enough, however, this is no longer true. We show below in a mean-field manner that there is an inhomogeneous solution with a lower total system energy.

Let us consider the case of the inhomogeneous state in which the two condensates mutually exclude each other. For the moment we ignore the thickness of the interface and the corresponding extra energy. In this way we temporarily ignore the derivative terms in Eqs. (2) and (3) in determining the effective condensate wave functions. We call this situation the simplified mean-field approach, which is a useful one that has already given us a lot of physical insight [1]. Let V_i be the volume inside the trap occupied by the condensate i. We have $|\psi_i|^2 = \rho_{i0} = N_i/V_i$ and the total energy of the inhomogeneous state $E_{in} = \frac{1}{2}\Sigma_{i=1,2}G_{ii}(N_i^2/V_i)$. Minimizing E_{in} with respect to V_1 or V_2 under the constraint $V_1 + V_2 = V$, we obtain the spatial volume occupied by each condensate:

$$V_1 = \frac{1}{1 + \sqrt{G_{22}/G_{11}}(N_2/N_1)} V,$$

$$V_2 = \frac{1}{1 + \sqrt{G_{11}/G_{22}}(N_1/N_2)} V.$$

The corresponding condensate densities are

$$\rho_{10} = \left(1 + \sqrt{\frac{G_{22}}{G_{11}}}\frac{N_2}{N_1}\right)\frac{N_1}{V}, \quad \rho_{20} = \sqrt{\frac{G_{11}}{G_{22}}}\rho_{10}, \quad (5)$$

and the chemical potentials $\mu_i = G_{ii}\rho_{i0}$. We note here $\mu_1\rho_{10} = \mu_2\rho_{20}$. The total energy for this inhomogeneous state is

$$E_{in} = \frac{1}{2}\left[G_{11}\frac{N_1^2}{V} + G_{22}\frac{N_2^2}{V} + 2\sqrt{G_{11}G_{22}}\frac{N_1 N_2}{V}\right].$$

The energy difference from the homogeneous state is then

$$\Delta E = E_{in} - E_{ho} = -(G_{12} - \sqrt{G_{11}G_{22}})\frac{N_1 N_2}{V}. \quad (6)$$

This equation reveals that for a large enough mutual repulsive interaction, that is, if

$$G_{12} > \sqrt{G_{11}G_{22}}, \quad (7)$$

the inhomogeneous state has a lower total energy. Hence, the inhomogeneous state, the phase segregation state, will be favored for a large mutual repulsive interaction G_{12}. We note that this criterion for the mutual repulsive interaction strength is independent of the condensate-atom numbers as well as of the trap size. We shall return to this point below. The critical value for G_{12}, Eq. (7), has been found using a stability analysis from the excitation spectrum in the homogeneous state [6], while it is obtained here from a simple energetic consideration.

B. Interface profile

In the absence of the derivative terms in the determination of the condensate wave functions studied above, the shape of the boundary between the two condensates in the phase segregated state will take any form. Now, we consider the effect of the derivative terms. Their inclusion will make the thickness of the interface finite and introduce a finite interface energy, the surface tension. The presence of the surface tension will fix the shape of the interface between the two condensates by minimization of the total surface energy. First, we look for the condensate profiles at the interface with a finite thickness. We rescale the effective wave functions by the values deep inside their own condensates:

$$\psi_i = f_i\sqrt{\rho_{i0}}.$$

We shall assume here that condensate 1 occupies the region in the trap specified by $z > 0$ and condensate 2 occupies the region specified by $z < 0$. The interface plane is $z = 0$.

Deep inside the region of condensate 1, we have $f_1 \rightarrow 1$ and $f_2 \rightarrow 0$. In this region, using $\mu_i = G_{ii}\rho_{i0}$ and only keeping the leading contributions, the coupled nonlinear Schrödinger equations, Eqs. (2) and (3), become

$$-\frac{\hbar^2}{2m_1}\nabla^2\delta f_1 + 2G_{11}\rho_{10}\delta f_1 + G_{12}\rho_{20}f_2^2 = 0, \quad (8)$$

$$-\frac{\hbar^2}{2m_2}\nabla^2 f_2 - G_{22}\rho_{20}f_2 + G_{12}\rho_{10}f_2 = 0. \quad (9)$$

Here $f_1 = 1 + \delta f_1$. These equations may be written in the following more suggestive form:

$$-\xi_1^2\nabla^2\delta f_1 + 2\delta f_1 + \frac{G_{12}}{\sqrt{G_{11}G_{22}}}f_2^2 = 0,$$

$$-\xi_2^2\nabla^2 f_2 + \left(\frac{G_{12}}{\sqrt{G_{11}G_{22}}} - 1\right)f_2 = 0,$$

with the ''healing lengths'' ξ_i defined as

$$\xi_i = \sqrt{\frac{\hbar^2}{2m_i}\frac{1}{G_{ii}\rho_{i0}}}. \quad (10)$$

From Eq. (9) we find the density profile of condensate 2 in condensate 1 is

$$f_2(z) = f_2(0)e^{-z/\Lambda_2}, \quad (11)$$

with the ''penetration depth''

$$\Lambda_2 = \frac{1}{\sqrt{G_{12}/\sqrt{G_{11}G_{22}} - 1}}\xi_2, \quad (12)$$

which is the length scale for condensate 2 penetrating into 1. Similarly, for the penetration of condensate 1 into condensate 2 in the region $z < 0$, we have $f_1(z) = f_1(0)e^{z/\Lambda_1}$, with the penetration depth $\Lambda_1 = \xi_1/\sqrt{G_{12}/\sqrt{G_{11}G_{22}} - 1}$. The healing length scale ξ here

describes the ability of a condensate to recover from a disturbance, similar to the same length scale in superfluid helium 4. The newly introduced length scale here, the penetration depth Λ, describes the degree of the mixing between the two condensates. Obviously, as $G_{12} \rightarrow \sqrt{G_{11}G_{22}}$, the penetration depth goes to infinity, in coincidence with the disappearing of the phase segregation.

It is also useful to study the behavior of condensate 1 in the region $z > 0$. Deep inside condensate 1, δf_1 is small. If f_2^2 approaches zero faster than δf_1, that is, $f_2^2 < \delta f_1$, the last term in Eq. (8) may be dropped, and we have

$$\delta f_1 = \delta f_1(0) e^{-\sqrt{2}z/\xi_1}. \tag{13}$$

Here it is the healing length ξ_1 of condensate 1, not the penetration depth Λ_2, that determines the profile of condensate 1. The validity of self-consistency for this solution requires $\Lambda_2 < \sqrt{2}\xi_1$. In this parameter regime the mutual repulsive interaction is so strong that condensate 1 stays away from 2, which is similar to the Meissner state where the magnetic field is completely excluded outside of a bulk superconductor. We shall call this parameter regime the strongly segregated phase. In the opposite limit, that is, $\Lambda_2 > \sqrt{2}\xi_1$, δf_1 will be determined by f_2 through Eq. (8):

$$\delta f_1 = -\frac{1}{2(1-2\xi_1^2/\Lambda_2^2)}\frac{G_{12}}{\sqrt{G_{11}G_{22}}}f_2^2, \quad \Lambda_2 > \sqrt{2}\xi_1. \tag{14}$$

The only relevant length scale here is the penetration depth, which is larger than the healing length. There is still a considerable mixing of the two condensates in this parameter regime, which we shall call the weakly segregated phase.

C. Surface tension

With the inclusion of the gradient terms in the determination of the condensate wave functions, the presence of the interface will cost a finite amount of energy. The surface energy per unit area, the surface tension, may be defined as $\sigma = \Delta E_s / S$. Here S is the interface area. The energy difference ΔE_s may be calculated in the following manner: In the presence of the interface at $z = 0$ we first solve the full Eqs. (2) and (3) with derivative terms for the condensate wave functions ψ_i, calculate the corresponding total energy from Eq. (1), then subtract from this total energy by the amount given by Eq. (5), the total energy of the system in the segregated phase without the effect of the derivative terms in Eqs. (2) and (3). Specifically, the energy difference ΔE_s is

$$\Delta E_s = \int d^3x \left\{ \sum_{i=1,2} \left[\rho_{i0}f_i \left(\frac{-\hbar^2\Delta^2}{2m_i} \right) f_i + \frac{G_{ii}}{2}\rho_{i0}^2 f_i^4 \right] \right.$$
$$\left. + G_{12}\rho_{10}\rho_{20}f_1^2 f_2^2 \right\} - \sum_{i=1,2} \frac{G_{ii}}{2}\rho_{i0}N_i.$$

Because of the normalization condition $\int d^3x \; \rho_{i0}f_i^2 = N_i$, from Eqs. (2) and (3), we obtain the surface tension as

$$\sigma = \frac{1}{2}\int_{-\infty}^{\infty}dz \sum_{i=1,2}\rho_{i0}f_i(z)\left(-\frac{\hbar^2\nabla^2}{2m_i} \right)f_i(z). \tag{15}$$

Though Eq. (15) is a general expression for the surface tension, to gain a concrete understanding, we consider the case in which the two condensates have an identical set of parameters: $\Lambda_i = \Lambda$ and $\xi_i = \xi$. In the strongly segregated phase of $\xi \gg \Lambda/\sqrt{2}$, Eq. (15) gives

$$\sigma = \frac{\xi}{\sqrt{2}}\sqrt{G_{11}G_{22}}\rho_{10}\rho_{20}, \tag{16}$$

which is independent of the penetration depth and the mutual repulsive interaction. In the weakly segregated phase of $\xi \ll \Lambda/\sqrt{2}$, Eq. (15) gives

$$\sigma = \frac{\xi^2}{\Lambda}\sqrt{G_{11}G_{22}}\rho_{10}\rho_{20}, \tag{17}$$

which goes to zero as $\Lambda \rightarrow \infty$. We note that this occurs when $G_{12} \rightarrow \sqrt{G_{11}G_{22}}$, in agreement with our above mean-field analysis of the phase segregation. The existence of the finite surface tension leads to another branch of gapless excitations, the interface or surface mode, which we are not going to discuss here.

D. Finite trap size effect I: Broken-symmetry ground state

Now we consider the effects of finite surface tension and the finite trap size. For a very large system, it is known that the minimization of surface energy leads to the minimum surface area, whose shape is usually spherical in three dimensions (3D) and circular in 2D. For a finite-size trap, one might expect that the shape of the ground state of the binary BEC mixture should take the same symmetry of the trap, particularly if it is cylindrically or spherically symmetric. We show here that this may not be true in a segregated phase, and the condensates may break the cylindrical symmetry defined by the trap. To demonstrate the essential physics, we consider the case of two condensates in two spatial dimensions with an identical set of parameters: $\Lambda_i = \Lambda$, $\xi_i = \xi$, and $\rho_{i0} = \rho_0$. Let R be the radius of the square-well potential trap. Supposing that condensate 1 occupies a circular area with a radius $R' = R/\sqrt{2}$; the associated surface energy is the length of the interface $2\pi R'$ times the surface tension σ:

$$E_s = \sqrt{2}\pi R\sigma.$$

On the other hand, supposing that each condensate occupies a half circular shape of the trap, the corresponding surface energy is

$$E_b = 2R\sigma,$$

which is much lower than the circular shape with the same symmetry as the trap, because the interface length here is shorter than that with the circular symmetry. Therefore, each condensate will take a different shape than that of the symmetry of the trap. The broken cylindrical symmetry state occurs, discovered first numerically [7].

Though the circular symmetry is broken for each condensate, in the weakly segregated phase where $\Lambda > \sqrt{2}\xi$, the total density $\rho_1 + \rho_2$ still appears circularly symmetric, and it retains the symmetry of the trap. In the strongly segregated phase where $\Lambda < \sqrt{2}\xi$, the two condensates tend to avoid each other. In this regime the circular symmetry of the total density profile is broken. Here we give a heuristic demon-

stration of such different behaviors of the total density profile in two segregated phases. We first show that there is a ditch in the total density profile at the interface in the strongly segregated phase. Following the analysis above, we take $z = 0$ as the interface position. Condensate 1 (2) occupies the $z > 0$ ($z < 0$) region of the trap. In the region $z > 0$, the condensate densities take the forms $\rho_1(z) = \rho_0(1 - b_1 e^{-\sqrt{2}z/\xi})$ and $\rho_2(z) = \rho_0 b_2 e^{-2z/\Lambda}$, consistent with Eqs. (8) and (9). Similarly, in the region $z < 0$, $\rho_1(z) = \rho_0 b_2 e^{2z/\Lambda}$, and $\rho_2(z) = \rho_0(1 - b_2 e^{\sqrt{2}z/\xi})$. Here b_1 and b_2 are two numerical constants. To determine b_1 and b_2, we make use of the fact that because Eqs. (2) and (3) are second-order differential equations, the solutions and their first-order derivatives must be continuous. This immediately gives us two algebraic equations at the interface $z = 0$:

$$1 - b_1 = b_2, \quad \sqrt{2}b_1/\xi = 2b_2/\Lambda.$$

The numerical constants are then $b_1 = \sqrt{2}\xi/(\sqrt{2}\xi + \Lambda)$ and $b_2 = \Lambda/(\sqrt{2}\xi + \Lambda)$. Evidently, the total density $\rho_1(z) + \rho_2(z)$ has its minimum value $\rho_0 2\Lambda/(\sqrt{2}\xi + \Lambda)$ at the interface $z = 0$, which goes to zero as $\Lambda \to 0$ or, equivalently, as $G_{12} \to \infty$. The total density has a ditch at the interface, an indication of broken symmetry in the strongly segregated phase. For the weakly segregated phase, replacing $\sqrt{2}\xi$ by 2Λ and following the same procedure, we obtain $b_1 = b_2 = 1/2$ and find that the total density remains constant in the trap, not affected by the phase segregation. There is no broken symmetry for the total density in the weakly segregated phase.

We note that in terms of interactions the weakly segregated phase is specified by $1 < G_{12}/\sqrt{G_{11}G_{22}} < (1 + 1/\sqrt{2})$, and the strongly segregated phase by $G_{12}/\sqrt{G_{11}G_{22}} > (1 + 1/\sqrt{2})$.

Another interesting feature of the finite surface tension is the floating of the condensate droplet. This may be regarded as a special case of the symmetry broken state. Suppose one condensate, say condensate 2, has a particle number much smaller than that of condensate 1, but still large enough to have a well-defined interface and surface. Then the condensate 2 may form a droplet inside condensate 1 in a phase segregated regime. Because of the finite surface tension, this droplet may move to and stay at the edge of the trap to reduce the common boundary length in 2D (or area in 3D) between condensates 1 and 2, to minimize the surface energy. This tendency may be called the floating of the condensate 2 droplet.

E. Finite trap size effect II: Lower critical condensate-atom number for phase segregation

In the above analysis, we have implicitly assumed that the thickness of the interface is much smaller than the trap size, such that we have a well-developed phase segregation. We examine the limitation of this assumption here. According to the above analysis, the penetration of condensate 2 into 1 is determined by Λ, and the recovery of condensate 1 from the presence of the interface by ξ or Λ in the strongly or weakly segregated phase. As an estimation, we may have the interface thickness l_{12} as

$$l_{12} \sim \xi + \Lambda. \tag{18}$$

This implies that $l_{12} \propto 1/\sqrt{\rho_{10}}$. When the interface thickness is larger than the trap size, $l_{12} > R$, we do not have a well-defined phase segregated state. A conclusion inferred from this is that, if the condensate atom number is too small, there is no complete phase segregation in the trap even with a strong mutual repulsive interaction between the condensates.

We should point out that the analyses in Secs. II D and II E are based on the assumption that the two condensates have the same sets of healing length and penetration depth. This implies that the surface energy contributions caused by the edge of the square-well trap are the same for both condensates. Hence we have ignored their effect in the determination of the symmetry of the ground state. In general, this may not be true, and one has to consider the competition among four lengths: two healing lengths and two penetration depths, as well as the surface energy from the trap edge. This will generate an even richer physics than what has been presented above. We believe our above discussions have provided the framework for further explorations. One such example will be discussed in Sec. III.

III. NUMERICS AND DISCUSSIONS

In terms of the atomic scattering lengths of condensate atoms a_{ii}, the interactions are $G_{ii} = 4\pi\hbar^2 a_{ii}/m_i$. The typical value of a_{ii} for ^{87}Rb is about 50 Å. The typical density realized for the binary BEC mixture is about $\rho_{i0} \sim 10^{14}/\text{cm}^3$. Hence the healing length is $\xi = \sqrt{(\hbar^2/2m)(1/G_{ii}\rho_{i0})} = \sqrt{1/(8\pi a_{ii}\rho_{i0})} \sim 3000$ Å. For the different hyperfine states of ^{87}Rb, we may take $G_{12}/\sqrt{G_{11}G_{22}} = 1.04$, whose precise value is uncertain and may be smaller. Then the penetration depth is $\Lambda = \xi/\sqrt{G_{12}/\sqrt{G_{11}G_{22}} - 1} \sim 1.5$ μm. The length scale for the harmonic trap potential determined by oscillator frequencies ranges from 1.3 to 4 μm, and the condensate occupies a region with a diameter of about 20 μm for about 10^6 atoms, which is comparable to or larger than the size of the interface thickness. Hence it is reasonable in practice to apply the mean-field results obtained for a square well potential to the case of a harmonic trapping potential, because on the scale of interface thickness the trapping potential appears smooth. The measurement of the penetration depth can be used to determine the mutual repulsive interaction in the ^{87}Rb system, which is in the weakly segregated phase, because G_{12} is believed [2] to be slightly larger than $\sqrt{G_{11}G_{22}}$.

Now we consider whether or not the ground-state symmetry of the hyperfine states ^{87}Rb can be broken. As pointed out at the end of Sec. II E, there is a complication arising from the trap edge surface energy contribution, due to the difference in healing lengths or interactions. In accordance with the experimental situation and for the sake of simplicity of analysis, we take two condensates having a equal number of particles. The differences in interactions are small: $\{\delta_i = (G_{ii} - G_{12})/G_{12}, i = 1,2\}$ are close to zero, and their sum $\delta_1 + \delta_2 \sim 0$. A condensate near the edge of the square-well potential is identical to the strong segregated phase, because there is no penetration into the hard wall. The surface tension at the trap edge can be readily evaluated according to an expression similar to Eq. (15) in the strongly segregated phase but with only one condensate. The difference in those

surface tensions is then, up to the first order in δ_i,

$$\Delta\sigma = \sigma_1 - \sigma_2 = \frac{1}{2\sqrt{2}}\xi_1 G_{11}\rho_{10}^2 \times \frac{1}{4}(\delta_2 - \delta_1).$$

Here we have used Eq. (5), that $\sqrt{G_{22}}\rho_{20} = \sqrt{G_{11}}\rho_{10}$. If there were no symmetry breaking in the ground state, the condensate with the lower surface energy at the trap edge, say the condensate 2, would stay close to the trap edge. Condensate 1 stays inside. If there is a symmetry breaking such that each occupies half of the trap as discussed in Sec. II E, then condensate 1 will get in contact with half of the trap edge. There is an increase in total energy as

$$\Delta E_{\text{edge}} = \pi R \Delta\sigma = \frac{\pi}{8\sqrt{2}}R\xi_1 G_{11}\rho_{10}^2(\delta_2 - \delta_1). \quad (19)$$

For the symmetry breaking to occur, this surface energy cost from the trap edge must be smaller than the interface energy gained, which is

$$\Delta E_{\text{interface}} = E_s - E_b = \frac{\pi - \sqrt{2}}{2}R\xi_1 G_{11}\rho_{10}^2(\delta_2 - \delta_1). \quad (20)$$

Here we have used $\xi_i/\Lambda_i = (\sqrt{2}/4)(\delta_2 - \delta_1)$ and $\delta_1 + \delta_2 = 0$. One can readily check now that indeed $\Delta E_{\text{interface}} > \Delta E_{\text{edge}}$. We note that in the case of the harmonic trapping potential, the density of a condensate is smaller near the edge, which gives an even smaller edge surface energy contribution. Therefore the symmetry breaking will occur in the system of hyperfine states of ^{87}Rb according to the present analysis. We believe this is precisely what was observed in a very recent experiment [3]. Furthermore, since it is in the weakly segregated phase, one should also expect that the symmetry break occurs only for the density of each individual condensate, not for the total density. Again, this is what was reported in Ref. [3].

Given the size of the trap to be on the order of 20 μm, the interface thickness must be smaller than this length to have a well-defined segregated phase. For the different hyperfine states of ^{87}Rb, this implies that, according to Eq. (18), a lower critical number N_c of condensate atoms $N_C = 1/(G_{12}\sqrt{G_{11}G_{22}} - 1)V^{1/3}/(8\pi a_{ii}) \sim 4000$. We should point out that the precise value of the lower critical atom number depends on details of a realistic trapping potential, such as the oscillator frequency and the anisotropy ratio. For a condensate-atom number of less than this value, there is no complete phase segregation.

IV. CONCLUSION

From the mean-field analysis, by tuning the strength of the mutual repulsive interaction we have found that there are two segregated phases: The interface profile is determined by the penetration depth in the weakly segregated phase, and by the healing length in the strongly segregated phase. The broken cylindrical symmetry state starts to appear in the weakly segregated phase for each condensate, and persists into the strongly segregated phase. For the total condensate density, the cylindrical symmetry is maintained in the weakly segregated phase, and disappears in the strongly segregated phase. We have also found that a condensate droplet inside another condensate in a segregated phase tends to move to and to stay at the trap boundary, and that if the condensate atom number is smaller than a critical value, there is no well-developed phase segregation. A comparison between the present results and a recent experiment has suggested the weakly segregated phase has been observed in ^{87}Rb condensates.
