(Received 1 March 2000; published 13 September 2000)

We present an alternative scheme for the generation of a two-qubit quantum gate interaction between laser-cooled trapped ions. The scheme is based on the ac Stark shift (light shift) induced by laser light resonant with the ionic transition frequency. At *specific* laser intensities, the shift of the ionic levels allows the resonant excitation of transitions involving the exchange of motional quanta. We compare the performance of this scheme with respect to that of related ion-trap proposals and find that, for an experimental realization using traveling-wave radiation and working in the Lamb-Dicke regime, an improvement of over an order of magnitude in the gate switching rate is possible.

I. INTRODUCTION

The last few years have seen impressive progress in the experimental demonstration of quantum information processing [1]. Among the growing number of possible physical scenarios for these demonstrations, the system of laser-cooled trapped ions still remains one of the most experimentally attractive [2–5] (for reviews of ion-trap quantum computing, see, e.g., [6–8]). Ever since the original ion-trap proposal of Cirac and Zoller (CZ) [9], a number of modifications and extensions to their idea have been proposed [4,10–15]. Many of these have aimed at bypassing two experimental hurdles of CZ's proposal, namely: (i) cooling the ionic motion to the ground state, while (ii) at the same time keeping the ions sufficiently far apart that individual laser access to each of them is possible. On the one hand, 'hot' gate implementations have been suggested [11–13] that aim to function even in the presence of moderate motional heating. On the other hand, an ingenious method has been suggested that exploits the ionic micromotion induced by dc offset potentials to address individual ions even while simultaneously illuminating all ions with the same beam [4,14]. Each of these proposals has its own merits and difficulties, and their feasibility and/or scalability have yet to be demonstrated experimentally. In the mean time, at least one experiment currently under development [5] aims to tackle the two problems directly, achieving the conditions required by CZ.

In the present paper, we assume that these conditions will indeed become feasible, and focus instead on another aspect of these experiments: the gate switching rates. Evidently, it is desirable that these should be as large as possible, so that a reasonably complex sequence of quantum operations can be realized before decoherence sets in. It has been remarked [6,7] that the speed of any two-qubit gate realized by coupling two ions via a motional mode must be bounded from above by the frequency of that mode (roughly speaking, the ions must be able to "realize that they are moving" before they can influence each other). At the present moment, no experiment realizing a true two-qubit ion-ion gate has been reported to our knowledge. However, at least two experiments have used schemes similar to the CZ proposal to implement two-qubit gates between a single ion and a motional mode [2,16]. Strikingly, in both cases the reported gate

speeds fell far short of the mode frequency, by two to three orders of magnitude. This limitation was not circumstantial, but inherent in the experimental technique that was used. The problem was the existence of strong off-resonant ion-mode transitions, whose unwanted driving would spoil the desired gate dynamics [6,7,9]. In order to avoid this, the laser power had to be kept at a relatively modest level, resulting in slow gates. (Very recently, a modification of the CZ scheme, which allows for somewhat faster gates, has been proposed [17], see *Note added*.)

In this paper, we propose an alternative scheme for two-qubit gates that should allow for an increase in gate speed by at least an order of magnitude with respect to these experiments. Furthermore, this gain is achieved without significant changes in experimental requirements with respect to existing setups, apart from an increase in laser power and good intensity stability. The key feature of our scheme is that it exploits the ac Stark shift (light shift) induced by light resonant with the ionic carrier transition. Using a coordinate transformation suggested by Moya-Cessa *et al.* [18] we demonstrate that, within the Lamb-Dicke regime, and at specific shift magnitudes (i.e., laser intensities), the ion-mode dynamics assumes the form of a Jaynes-Cummings interaction [19]. This interaction can be exploited to generate a two-qubit gate in a manner analogous to the CZ proposal.

We then proceed to compare our scheme with other existing proposals for faster cold-atom gates. For example, already in [9] it has been pointed out that if the traveling-wave radiation used in current experiments is replaced with a standing laser field, with the ion located at a node, then a substantial increase in gate speed would be possible. The elegant "magic Lamb-Dicke parameter" (MLDP) method proposed by Monroe *et al.* [10] could also in principle lead to faster gates. We argue, however, that our method, or possibly a combination of it with the MLDP method, is the one most amenable to practical implementation within the cold-ion scenario.

The paper is organized as follows: in Sec. I, we introduce our gate scheme, explaining its basic principle, the pulse sequences it requires, and the ways in which it differs from existing schemes. We also discuss its scalability to many-atom arrays. We then provide numerical confirmation of our analysis, and compare the performance of our scheme with

that of the Cirac-Zoller scheme in both its regimes (using traveling-wave or standing-wave radiation). Finally, we present our conclusions.

II. TWO-QUBIT GATES BASED ON THE ac STARK-SHIFT EFFECT

An important feature of the Cirac-Zoller gate scheme [9] is that the frequencies of the pulses it uses are chosen to be resonant with the transitions between the “bare” (uncoupled) ion-mode levels. This choice reflects a “perturbative” point of view in which these level spacings are assumed to be unaffected by the coupling itself, or in other words that the level shifts due to the ac potential of the coupling field itself can be disregarded. For a sufficiently strong field, this assumption breaks down and the normally disregarded off-resonant transitions become important (see, e.g., [6], Sec. 4.4.6). A number of authors have speculated that it might be possible to design a gate scheme incorporating these shifts as an integral feature [7,20]. In this section we construct a concrete realization of this idea, implementing two-bit gates by exploiting the light shift generated by light resonant with the ionic carrier.

A. One ion interacting with a traveling laser field

In order to present our underlying idea in its clearest form, we consider first the relatively simple situation of a single trapped ion interacting with a traveling-wave field. Also for simplicity, we assume the relevant ionic levels to be coupled by a direct (optical) transition. As is well known, the analysis can be straightforwardly adapted to the case of a Raman two-photon transition by a suitable redefinition of parameters [6,8]. In later sections we demonstrate how the scheme is scalable to traps containing an N -ion chain, allowing two-qubit gates to be realized between the internal states of any two of the ions.

In the standard interaction representation, the Hamiltonian for the one-ion system can be written as [6]

$$H = \hbar\Omega\{\sigma_+ \exp(i\eta[a e^{-i\nu t} + a^\dagger e^{i\nu t}] - i\delta t) + \text{H.c.}\}. \quad (1)$$

Here, $\delta = \omega_l - \omega_a$ is the laser-atom detuning, ν the trap frequency, $\eta = \sqrt{(\hbar k^2/2m\nu)}$ is the Lamb-Dicke parameter of the trap, and we have already taken into account a rotating-wave approximation (RWA) that assumes $\delta \ll \omega_a + \omega_l$ (the detuning is far smaller than optical frequencies).

Let us briefly recapitulate the approach that is usually taken to this problem (see, e.g., [6,8,21] and references therein for detailed treatments). First, one expands the exponentials in powers of a, a^\dagger and looks for the resonances that arise whenever the laser frequency is tuned to a motional sideband, i.e., $\delta = \pm m\nu$. A second RWA is then realized, ignoring off-resonant terms that rotate at multiples of the trap frequency ν . The remaining resonant terms can be interpreted in general as intensity-dependent “multiphonon” transitions [21]. If the Lamb-Dicke parameter is also small ($\eta \ll 1$), and the ion is sufficiently cooled, the intensity dependence of the coupling constant can be ignored to lowest order in η . For example, if the laser is resonant with the

FIG. 1. Scheme for two-qubit ion-mode interaction based on the ac Stark-shift (light-shift) effect. (a) Radiation resonant with the ionic carrier transition induces a splitting of the dressed levels $|\pm\rangle$ in the interaction picture, by an amount proportional to the laser’s electric field amplitude. (b) When the splitting becomes equal to one motional quantum $\hbar\nu$, coherent population oscillations are induced between states $|+\rangle|0\rangle$ and $|-\rangle|1\rangle$.

carrier transition ($m=0$), or with the first red sideband ($m=-1$), we have, respectively, the simple forms

$$H_{1CZ} \approx \hbar\Omega e^{-(1/2)\eta^2} [\sigma_+ + \sigma_-], \quad (2a)$$

$$H_{2CZ} \approx i\hbar\Omega \eta e^{-(1/2)\eta^2} [\sigma_+ a - \sigma_- a^\dagger]. \quad (2b)$$

These are the interactions that form the basis of the standard Cirac-Zoller scheme for realizing one- and two-qubit quantum logic gates [9]. A slight modification of this scheme (using blue sideband-detuned pulses) has been implemented experimentally in single-ion traps [2,16].

B. Two-qubit light-shift-based quantum gates

We now demonstrate that, even if only radiation resonant with the carrier is used, and without leaving the Lamb-Dicke limit, there is still a regime where two-qubit dynamics can be obtained. The basic physical idea behind this is as follows: we know that, apart from driving the one-qubit transition described in Eq. (2a), any radiation resonant with the carrier will also lead to an ac level splitting of the ionic semiclassical dressed states $|\pm\rangle = (1/\sqrt{2})(|g\rangle \pm |e\rangle)$ [22]. The magnitude of the splitting is $2\hbar\Omega$, where Ω is the Rabi frequency. When the intensity of the laser is such that the splitting equals *exactly* one vibrational energy quantum $\hbar\nu$, the levels $|+\rangle|0\rangle$ and $|-\rangle|1\rangle$ become degenerate, and we can expect transitions between them. This amounts effectively to an exchange of excitation between the motional and internal states, i.e., to two-qubit dynamics.

To see how this happens in detail, let us begin by first making the Lamb-Dicke approximation (to first order in η) directly in Eq. (1):

$$\begin{aligned}
H &\simeq \hbar\Omega e^{-(1/2)\eta^2} [\sigma_+ e^{-i\delta t} (1 + i\eta[ae^{-i\nu t} + a^\dagger e^{i\nu t}]) + \text{H.c.}] \\
&= \hbar\Omega' \{(\sigma_+ e^{-i\delta t} + \sigma_- e^{+i\delta t}) + i\eta(\sigma_+ e^{-i\delta t} - \sigma_- e^{+i\delta t}) \\
&\quad \times [ae^{-i\nu t} + a^\dagger e^{i\nu t}]\} \quad (3)
\end{aligned}$$

[where we have defined $\Omega' \equiv \Omega e^{-(1/2)\eta^2}$]. When the radiation is resonant with the ionic transition (or ‘‘carrier’’) frequency ($\delta=0$), this reduces to

$$H = \hbar\Omega' [\sigma_+ + \sigma_- + i\eta(\sigma_+ - \sigma_-)(ae^{-i\nu t} + a^\dagger e^{i\nu t})]. \quad (4)$$

Comparing these equations with Eq. (2a), we see that the usual derivation corresponds to neglecting the terms rotating at frequency $\pm\nu$ in this expression. These terms are the first-order correction to the semiclassical ion-field interaction due to the presence of the trapping potential, and their effect is to cause the dressed states $|\pm\rangle$ to become nonstationary. To see how these evolve, we first move into the ‘‘dressed-state’’ picture obtained by rotating the atomic basis states with the transformation

$$R = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \quad (5)$$

so that $|\pm\rangle$ become, respectively, $|e\rangle$ and $|g\rangle$ [note that, in our notation, $|e\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$, $|g\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$, $\sigma_+ = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$, $\sigma_- = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}$].

Using the fact that

$$R\sigma_\pm R^\dagger = \frac{1}{2} [\sigma_z \pm (\sigma_+ - \sigma_-)], \quad (6)$$

we can see that, in this picture, the Hamiltonian has the Jaynes-Cummings [19] form

$$H' = \hbar\Omega' [\sigma_z + i\eta(\sigma_+ - \sigma_-)(ae^{-i\nu t} + a^\dagger e^{i\nu t})]. \quad (7)$$

(This transformation of the Hamiltonian is a special case of the construction given in [18], where it is shown that the ion-laser interaction is *always* unitarily equivalent to a Jaynes-Cummings form, without any approximations.)

Making a further ‘‘interaction picture’’ transformation of the Hamiltonian by the unitary operator $\exp(i\Omega't\sigma_z/\hbar)$, we have

$$\begin{aligned}
H'' &= i\hbar\eta\Omega' [e^{i(2\Omega' - \nu)t}\sigma_+ a - e^{-i(2\Omega' - \nu)t}\sigma_- a^\dagger \\
&\quad + e^{i(2\Omega' + \nu)t}\sigma_+ a^\dagger - e^{-i(2\Omega' + \nu)t}\sigma_- a], \quad (8)
\end{aligned}$$

which gives us the resonance condition

$$\Delta = \Omega' - \frac{\nu}{2} = 0. \quad (9)$$

Apart from the small correction to Ω given by the Debye-Waller factor $e^{-(1/2)\eta^2}$ [6], this is precisely the condition depicted in Fig. 1. In this case, the first two (‘‘rotating’’) terms in Eq. (8) become constant while the second two (‘‘counter rotating’’) oscillate at a frequency of 2ν . We can ignore them, making the Jaynes-Cummings RWA, as long as

the secular frequency $\eta\Omega' = (1/2)\eta\nu$ of the resulting evolution is much smaller than this [19]. This requires $\eta \ll 4$, which is compatible with the Lamb-Dicke assumption $\eta \ll 1$ we have already made. Thus if the laser’s frequency and intensity are such that they satisfy the *double resonance* condition $\delta = \Delta = 0$, the evolution of the system can be described by the simple Jaynes-Cummings form

$$H_{2SS} = \frac{i\hbar\eta\nu}{2} [\sigma_+ a - \sigma_- a^\dagger]. \quad (10)$$

What this teaches us is that off-resonant transitions cannot always be disregarded, but, under the right conditions, may in fact lead to resonant effects. Intuitively, if the off-resonant terms in the Hamiltonian given in Eq. (4) rotate precisely in step with the secular evolution generated by the resonant terms, their contribution does not ‘‘average out’’ but rather adds up over each cycle, in a manner reminiscent of an oscillator being driven by a resonant force. In the present case this effect allows a field resonant with the carrier to couple the internal and motional ionic variables in a way exactly analogous to a red sideband-detuned pulse as described by Eq. (2b) [Figs. 2(a) and 2(b)]. In particular, it can just as well be used to implement two-qubit logic gates between these two degrees of freedom. Of course, the Hamiltonian (10) is valid only in the ‘‘dressed’’ picture defined by the operator R in Eq. (5). In the normal or ‘‘bare’’ picture, its effect can be seen as a beating at frequency $\eta\nu$ superposed on the usual Rabi flops between states $|g\rangle|n\rangle$ and $|e\rangle|n\rangle$ [Fig. 2(c)]. It is not necessarily obvious that this ‘‘dressed-picture’’ Jaynes-Cummings interaction can be used to implement quantum logic gates in the ‘‘real world.’’ Nevertheless, in Sec. III we show how, with a suitable generalization to the N -ion situation, this interaction can indeed realize a control-NOT (C-NOT) gate between the internal variables of two separate ions. (Recall that a C-NOT gate together with one-qubit rotations form a universal set of gates for quantum computing [23].)

Finally, let us briefly consider the experimental requirements of our proposal. Apart from the usual demands of the CZ quantum gate proposal (individual ion access, ground-state cooling), the only new requirement we make is that the laser should have a fixed intensity satisfying the resonance condition in Eq. (9) (or its N -ion generalization; see below). In more quantitative terms, our numerical simulation (see Sec. III B 1) indicates that the laser power must be stable to within about $\pm 0.5\%$. This does not seem to require significant improvements in the laser power and intensity stability already available in current experimental setups [24]. There is also a bonus in the fact that a single laser can be used to perform both one- and two-qubit interactions. Therefore we expect that a proof-of-principle experiment using a single trapped ion should not be hard to realize.

C. Light-shift gates in a chain of N ions

The results we have just described are almost immediately generalizable to the case where there are N identical ions (and therefore N motional modes) in a linear trap [6,8]. Assuming that each of the ions can be illuminated individually by a (traveling) laser beam, then resonance conditions simi

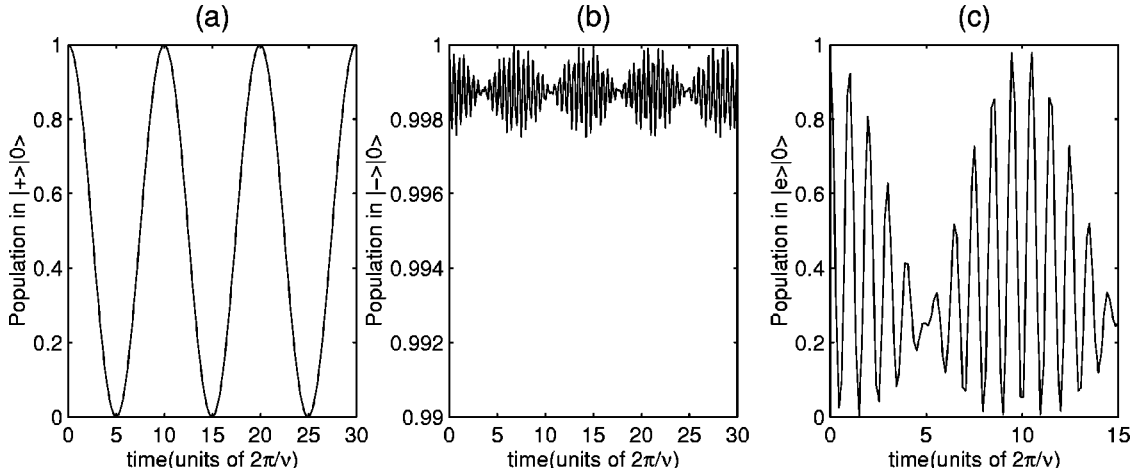

FIG. 2. Simulation of a light-shift-based ion-mode gate operating on a single trapped ion. The laser is tuned on resonance with the carrier, and also at an intensity such that the Rabi frequency Ω' is equal to exactly half the trap frequency ν . The Lamb-Dicke parameter is $\eta=0.1$. (a) In the interaction picture, state $|+\rangle|0\rangle$ exchanges population with $|-\rangle|1\rangle$; an exchange rate of over 99% is achieved. (b) Meanwhile, state $|-\rangle|0\rangle$ is stationary. The resulting ion-mode “conditional dynamics” can be used to implement a two-qubit quantum gate. (c) In the Schrödinger picture, this effect appears as a modulation of the Rabi oscillations between states $|e\rangle|0\rangle$ and $|g\rangle|0\rangle$.

lar to those in Eq. (9) turn out to exist for each separate mode frequency ν_j . Before showing how the resulting ion-mode interaction can be used to implement ion-ion gates, we would like to call attention to an important aspect of the N -ion situation. In principle, any of the N motional modes can be used to couple the internal ionic variables. However, in order for the light-shift scheme to function with higher-order modes, it is necessary to drive the system deeper into the Lamb-Dicke regime. To see this, consider the interaction-picture Hamiltonian describing the coupling of the j th ion with a (traveling-wave) laser [8]:

$$H = \hbar\Omega \left[\sigma_+^j \exp \left(i \sum_{p=1}^N \eta_{jp} [a_p e^{-i\nu_p t} + a_p^\dagger e^{i\nu_p t}] - \delta t \right) + \text{H.c.} \right]. \quad (11)$$

Here, p indexes the normal modes. The parameter η_{jp} , which functions as the “effective” Lamb-Dicke parameter of the p th mode, corresponds to the product $\eta_p b_j^{(p)}$, where $\eta_p = \sqrt{(\hbar k^2/2m\nu_p)}$ is the “conventional” Lamb-Dicke parameter and $b_j^{(p)}$ is the relative weight of the j th ion’s displacement in this mode. For the center-of-mass mode, $b_j^{(1)} = 1/\sqrt{N}$ is independent of which ion is being driven. For other modes this is no longer true. James [8] has given values of $b_j^{(p)}$ for all ions and modes up to $N=10$.

If all modes are suitably cooled and within the Lamb-Dicke regime, and if the laser is resonant with the ionic carrier transition ($\delta=0$), then a procedure entirely analogous to the one described in Eqs. (3)–(8) can be followed. One then obtains that, in the “dressed-state” picture defined by

$$V(t) = \exp(i\Omega' t \sigma_z^j) R_j, \quad (12)$$

the Hamiltonian given above can be rewritten as

$$H'' = i\hbar\Omega' \sum_p \eta_{jp} [e^{i(2\Omega' - \nu_p)t} \sigma_+^j a_p - e^{-i(2\Omega' - \nu_p)t} \sigma_-^j a_p^\dagger + e^{i(2\Omega' + \nu_p)t} \sigma_+^j a_p^\dagger - e^{-i(2\Omega' + \nu_p)t} \sigma_-^j a_p], \quad (13)$$

where $\Omega' = \Omega e^{(-1/2)(\sum_p \eta_{jp}^2)}$. As expected, there are multiple resonance conditions analogous to Eq. (9), one for each mode frequency ν_p . If any of these are met [say, $\Omega' = (\nu_q/2)$ for the q th mode], then the terms in this Hamiltonian can be divided into three categories according to their time dependence:

(i) The rotating terms of the q th mode are resonant, and represent a Jaynes-Cummings interaction of the form

$$H_{2SS} = \frac{i\hbar\nu_q\eta_{jq}}{2} (\sigma_+^j a_p - \sigma_-^j a_p^\dagger). \quad (14)$$

(ii) All counter-rotating terms oscillate at frequencies equal (in modulus) to at least $\nu_q + \nu_1 \gg (\nu_q\eta_{jq}/2)$, where ν_1 is the lowest energy mode. Assuming the effective Lamb-Dicke parameter η_{jq} is small ($\eta_{jq} \lesssim \frac{1}{10}$), they can therefore be discarded in a RWA.

(iii) The rotating terms of the other modes oscillate at frequencies equal to $\pm|\nu_p - \nu_q|$. For a similar η_{jq} , these terms can be discarded as long as

$$\frac{|\nu_p - \nu_q|}{\nu_q} \gg \frac{\eta_{jq}}{2}. \quad (15)$$

If this is true for all $p \neq q$, then the Hamiltonian (13) can be reduced to the resonant term given in Eq. (14). In this case, only the q th mode is coupled to the ion’s internal state, just as in the usual perturbative scheme when the laser is tuned to the first red sideband of this mode. The off-resonant terms will lead to a small population leakage into the unwanted modes, of the order

$$\epsilon^2 = \left(\frac{\eta_{jq}\nu_q}{2|\nu_p - \nu_q|} \right)^2 \ll 1. \quad (16)$$

As we discuss in Appendix A, for high enough precision (small enough ϵ), this population loss gives an upper bound to η_{jq} , and therefore to the overall Rabi frequency $\frac{1}{2}\eta_{jq}\nu_q$ at which the scheme can function. For example, in the case of the lowest (center-of-mass) mode, $\epsilon^2 \leq 0.005$ requires $\eta_1 \leq 0.1$. In addition, it has been shown by James [8] that the spacing $|\nu_{q+1} - \nu_q|$ between successive modes decreases as their order increases. It follows that attaining a given precision ϵ requires η_{jq} to be made smaller and smaller as q grows. In effect, we find that the potential increase in Rabi frequency afforded by using higher modes is completely counterbalanced by this requirement, with the result being that the maximum value for the overall switching rate actually decreases as higher modes are used.

D. Two-ion C-NOT gates

Assuming the effective Hamiltonian (14) is valid, we can use it to implement two-qubit quantum logic gates between two ions in a manner similar to the usual Cirac-Zoller scheme [9]. The analogy is not perfect because in the present case the Jaynes-Cummings Hamiltonian H_{2SS} is valid only in the picture defined by the unitary operator in Eq. (12), which varies according to which atom is being addressed. Before we realize a gate, we must first transform back into the ‘‘common’’ picture [i.e., the one where the Hamiltonian in Eq. (11) is defined] and see how the time evolution behaves there. In this case we have that an initial state $|\psi(0)\rangle$ evolves according to

$$|\psi(t)\rangle = V^\dagger(t) U_{JCM}(t) V(0) |\psi(0)\rangle, \quad (17)$$

where $V(t)$ is given in Eq. (12) and $U_{JCM}(t) = \exp[(-it/\hbar)H_{2SS}]$. In particular, the following states have a simple time evolution:

$$|-\rangle|0\rangle \rightarrow \exp\left(\frac{i\nu_q t}{2}\right) |-\rangle|0\rangle \quad (18)$$

$$\begin{aligned} |+\rangle|0\rangle &\rightarrow e^{(-i\nu_q t/2)} \cos\left(\frac{\nu_q \eta_{jq} t}{2}\right) |+\rangle|0\rangle \\ &\quad - e^{(i\nu_q t/2)} \sin\left(\frac{\nu_q \eta_{jq} t}{2}\right) |-\rangle|1\rangle, \end{aligned} \quad (19)$$

$$\begin{aligned} |-\rangle|1\rangle &\rightarrow e^{(i\nu_q t/2)} \cos\left(\frac{\nu_q \eta_{jq} t}{2}\right) |-\rangle|1\rangle \\ &\quad + e^{(-i\nu_q t/2)} \sin\left(\frac{\nu_q \eta_{jq} t}{2}\right) |+\rangle|0\rangle, \end{aligned} \quad (20)$$

$$\begin{aligned} |+\rangle|1\rangle &\rightarrow e^{(-i\nu_q t/2)} \cos\left(\frac{\nu_q \eta_{jq} t}{\sqrt{2}}\right) |+\rangle|1\rangle \\ &\quad - e^{(i\nu_q t/2)} \sin\left(\frac{\nu_q \eta_{jq} t}{\sqrt{2}}\right) |-\rangle|2\rangle. \end{aligned} \quad (21)$$

As we can see, we obtain the usual Jaynes-Cummings Rabi flows, except that here the atomic states for which the atom

and mode dynamically entangle and disentangle themselves are the dressed states $|\pm\rangle$, not the bare states $|g\rangle, |e\rangle$. There are also some additional time-dependent phases.

In Appendix B, we demonstrate explicitly how this evolution can be used to implement a two-qubit gate between two ions. We follow the same basic three-step pulse sequence proposed by Cirac and Zoller [9]: first, a π pulse is realized between ion 1 and the chosen vibrational ‘‘data bus’’ mode, which is initially cooled to the ground state. This effectively maps the internal state onto the motional one and vice versa, implementing the so-called SWAP gate (defined here as the operation that maps states $| -1\rangle$ and $| +0\rangle$ onto each other, leaving $| -0\rangle$ and $| +1\rangle$ unaffected). Second, a 2π pulse is applied between the mode and ion 2, realizing an entangling gate between the two systems. Finally, a second π pulse maps the motional state back onto the first ion, completing the ion-ion gate. In the light-shift scheme, some minor modifications in the sequence are necessary due to the fact that the ‘‘computational basis states’’ of the ions (generally assumed to be the bare states $|g\rangle, |e\rangle$) are not favored by the time evolution above. This will then require a few extra one-qubit rotations in between the three basic steps. In the end, we are able to implement a C-NOT gate, with ion 2 acting as the ‘‘control’’ qubit, using a sequence of six pulses (three one-qubit and three two-qubit pulses). In comparison, the original CZ proposal requires five pulses to implement a C-NOT gate, with the ions assuming the opposite roles: ion 1 is the ‘‘control’’ and ion 2 the ‘‘target’’ qubit. We note that, in our protocol, some of the one-qubit pulses may (at least in principle) be realized simultaneously with a two-qubit pulse: pulses one and two in Appendix B can be realized together, and the same is true of pulses four and five. In contrast, in the CZ scheme each of the five pulses must be realized in sequence.

III. COMPARATIVE PERFORMANCE OF GATE SCHEMES

We now study the performance of our ‘‘light-shift-based’’ (LB) gate scheme, comparing it to that of Cirac and Zoller’s original ‘‘red-sideband pulse’’ proposal [9]. Briefly speaking, our goal is to estimate the overall switching rate for an ion-ion C-NOT gate that can likely be attained using each scheme.

We begin by recalling that this rate will be essentially governed by the speed of the three two-qubit steps in either scheme’s pulse sequence. This follows since one-qubit ionic gates are unlimited by the mode frequency, and can therefore be implemented at a much greater speed than two-qubit ion-mode pulses [6]. If we also assume for simplicity that the same ionic transition is used for both π and 2π pulses, then the overall ion-ion gate frequency should be approximately equal to the two-qubit Jaynes-Cummings Rabi frequency. Here we are using the convention that one complete Rabi oscillation, i.e., when all states *and* their phases have returned to their initial values, corresponds to a 4π pulse.

For the LB scheme, this frequency is just $\eta\nu/2$. For a typical value $\eta=0.1$ of the Lamb-Dicke parameter, we obtain therefore an overall C-NOT switching rate of about $\nu/20$. Although still well under the limit posed by the mode frequency ν itself, such a rate would represent a substantial

FIG. 3. Driving an ion with traveling radiation detuned to the first red sideband generates a situation in many ways analogous to a three-level system. The resonant $1 \leftrightarrow 2$ transition corresponds to the relatively weak sideband transition (coupling constant $\eta\Omega$), while the off-resonant $1 \leftrightarrow 3$ transition is analogous to the strong carrier transition (coupling constant $\Omega \gg \eta\Omega$). The off-resonant transition can be ignored, leaving an effective two-level system formed by levels one and two, only if Ω satisfies the condition in Eq. (22).

improvement with respect to current experiments. For example, in the (single-ion) two-qubit gate experiment reported in [2], the two-qubit Rabi frequency was approximately $10^{-3}\nu$. In what follows, we elaborate on this comparison by making a more thorough analysis of the limits of validity of the two methods. In particular, we include numerical confirmation of the efficiency of the LB scheme.

A. Regimes of the Cirac-Zoller scheme

Unlike in the LB scheme, in the CZ method the speed of the two-qubit gates is directly proportional to the laser field used to drive the red-sideband transition. This field cannot, however, be made too intense without driving unwanted off-resonant transitions, which therefore are the limiting factors on the resulting gate speed. Before we can properly assess this limit quantitatively, we must first recall that the CZ scheme operates in two strikingly different regimes, depending on the spatial profile of the laser field [9,20]. The origin of this difference lies in the presence or absence of strongly coupled off-resonant levels. It turns out that the conditions under which transitions to these levels can be safely ignored (as is implied in the derivation of the CZ scheme) depend crucially on whether *traveling-wave* or *standing-wave* laser radiation is employed to drive the red-sideband transition.

When a traveling beam is used, the closest-lying off-resonant transition is the carrier transition itself, which is detuned by the mode frequency ν . Despite this, the carrier is also *stronger* than the resonant transition by a factor of $\eta^{-1} \gg 1$. Intuitively, this situation is analogous to a V-type three-level atom where a weak transition (of strength $\eta\Omega'$) is being resonantly driven, and where there is another closely lying transition, detuned by ν , which has a much stronger coupling constant Ω' (Fig. 3). The effects of both transitions must then be carefully weighed against each other: if ν is large with respect to $\eta\Omega'$, then we may expect the off-resonant transition to be “washed out” on average, as usually happens in rotating-wave approximations. However, this condition alone is not sufficient, since in the limit $\eta \rightarrow 0$ the off-resonant transition must dominate the time evolution, resulting in oscillations with an effective Rabi frequency (Ω'^2/ν). We can therefore expect the resonant transition to dominate only if its secular Rabi frequency $\eta\Omega'$ is much greater than this value, i.e., if

$$\Omega' \ll \eta\nu. \quad (22)$$

The validity of this heuristic argument for the actual Cirac-Zoller Hamiltonian can be confirmed via a straightforward perturbation-theory calculation [25].

In other words, in order to ignore off-resonant transitions, the Rabi frequency Ω' of the ion-mode interaction must be extremely small, of the order $\nu/100$ for a typical value $\eta=0.1$. This in turn implies that the switching rate of the resulting logic gates will be of the order $\eta\Omega' \lesssim \nu/1000$, way below the upper limit set by ν . It is worthwhile to note that Eq. (22) was indeed satisfied in both published experiments that implemented CZ-like Rabi flops using traveling-wave radiation and a single trapped ion [2,16].

A very different situation arises if the laser field forms a sinusoidal standing wave (such as could be obtained by bouncing the beam back on itself from a mirror), and if the ion is located exactly in one of the *nodes* of this wave. In this case, interference from the two traveling components of the wave completely cancels many of the off-resonant transitions, in particular the carrier [6,8,9]. This effective selection rule greatly increases the laser power that can be used, since the most important off-resonant terms remaining in the Hamiltonian (Jaynes-Cummings counter-rotating terms and terms describing the accidental driving of the wrong modes) are no longer stronger than the resonant one. Standard perturbation-theoretic arguments [20,8] show that in this case the laser power should satisfy

$$\Omega' \ll \frac{\nu}{\eta}. \quad (23)$$

For $\eta=0.1$, this implies an increase by two orders of magnitude with respect to the traveling-wave case. As a result, this configuration could potentially lend itself to the implementation of much faster gates than the ones already achieved experimentally. Unfortunately, the technical difficulty of reliably maintaining an ion precisely in a wave node seems to have discouraged researchers from attempting such an experiment [26]. We are also not aware of any current plans for experiments in this direction.

B. Efficiency of gate implementations

In what follows, we compare our “light-shift-based” proposal to both regimes of the CZ scheme. We find that its performance can approach that of the standing-wave CZ configuration, without the latter’s technical drawbacks. In other words, an improvement of over an order of magnitude in the switching rate can be achieved with respect to current traveling-wave-based experiments without a great change in the experimental setup itself. It must be emphasized again that we are only interested here in the *theoretical* limits to the gate performance, arising exclusively from the existence of stray off-resonant excitations in the system. In other words, we are not concerned with external noise or dissipative effects such as spontaneous emission [27], but with the maximum performance obtainable even under ideal experimental conditions.

FIG. 4. Average fidelity measure $F(\eta=0.1, \Omega')$ (see Sec. III B), plotted against the ratio Ω'/ν , for different quantum gate schemes in a two-ion trap: (a) The traveling-wave CZ scheme, (b) the standing-wave CZ scheme, and (c) the “light-shift-based” (LB) scheme. Around the resonance $\Omega' = \nu/2$ [see Eq. (9)], the LB scheme attains a peak efficiency close to 100%. The peak stays above 99% for values of Ω'/ν within about $\pm 0.5\%$ of the resonance (inset). Since Ω' governs the gate switching rate, this scheme should allow the implementation of efficient gates over an order of magnitude faster than those obtained in current experiments based on the traveling-wave CZ method. Although this is still a few times smaller than the rate attainable using the standing-wave CZ scheme, the LB scheme should be easier to implement experimentally.

A useful figure of merit for comparing the performance of the different schemes can be defined as follows. First, we determine how efficiently the π -pulse (or “SWAP gate”) step is implemented in each scheme as a function of a relevant external parameter of the system, for instance laser power (a precise definition of what we mean by “efficiency” is given below). We can then define the *maximum switching rate* for each scheme as the greatest speed that can be attained while simultaneously keeping the efficiency above a sufficiently high threshold, which we (arbitrarily) set at 99%.

The definition of “efficiency” is also somewhat arbitrary. We take it to be the *average fidelity* with which the SWAP gate operates, maximized over one cycle, or

$$F(\eta, \Omega) = \max_{\text{1st cycle}} \left| \frac{1}{n} \sum_{k=1}^n \langle \psi_f^k | U(\eta, \Omega, t) | \psi_i^k \rangle \right|^2, \quad (24)$$

where the average is taken over some set of “relevant” initial states $\{\psi_i^k\}_{k=1}^n$, with ideal images under SWAP given by $\{\psi_f^k\}_{k=1}^n$, and where $U(\eta, \Omega, t)$ represents the full time evolution of the ion-trap system. For simplicity, we take this set to be the basis states $\{|g\rangle|0\rangle, |g\rangle|1\rangle\}$ (in the case of the CZ gate) or $\{|-\rangle|0\rangle, |-\rangle|1\rangle\}$ (in the case of the LB gate).

Numerical results

In Fig. 4 we plot the efficiency function $F(\eta, \Omega')$, with η fixed at 0.1, for three different gate schemes: the CZ scheme using (a) traveling-wave radiation or (b) standing-wave radiation; and (c) the “light-shift-based” scheme. The graphs were obtained by numerical integration of the full Schrödinger equation describing an ion–center-of-mass mode interaction in a two-ion trap, including all off-resonant transitions and all orders of the Lamb-Dicke parameter. The second or “stretch” mode is assumed to be cooled to the ground state.

As should be expected, in the CZ schemes the efficiency decreases essentially monotonically with the laser power. In addition, the dramatic difference in performance between the standing- and traveling-wave CZ configurations is readily apparent (note the difference in scale of the two graphs). Indeed, if we consider 99% efficiency as the criterion for acceptable gate performance, then the upper limit for Ω' in the traveling-wave case is about $1.5 \times 10^{-2} \nu$, while in the standing-wave case it is about 1.25ν , in agreement with the estimates in Eqs. (22) and (23). Meanwhile, the efficiency of the LB scheme has a narrow peak around the resonance value $\Omega' = \nu/2$, with a maximum value well over 0.99. Note the presence of a small shift in the resonance due to the existence of weak off-resonant transitions. The width of the region where $F > 0.99$ is of the order of 0.005ν . We can conclude that highly efficient gate performance in this scheme is possible as long as the Rabi frequency of the laser-ion interaction is stable to within at least $\pm 0.5\%$.

C. Discussion

Our results indicate that, as long as the challenges of individual laser access and ground-state cooling can be met, the light-shift-based scheme should indeed allow highly efficient two-qubit gates to be implemented within the Lamb-Dicke regime. Furthermore, the relatively high laser power employed in this scheme means these gates should be over an order of magnitude faster than their counterparts obtainable via the traveling-wave CZ scheme used in current experiments. Specifically, an ion-ion C-NOT gate with a switching rate around $\nu/20$ may be realized. This speed is comparable to the one obtainable in principle with a standing-wave CZ configuration, but our proposal achieves it without requiring a precisely controlled standing-wave field. We believe that these features should make the light-shift-based scheme a attractive candidate for the realization of

faster quantum gates. Furthermore, testing the underlying principle of the scheme in existing single-ion traps should present no difficulty.

Finally, we would like to briefly compare our scheme with the “magic Lamb-Dicke parameter” (MLDP) proposal of Monroe *et al.* [10]. This elegant scheme exploits the fact that the one-qubit Rabi frequency Ω in Eq. (2a) is in fact dependent on the number of motional excitations of the ion. It turns out that, for specific “magic” values of the Lamb-Dicke parameter, the values of Ω corresponding to zero and one phonons become commensurate. This then means that, after a sufficient number of Rabi periods, the atomic state is flipped or not flipped depending on the state of the mode; in other words, a C-NOT gate with the mode as the control qubit can be implemented. The scheme has a number of experimental advantages, notably the absence of the “auxiliary” level needed in the CZ and LB schemes. Also, since it only uses the strong ionic ‘carrier’ transition, the laser power used can be quite considerable, leading also to relatively fast gates. The exact switching rate that can be obtained depends on the chosen “magic” value, but should be at least as large as the ones obtained by the other methods discussed in this paper (see [17] for a discussion).

The method, however, also has at least two drawbacks. First of all, even the smallest magic value of η quoted in [10] is 0.316. This is already a bit too large for the validity of the Lamb-Dicke regime required by currently used cooling mechanisms such as sideband cooling [6]. Unless more sophisticated cooling methods are employed (possibly involving the use of higher-order sidebands [28]), one would then need the ability to fine tune η to different values at different stages of the experiment, a feat that has not yet been accomplished in practice, to our knowledge.

A second drawback comes the fact that the MLDP scheme can only implement universal ion-ion quantum logic [23] if it is supplemented with another mechanism capable of realizing SWAP gates between internal and motional states. For example, in [10] Monroe *et al.* point out that an ion-ion C-NOT gate can be realized by “sandwiching” an MLDP-based ion-mode C-NOT between two SWAP gates, just as happens in the CZ scheme. However, the dispersive interaction exploited in the MLDP scheme does not itself allow the transfer of excitations from the internal to the motional states. This can be seen by noting that none of the available gates (one-qubit ionic rotations and C-NOT gates *with the mode as the control qubit*) changes the populations in any motional state. (In other words, these operations alone do *not* constitute a universal set of gates [29].) SWAP gates can only be realized via some different mechanism, for instance the CZ red-sideband method or our LB method. In particular, a gate using LB-based SWAP steps and an MLDP-based entangling step would combine the best features of both these schemes, including both speed and the absence of complications such as auxiliary levels and standing waves (note though, that since the LB scheme requires a smaller value of η , the ability to tune this parameter would still be required). Whether in this “hybrid” combination or on its own, we hope that the LB scheme will prove to be a useful tool for ion-trap quantum information processing.

Note added. Recently, another study of the speed limits of Cirac-Zoller gates was put forward by Steane *et al.* [17]. Apart from presenting results that support and extend the discussion in Sec. III A above, these authors also propose and experimentally test an independent method for increasing the gate switching rates within a traveling-wave scenario. Their idea is somewhat complementary to the one presented in this paper: they argue that the rapid decay in gate efficiency shown in Fig. 4(a) is partly due to a shift in the sideband transition frequency caused by the nearby strong carrier transition. This shift can be compensated for by choosing the laser beam to be slightly detuned from the first sideband frequency, resulting in gates that are considerably faster than the “standard” CZ gates we have considered in our analysis. Nevertheless, it appears that, if a sufficiently high gate fidelity is demanded, then our light-shift-based scheme is still faster than even this enhanced scheme [30].

APPENDIX A: LIMITS TO LIGHT-SHIFT GATES IN N -ION STRINGS

James [8] has given detailed numerical data for the mode parameters of up to ten trapped ions. It turns out that the frequency ν_q of a mode of any given order q is roughly independent of the number of ions (to about 0.5% over the range of ion numbers investigated). In the second line of Table I, we reproduce these rough frequency values for the first six modes, relative to the frequency ν_1 of the lowest (CM) mode [31].

We can use these data along with the condition in Eq. (16), i.e.,

TABLE I. Properties of the lowest longitudinal modes of a linear ion chain, adapted from data in Table II of James [8] (see text for details).

q	1	2	3	4	5	6
$\frac{\nu_q}{\nu_1}$	1	$\sqrt{3} \approx 1.73$	2.41	3.06	3.68	4.28
$\min_p \frac{ \nu_p - \nu_q }{\nu_q}$	0.73	0.39	0.27	0.20	0.16	
η_{\max}	0.146	0.08	0.05	0.04	0.03	
$\frac{\eta_{\max} \nu_q}{2\nu_1}$	0.073	0.069	0.065	0.061	0.055	

$$\epsilon^2 = \left(\frac{\eta_{jq} \nu_q}{2|\nu_p - \nu_q|} \right)^2 \ll 1, \quad (\text{A1})$$

in order to estimate the range of values of the Lamb-Dicke parameter η_{jq} for which the light-shift-based scheme should work within a given precision. [It can be verified that losses due to other off-resonant transitions such as the counter-rotating terms in Eq. (13) are relatively small in the limit of small η_{jq} .] For each mode, we list in the third line the relative frequency spacing to its closest-lying neighbor. Note that the closest mode is always the next-highest one, and that their relative spacing *decreases* with increasing mode order. In the fourth line, we list the maximum value η_{\max} that η_{jq} can assume such that $\epsilon^2 \leq 0.01$. Within this limit we should be able to discard all off-resonant terms in the Hamiltonian in Eq. (13), and the dynamics is then well described by the effective Jaynes-Cummings interaction in Eq. (14). Finally, in the fifth line we give the resulting maximum Rabi frequency achievable using each mode (relative to the CM mode frequency). Note that the increase of the mode frequencies themselves is completely compensated by the decrease in the allowed Lamb-Dicke parameters, with the effect being that the overall Rabi frequency also diminishes as the mode order is increased.

APPENDIX B: C-NOT GATE IN THE LIGHT-SHIFT SCHEME

The following sequence of pulses realizes a C-NOT gate between the internal states of two trapped ions, using the LB ion-mode interaction given in Eqs. (18)–(21).

(1) First, assuming the “bus” mode is initially in the ground state, the state of ion 1 *in the* $|\pm\rangle_1$ *basis* is mapped onto the $|0\rangle$ and $|1\rangle$ phonon states by a two-qubit π pulse of duration $\tau_1 = (\pi/\nu_q \eta_{qj})$:

$$|-\rangle_1|0\rangle \xrightarrow{\tau_1} e^{(i\pi/2)\eta_{jq}} |-\rangle_1|0\rangle, \quad (\text{B1a})$$

$$|+\rangle_1|0\rangle \xrightarrow{\tau_1} -e^{(i\pi/2)\eta_{jq}} |-\rangle_1|1\rangle. \quad (\text{B1b})$$

The phase is identical for both initial states and can be ignored; ion 1 is left in the $|-\rangle_1$ state. In terms of the logical basis $|g\rangle_1, |e\rangle_1$, this transformation corresponds to applying a sequence of three gates: first a Hadamard rotation of the ion, followed by a SWAP gate with the mode, and finally a second Hadamard rotation.

(2) A one-qubit $\pi/2$ pulse coupling $|g\rangle_2$ to an unpopulated “auxiliary” level $|e'\rangle$ is then applied on ion 2, mapping $|g\rangle_2 \rightarrow (1/\sqrt{2})(|g\rangle_2 - |e'\rangle_2) \equiv |-\rangle_2$. As in the CZ scheme, this $|g\rangle_2 \leftrightarrow |e'\rangle_2$ transition should be chosen such that level $|e\rangle_2$ is not affected (for instance, by using a different polarization).

(3) A two-qubit 2π pulse of duration $\tau_2 = (2\pi/\nu_q \eta_{jq})$, resonant with the $|g\rangle_2 \leftrightarrow |e'\rangle_2$ transition, is applied on ion 2. States $|e\rangle_2|0\rangle_2$ and $|e\rangle_2|1\rangle_2$ of the ion-mode system are unaffected by this, while states $|-\rangle_2|0\rangle_2, |-\rangle_2|1\rangle_2$ evolve according to

$$|-\rangle_2|0\rangle_2 \xrightarrow{\tau_2} \exp\left(\frac{i\pi}{\eta_{jq}}\right) |-\rangle_2|0\rangle_2, \quad (\text{B2a})$$

$$|-\rangle_2|1\rangle_2 \xrightarrow{\tau_2} -\exp\left(\frac{i\pi}{\eta_{jq}}\right) |-\rangle_2|1\rangle_2. \quad (\text{B2b})$$

(4) Another one-qubit $\pi/2$ pulse coupling $|g\rangle_2$ to $|e'\rangle_2$ is then applied, mapping $|-\rangle_2$ back to $|g\rangle_2$. For convenience, we assume here that this pulse also cancels the phase acquired in the previous step. The overall effect of the previous three pulses is to implement a “control- σ_z ” gate between the mode and ion 2, which maps

$$|g\rangle_2|0\rangle \rightarrow |g\rangle_2|0\rangle, \quad |g\rangle_2|1\rangle \rightarrow -|g\rangle_2|1\rangle, \quad (\text{B3})$$

$$|e\rangle_2|0\rangle \rightarrow |e\rangle_2|0\rangle, \quad |e\rangle_2|1\rangle \rightarrow |e\rangle_2|1\rangle. \quad (\text{B4})$$

(5) The state of the mode is then mapped back onto ion 1 by a second two-qubit π pulse:

$$|-\rangle_1|0\rangle \xrightarrow{\tau_1} \exp\left(\frac{i\pi}{2\eta_{jq}}\right) |-\rangle_1|0\rangle, \quad (\text{B5a})$$

$$|-\rangle_1|1\rangle \xrightarrow{\tau_1} \exp\left(\frac{-i\pi}{2\eta_{jq}}\right) |+\rangle_1|0\rangle. \quad (\text{B5b})$$

(6) Finally, a one-qubit pulse removes the phase acquired in the previous step, mapping states $\exp(\mp i\pi/2\eta_{jq})|\pm\rangle_1$ of ion 1 into $|\mp\rangle_1$. This completes the gate, whose overall effect in the computational basis is a C-NOT between ion 2 (the control qubit) and ion 1 (the target qubit):

$$\begin{aligned} |g\rangle_1|g\rangle_2|0\rangle &\xrightarrow{1} |-\rangle_1|g\rangle_2(|0\rangle - |1\rangle) \xrightarrow{2-4} |-\rangle_1|g\rangle_2(|0\rangle + |1\rangle) \\ &\xrightarrow{5-6} |g\rangle_1|g\rangle_2|0\rangle, \end{aligned} \quad (\text{B6a})$$

$$\begin{aligned} |g\rangle_1|e\rangle_2|0\rangle &\xrightarrow{1} |-\rangle_1|e\rangle_2(|0\rangle - |1\rangle) \xrightarrow{2-4} |-\rangle_1|e\rangle_2(|0\rangle - |1\rangle) \\ &\xrightarrow{5-6} |e\rangle_1|e\rangle_2|0\rangle, \end{aligned} \quad (\text{B6b})$$

$$\begin{aligned} |e\rangle_1|g\rangle_2|0\rangle &\xrightarrow{1} -|-\rangle_1|g\rangle_2(|0\rangle + |1\rangle) \xrightarrow{2-4} |-\rangle_1|g\rangle_2(|1\rangle - |0\rangle) \\ &\xrightarrow{5-6} |e\rangle_1|g\rangle_2|0\rangle, \end{aligned} \quad (\text{B6c})$$

$$\begin{aligned} |e\rangle_1|e\rangle_2|0\rangle &\xrightarrow{1} -|-\rangle_1|e\rangle_2(|0\rangle + |1\rangle) \\ &\xrightarrow{2-4} -|-\rangle_1|e\rangle_2(|0\rangle + |1\rangle) \xrightarrow{5-6} |g\rangle_1|e\rangle_2|0\rangle. \end{aligned} \quad (\text{B6d})$$

Note that the first five pulses already generate a “maximally entangling” two-qubit gate, which is equivalent to the C-NOT gate except for a local rotation.

- [29] Note that excitation transfer would indeed be possible if one-qubit rotations could also be implemented directly on the motional state. This follows since surrounding a C-NOT gate with Hadamard rotations on both qubits exchanges the role of control and target qubit, and since a sequence of three alternating C-NOT gates is equivalent to the SWAP gate. However, since the motional state cannot be manipulated independently, a SWAP gate cannot be realized with this method alone.
