#### Abstract

Various theoretical and numerical problems relating to heliumlike systems in their ground states are treated. New developments in the numerical solution of the Schrödinger equation permit the solution of 256 -body systems with hard-sphere forces. Using periodic boundary conditions, fluid and crystal states can be described; results for the energy and radial-distribution functions are given. A new method of correcting for low-lying phonon excitations so as to extrapolate the energy of fluids to an infinite system is described. A perturbation theory relating the properties of the system with pure hard-sphere forces to those with smoother, more realistic two-body forces is introduced. As in recent work on classical systems the potential is divided into two continuous parts: One is repulsive, one attractive, the latter being treated as a perturbation. The solution for the repulsive part is taken directly from the hard-sphere problem when the radius is identified as the scattering length of the repulsive part of the smooth potential. The convergence for the Lennard-Jones potential is very good. Using our numerical results for the hard-sphere problem, with phonon corrections, together with this perturbation theory, results for energy versus density agree with experiment within our error of $(3-10) \%$ except at high crystal densities. We carry further Schiff's recent application of this perturbation theory to $\mathrm{He}^{3}$ and conclude that antisymmetrization by the method of Wu and Feenberg is the reason for lack of agreement with experiment in that system.

## I. INTRODUCTION

In this paper we investigate in some detail the properties of the ground state of the hard-sphere boson system and apply the results of this study to the real helium case at zero temperature. It is generally assumed that the significant features of the structure of liquid helium are related to the repulsive part of the interaction, the weak attraction for the most part playing the role of keeping the system bound. A good qualitative description of helium should be contained in the hard-sphere problem. This is our first motivation to study that simple system. In view of the success of perturbation theory in the case of classical fluids, where an expansion is carried out around a suitably defined hard-sphere reference system, one may try to build the same kind of perturbation theory in the case of liquid helium, where the hard-sphere properties are also essential ingredients. We shall show that such a theory can be built and that it is very simple and quantitatively successful.

The interest in the hard-sphere Bose system is, of course, not new. Bogolioubov, ${ }^{1}$ Lee and Yang, ${ }^{2}$ and others ${ }^{3}$ have given expressions for the energy of the ground state which are exact in the low-density limit. These expressions are unfortunately useless for densities of physical interest. The only existing computations in the high-density
domain are due to Hansen, Levesque, and Schiff ${ }^{4}$ (HLS), who use in the case of the fluid phase a variational wave function of the Bijl-Jastrow type,

$$
\begin{equation*}
\psi_{J}\left(\overrightarrow{\mathrm{r}}_{1}, \ldots, \overrightarrow{\mathrm{r}}_{N}\right)=\prod_{i<j} e^{-u\left(r_{i j}\right) / 2} \tag{1.1}
\end{equation*}
$$

where $u$ is a trial function. The solid is described by multiplying the function $\psi_{J}$ by a product of oneparticle Gaussian factors centered around the prescribed sites of the equilibrium lattice. Solving this problem numerically through the usual Monte Carlo technique used in classical statistical mechanics, HLS obtained the energy as a function of density for the liquid and solid phase, and the parameters of the first-order transition which lies between these phases.
The first part of this paper is devoted to the solution of the quantum hard-sphere problem (Secs. II-V). This solution based on a method devised by one of $u s^{5}$ is numerical but essentially exact.

In Sec. II we give a summary of this numerical method. It relies on the fact that the wave function of bosons at zero temperature, and the Green's function of the Schrödinger equation written as an integral equation are positive quantities which can be used as probabilities in a Monte Carlo computation. In the case of the hard-sphere system the only-but very great-complication in the Green's function lies in the complex boundary conditions
imposed by the $N(N-1) / 2$ conditions stating that the hard cores do not overlap. A similar Green's function can, however, be sampled in a practical way on simpler subdomains included in the general complex domain; one can write and solve an integral equation which makes it possible to cover the complicated large domain with the simpler subdomains and thus to build the general Green's function. The use of the Jastrow function as a biasing factor in the Monte Carlo method makes the computation feasible.

Section III is devoted to the construction and sampling of the Green's function in the simple subdomains.
In Sec. IV we give some indications of the technical aspects of the method.
The results of the computation are given in Sec. V. A comparison is made (Table VI) with the variational results. The energies obtained through the "exact" computation are slightly, although significantly, lower than the variational ones. In the liquid state the radial-distribution functions (rdf) clearly present more structure than the variational ones. The off-diagonal long-range (ODLR) parameters are very slightly smaller than the corresponding variational ones.

The results of Sec. V have been calculated for a small system: 256 in our study. In Sec. VI the extension to quasi-infinite systems is considered. It requires the inclusion of long-wavelength excitations which, as is well known, play an essential role in liquid helium. Owing to these longwavelength phonons the energy of the dense fluid is lowered by about $2 \%$. The use of the "exact" results for the energies, with phonon corrections, brings a displacement of the freezing and melting densities by about $10 \%$ as compared with the results obtained variationally by HLS.

In the rest of the paper, we apply the hardsphere results to the case of more realistic heliumlike systems.
In Sec. VII we introduce the relevant perturbation theory. We divide the interaction $v(r)$ into two parts, as is done for the classical liquids ${ }^{6}$ : a part $v_{0}(r)$ which gives rise to the repulsive forces and which will be replaced later on by hard spheres located at the scattering length of $v_{0}$, and the remainder of the interaction $w(r)$ which will be treated as a perturbation. The numerical tests are made using the Jastrow wave function and a Lennard-Jones (LJ) potential

$$
\begin{equation*}
v(r)=4 \epsilon\left[\left(\frac{\sigma}{r}\right)^{12}-\left(\frac{\sigma}{r}\right)^{\theta}\right] \tag{1.2}
\end{equation*}
$$

for which many variational computations have been made. ${ }^{7-10}$ The convergence of the theory is shown to be excellent. Terms of higher than first
order contribute to the energy below the noise level of the computation, i.e., about $0.1^{\circ} \mathrm{K}$. The physical reason for this good convergence appears to be the following. The ground-state wave function of the system must be nodeless and bent as little as possible to keep the kinetic energy down. This tends to keep the particles as far away from one another as possible. In the dense-fluid region this prevents large density fluctuations. The higher-order terms are therefore much smaller than what they would be for a classical system for the same (not very high) density. The fact that the particles keep away from each other contrasts with the opposite situation relative to the classical system for which the radial-distribution function has a peak near the core. This makes the quantum case much simpler than the corresponding classical case, where the replacement of the repulsive potential $v_{0}(r)$ by hard cores cannot be made without introducing some densitydependent corrections to take into account the shape of $v_{0}(r)$. Here these corrections may be neglected; the density-independent diameter is obviously the scattering length $a$ of the potential $v_{0}(r)$. To first order, the energy of the total system is simply given as

$$
\begin{equation*}
\frac{E}{N}=\frac{E_{H}\left(\rho a^{3}\right)}{N}+\frac{1}{2} \rho \int d \overrightarrow{\mathrm{r}} w(r) g_{H}(r), \tag{1.3}
\end{equation*}
$$

where $E_{H}$ and $g_{H}$ are, respectively, the energy and the rdf of hard spheres of density $\rho$ and diameter $a$. The theoretical justification of this perturbation theory is examined in Sec. VIII.
We then make (Sec. IX) a digression on the variational problem in the case of continuous potentials: The perturbation theory suggests a form of the Jastrow wave function closely related to the hard-sphere one and very different from the trial function usually used in the LJ case. We show that despite this difference this wave function yields the usual value, of the order of $-5.8^{\circ} \mathrm{K}$ for the energy, and an rdf which presents a little more structure than the ones previously obtained.
In Sec. X we give the results obtained with the perturbation theory. We first show that using the variational hard-sphere results obtained with the HLS trial function, one recovers the LJ variational energies both for the liquid and the not too dense solid phase. This shows the very large degree of success of the perturbation theory. We then introduce the "exact" results for the fluid with the phonon correction included. This has the effect of lowering the energy of the liquid by about $0.6^{\circ} \mathrm{K}$ and of bringing the location of the minimum of the energy versus density and the transition data into essential agreement with experiment.
In the last section (Sec. XI) we extend to the
quantum case the hard-sphere model introduced in the classical case in order to describe the structure factor obtained from x -ray and neutron scattering experiments.

Appendix A is devoted to a tabulation of the numerical results for the radial-distribution function.
In Appendix B, we make some remarks on the problem of $\mathrm{He}^{3}$ which complement the recent study by Schiff. ${ }^{11}$

## II. MONTE CARLO INTEGRATION OF THE SCHRÖDINGER EQUATION

We write the Schrödinger equation for a system of bosons interacting by hard-core forces in the following dimensionless form (with $\hbar^{2} / 2 m=1$, potential radius $=a$ ):

$$
\begin{equation*}
-\sum_{i} \nabla_{i}^{2} \psi\left(\vec{r}_{1}, \ldots, \overrightarrow{\mathrm{r}}_{N}\right)=E \psi\left(\overrightarrow{\mathrm{r}}_{1}, \ldots, \overrightarrow{\mathrm{r}}_{N}\right), \tag{2.1}
\end{equation*}
$$

with the boundary conditions

$$
\begin{equation*}
\psi\left(\overrightarrow{\mathrm{r}}_{1}, \ldots, \overrightarrow{\mathrm{r}}_{N}\right)=0 \text { when }\left|\overrightarrow{\mathrm{r}}_{i}-\overrightarrow{\mathrm{r}}_{j}\right| \leqslant a \text { for all } i \neq j \tag{2.2}
\end{equation*}
$$

In addition, the wave function is periodic in a box of side $L=(N / \rho)^{1 / 3}$ :

$$
\psi\left(\vec{r}_{1}, \ldots, \vec{r}_{i}, \ldots, \vec{r}_{N}\right)=\psi\left(\vec{r}_{1}, \ldots, \vec{r}_{i}+\overrightarrow{\mathrm{p}}_{j}, \ldots, \overrightarrow{\mathrm{r}}_{N}\right),
$$

where $\overrightarrow{\mathrm{p}}_{j}$ is $L$ times a unit vector in $x, y$, or $z$ directions, and $i=1, \ldots, N$. Equation (2.1) is written in the succinct form

$$
\begin{equation*}
-\nabla^{2} \psi(R)=E \psi(R) . \tag{2.3}
\end{equation*}
$$

Now suppose $G\left(R, R_{0}\right)$ satisfies

$$
\begin{equation*}
-\nabla^{2} G\left(R, R_{0}\right)=\delta\left(R-R_{0}\right) ; \tag{2.4}
\end{equation*}
$$

Eq. (2.3) may be rewritten as

$$
\begin{equation*}
\psi(R)=E \int G\left(R, R^{\prime}\right) \psi\left(R^{\prime}\right) d R^{\prime} \tag{2.5}
\end{equation*}
$$

If a succession of functions is defined by

$$
\begin{align*}
\psi^{(n+1)}(R)=E \int G\left(R, R^{\prime}\right) \psi^{(n)}\left(R^{\prime}\right) d R^{\prime} & \\
n & =0,1, \ldots, \tag{2.6}
\end{align*}
$$

then the ground state $\psi_{0}$ of Eq. (2.1) is the asymptotic $\psi^{(n)}$ for large $n$. The Monte Carlo method consists in sampling possible sets of coordinates $\left\{R_{0}\right\}$ at random from $\psi^{(0)}$, an initial or trial function. For any point $R_{n}$ drawn from $\psi^{(n)}\left(R_{n}\right)$, a point $R_{n+1}$ drawn from $\psi^{(n+1)}$ is obtained by sampling $E G\left(R_{n+1}, R_{n}\right)$ considered as a density function for $R_{n+1}$ conditional upon $R_{n}$. We will call a set of coordinates $R$ a "configuration" and refer to the population of configurations with a given value of
$n$ as a "generation."
$E_{0}$, the energy of the ground state, is that value of $E$ which makes the normalization of $\psi^{(n)}$ (i.e., the size of the population after $G$ has been used $n$ times) asymptotically stable. After the process has been judged to converge, based upon estimates of $E_{0}$ and other computed results, $E_{0}$ may be determined from

$$
\begin{equation*}
\bar{E}_{0}=E^{\prime} \int \psi^{(n)} d R / \int \psi^{(n+1)} d R \tag{2.7}
\end{equation*}
$$

where $E^{\prime}$ is a trial value of $E_{0}$ used in the sampling.

This process may be made computationally more efficient-to an arbitrary degree-by the following transformation. Let $\psi_{J}(R)$ be a trial function which may be the same as $\psi^{(0)}(R)$. Then let

$$
\begin{equation*}
\tilde{\psi}(R)=\psi_{J}(R) \psi(R) \tag{2.8}
\end{equation*}
$$

Equation (2.5) becomes

$$
\begin{equation*}
\tilde{\psi}(R)=E^{\prime} \int\left[\psi_{J}(R) G\left(R, R^{\prime}\right) / \psi_{J}\left(R^{\prime}\right)\right] \tilde{\psi}\left(R^{\prime}\right) d R^{\prime} \tag{2.9}
\end{equation*}
$$

formally the same as (2.5). A sequence of functions obtained by successive application of $G$ to $\psi_{J}(R) \psi^{(0)}(R)$ converges to $\psi_{J} \psi_{0}$ and $E_{0}$ is again that value that makes the population stable. It will be shown below that, as $\psi_{J} \rightarrow \psi_{0}$, the estimates of $E_{0}$ obtained from

$$
\begin{equation*}
\bar{E}_{0}=E^{\prime} \int \tilde{\psi}^{(n)} d R / \int \tilde{\psi}^{(n+1)} d R \tag{2.10}
\end{equation*}
$$

are correct on the average at $n=0$ (without requiring $\psi^{(0)}=\psi_{0}$ ). Furthermore, $E_{0}$ may in fact be estimated with zero statistical error. One ex-pects-and our experience strongly supportsthat a reasonable analytical trial function $\psi_{J}$ greatly reduces the computational effort required.

Unfortunately, the Green's function given in Eq. (2.4) is not known owing to the complexity of the boundary conditions. But all that is required is that a scheme be devised for sampling $G\left(R, R_{0}\right)$ for $R$ at random given any $R_{0}$. This is possible in a recursive way as follows. Let $D$ be the domain in configuration space not excluded by the hard-core boundary conditions. Let $D_{0}$ be another domain wholly contained within $D$ with $R_{0}$ in $D_{0}$. Let $G_{0}\left(R, R_{0}\right)$ satisfy (2.4) but vanish on the surface of $D_{0}$ (rather than that of $D$ ):

$$
\begin{equation*}
-\nabla^{2} G_{0}\left(R, R_{0}\right)=\delta\left(R-R_{0}\right) . \tag{2.11}
\end{equation*}
$$

With the boundary conditions that they vanish on prescribed surfaces, these Green's functions are symmetric. Thus,

$$
\begin{equation*}
-\nabla^{2} G\left(R_{1}, R\right)=\delta\left(R-R_{1}\right) . \tag{2.12}
\end{equation*}
$$

Multiply (2.11) by $G\left(R_{1}, R\right)$, (2.12) by $G_{0}\left(R, R_{0}\right)$, and integrate with respect to $R$ over $D_{0}$. With the help of Green's theorem, we find

$$
\begin{equation*}
G\left(R_{1}, R_{0}\right)=G_{0}\left(R_{1}, R_{0}\right)+\int_{S_{0}}\left[-\nabla_{n} G_{0}\left(R, R_{0}\right)\right] G\left(R_{1}, R\right) d R \tag{2.13}
\end{equation*}
$$

The integral on the right side is extended over the surface $S_{0}$ of $D_{0}$; the kernel is the normal derivative of $G_{0}$ which is everywhere positive. The substitution of (2.13) into itself yields a series of iterated integrals which may be sampled by the following random-walk procedure.

A point is started at $R_{0}$ and moved to $R^{\prime}$, chosen at random on $S_{0}$, using $-\nabla_{n} G_{0}\left(R^{\prime}, R_{0}\right)$ as the density function; then a new domain $D_{1}$ is constructed containing $R^{\prime}$ and a new point selected on the surface $S_{1}$. The process terminates only when a point arrives at the boundary of $D$ since (2.11) implies

$$
\begin{equation*}
\int_{S_{0}}\left[-\nabla_{n} G_{0}\left(R^{\prime}, R_{0}\right)\right] d R^{\prime}=1 \tag{2.14}
\end{equation*}
$$

The full Green's function is the sum of all $G_{0}\left(R, R_{n}\right)$ for the $R_{n}$ that appear in the random walk.

We must choose $D_{n}$ at every stage so that $G_{0}$ is known or can be sampled, and so that moves within $D_{n}$ do not produce overlap of hard cores. A particularly convenient domain for the purpose is a Cartesian product of $N$ spaces, each a sphere for one particle. The radii are chosen so as to prevent core overlap. This construction permits $G_{0}$ to be sampled in a straightforward numerical way (as seen in Sec. III below). As shown in Ref. 5, the requirement that the wave function, and hence Green's function, be periodic is met by the computational device of putting back on the left of the box those particles which leak out of the right.

As it stands (2.14) is satisfied, so in that form the random walk does not terminate. The modification required for Eq. (2.9) removes this difficulty. We have from (2.13)

$$
\begin{align*}
& \psi_{J}\left(R_{1}\right) G\left(R_{1}, R_{0}\right) / \psi_{J}\left(R_{0}\right) \\
&=\psi_{J}\left(R_{1}\right) G_{0}\left(R_{1}, R_{0}\right) / \psi_{J}\left(R_{0}\right) \\
&+\int_{S_{0}}\left\{\psi_{J}(R)\left[-\nabla_{n} G_{0}\left(R, R_{0}\right)\right] / \psi_{J}\left(R_{0}\right)\right\} \\
& \times\left\{\psi_{J}\left(R_{1}\right) G\left(R_{1}, R\right) / \psi_{J}(R)\right\} d R . \tag{2.15}
\end{align*}
$$

This has the same structure as (2.13) but a different kernel, $\left\{\psi_{J}\left[-\nabla_{n} G_{0}\left(R, R^{\prime}\right)\right] / \psi_{J}^{\prime}\right\}$, for which (2.14) does not hold. In fact, if

$$
\begin{equation*}
-\nabla^{2} \psi_{J}(R)=E_{J}(R) \psi_{J}(R), \tag{2.16}
\end{equation*}
$$

and if we multiply (2.16) by $G_{0}\left(R, R_{0}\right),(2.11)$ by $\psi_{J}(R)$, and integrate over $D_{0}$, we have

$$
\begin{align*}
\int_{S_{0}}\left\{\psi_{J}(R)[ \right. & \left.\left.-\nabla_{n} G_{0}\left(R, R_{0}\right)\right] / \psi_{J}\left(R_{0}\right)\right\} d R \\
& =1-\int\left[E_{J}(R) \psi_{J}(R) G_{0}\left(R, R_{0}\right) / \psi_{J}\left(R_{0}\right)\right] d R . \tag{2.17}
\end{align*}
$$

Thus, if $E_{J}(R)$, a "local energy," is everywhere positive, the norm on the left, which gives the probability at $R_{0}$ that the random walk continues, is now less than 1.

Note also that if $E_{J}(R)$ is replaced by $E$, then the integral on the right in (2.17) is that contribution to

$$
\int\left[\psi_{J} G\left(R, R^{\prime}\right) / \psi_{J}^{\prime}\right] \tilde{\psi}\left(R^{\prime}\right) d R^{\prime},
$$

the right side of (2.9), which comes from $G_{0}$ alone. Thus, when $\psi_{J}$ is the exact eigenfunction, the process of contributing to the next generation, and that of going on with the random walk which develops $G$, may be treated as mutually exclusive random events. Then the random walk always gives exactly one configuration in the next generation and the generation size has no sampling error.
Finally we observe that Eq. (2.17) is correct if $G_{0}$ is replaced by $G$ and the domain of integration is $D$. Then, since $\psi_{J}=0$ on the boundary,

$$
\begin{equation*}
\psi_{J}\left(R_{0}\right)=\int E_{J}(R) \psi_{J}(R) G\left(R, R_{0}\right) d R \tag{2.18}
\end{equation*}
$$

Again, if $-\nabla^{2} \psi_{J}=E_{0} \psi_{J}$,

$$
\begin{equation*}
E_{0}=\frac{1}{\int\left[\psi_{J}(R) G\left(R, R_{0}\right) / \psi_{J}\left(R_{0}\right)\right] d R} \tag{2.19}
\end{equation*}
$$

If in Eq. (2.10) we set $E^{\prime}=1$ and $\tilde{\psi}^{(n)}=\delta\left(R-R_{\cap}\right)$, then the expected value of the integral in the denominator of (2.10) is that of (2.19); the expected energy is identically $E_{0}$, independent of $R_{0}$. Taken together with the result stated in the preceding paragraph, we see that when $\psi_{J}$ is the exact eigenfunction, the energy is obtained with neither statistical nor convergence error. Expectation values are obtained by the method given in Ref. 5, in which the asymptotic size of the generations which arise from a configuration at $R_{0}$ gives an estimate of $\psi\left(R_{0}\right)$ which is statistically independent of the sampling that led to $R_{0}$. When $\psi_{J}$ is exact, the estimate of the asymptotic size is carried out with no sampling error.
The numerical calculations whose results are given below were carried out with $\psi_{J}(R)$ in the form suggested by Hansen, Levesque, and Schiff ${ }^{4}$ :

$$
\begin{equation*}
\psi_{J}(R)=\prod_{i<j} \tanh \left[\left(r_{i j}^{m}-1\right) / b^{m}\right] \tag{2.20}
\end{equation*}
$$

for the fluid, and

$$
\begin{align*}
\psi_{J}(R)= & \exp \left[-\frac{1}{2} A \sum_{i}\left(\overrightarrow{\mathrm{r}}_{i}-\overrightarrow{\mathrm{s}}_{i}\right)^{2}\right] \\
& \times \prod_{i<j} \tanh \left[\left(r_{i j}^{m}-1\right) / b^{m}\right] \tag{2.21}
\end{align*}
$$

for a crystal whose lattice sites are $\overrightarrow{\mathbf{s}}_{i}$. The parameters $b, m$, and $A$ were those used in the calculations of Ref. 4. Computational experience shows that the values which minimize the energy in a variational calculation are good ones for our purposes.

## III. CONSTRUCTION AND SAMPLING OF $G_{0}$ IN PRODUCT SPACES

In Sec. II it is assumed that at any stage in the random walk, $G_{0}\left(R, R_{m}\right)$ can be sampled for some convenient domain $D_{m}$ containing $R_{m}$. This is particularly simple to carry out if $D_{m}$ is a Cartesian product of subspaces. We consider the case where

$$
\begin{equation*}
D_{m}=d_{1} \otimes d_{2} \otimes \cdots \otimes d_{N} \tag{3.1}
\end{equation*}
$$

and each $d_{k}$ is a domain of the coordinates of the $k$ th particle of the system. The method holds equally for other decompositions; division into relative and center-of-mass coordinates may be worth considering in some problems.
Let $g\left(r_{k}, r_{k}^{\prime}, t\right)$ satisfy

$$
\begin{align*}
& -\nabla^{2} g\left(r_{k}, r_{k}^{\prime}, t\right)+\frac{\partial}{\partial t} g\left(r_{k}, r_{k}^{\prime}, t\right)=0  \tag{3.2}\\
& g\left(r_{k}, r_{k}^{\prime}, 0\right)=\delta\left(r_{k}-r_{k}^{\prime}\right)
\end{align*}
$$

and

$$
g\left(r_{k}, r_{k}^{\prime}, t\right)=0
$$

for $r_{k}$ on $\partial d_{k}$, the boundary of $d_{k}$, and outside $d_{k}$. Then for $R$ and $R^{\prime}$ in $D$, set

$$
\begin{equation*}
G_{0}\left(R, R^{\prime}\right)=\int_{0}^{\infty} \prod_{k} g\left(r_{k}, r_{k}^{\prime}, t\right) d t \tag{3.3}
\end{equation*}
$$

Clearly

$$
\begin{equation*}
\left(-\sum_{k} \nabla_{k}^{2}+\frac{\partial}{\partial t}\right) \prod_{k} g\left(r_{k}, r_{k}^{\prime}, t\right)=0 \tag{3.4}
\end{equation*}
$$

and

$$
\begin{equation*}
\prod_{k} g\left(r_{k}, r_{k}^{\prime}, 0\right)=\delta\left(R-R^{\prime}\right) \tag{3.5}
\end{equation*}
$$

$G_{0}\left(R, R^{\prime}\right)$ vanishes for $R$ on $\partial D$ (some $r_{l}$ on $\partial d_{l}$ ). Integrating (3.4) with respect to time and using (3.5) we find the result that

$$
\begin{equation*}
\left(-\sum_{k} \nabla_{k}^{2}\right) G_{0}\left(R, R^{\prime}\right)=\delta\left(R-R^{\prime}\right), \tag{3.6}
\end{equation*}
$$

as required.
In the form (3.3), sampling $G_{0}$ very nearly re-
quires only sampling $g\left(r_{k}, r_{k}^{\prime}, t\right)$ for a move from $r_{k}^{\prime}$ to $r_{k}$ for every particle. Consider the problem of sampling the normal derivative

$$
-\nabla_{n} G_{0}\left(R, R^{\prime}\right) \text { for } R \in \partial D
$$

Now

$$
\begin{equation*}
\partial D=\bigcup_{m} d_{1} \otimes d_{2} \otimes \cdots \otimes \partial d_{m} \otimes \cdots \otimes d_{N} . \tag{3.7}
\end{equation*}
$$

Sampling the kernel means first finding $m$, then sampling points $r_{l}(l \neq m)$ on the interior of $d_{l}$ and $r_{m}$ on the surface $\partial d_{m}$. Corresponding to (3.7),

$$
\begin{align*}
-\nabla_{n} G_{0}\left(R, R^{\prime}\right)= & \sum_{m} \int\left(\prod_{l \neq m} g\left(r_{l}, r_{l}^{\prime}, t\right)\right) \\
& \times\left[-\nabla_{n} g\left(r_{m}, r_{m}^{\prime}, t\right)\right] d t \tag{3.8}
\end{align*}
$$

Let

$$
\begin{equation*}
H_{l}(t)=\int_{d_{l}} g\left(r_{l}, r_{l}^{\prime}, t\right) d r_{l} \tag{3.9}
\end{equation*}
$$

$$
\begin{aligned}
& H_{l}(0)=1, \\
& H_{l}(\infty)=0 .
\end{aligned}
$$

Green's theorem applied to (3.4) shows that

$$
\begin{align*}
-H_{l}^{\prime}(t) & =-\frac{\partial H_{l}(t)}{\partial t} \\
& =\int_{\partial d_{l}}\left[-\nabla_{n} g\left(r_{l}, r_{l}^{\prime}, t\right)\right] d r_{l}>0 \tag{3.10}
\end{align*}
$$

Expand (3.8) into the form

$$
\begin{align*}
-\nabla_{n} G_{0}\left(R, R^{\prime}\right)= & \sum_{m}\left[-H_{m}^{\prime}(t) \prod_{i \neq m} H_{l}(t)\right] \\
& \times\left[\frac{-\nabla_{n} g\left(r_{m}, r_{m}^{\prime}, t\right)}{-H_{m}^{\prime}(t)}\right] \\
& \times \prod_{k \neq m} \frac{g\left(r_{k}, r_{k}^{\prime}, t\right)}{H_{k}(t)} d t . \tag{3.11}
\end{align*}
$$

The sampling procedure is as follows: (i) Sample $t$ and $m$ at random using the first quantity in brackets in (3.11). (ii) Conditional on $m$ and $t$, sample $r_{m}$ at random on $\partial d_{m}$ using the kernel $-\nabla_{n} g\left(r_{m}, r_{m}^{\prime}, t\right) /$ [ $\left.-H_{m}^{\prime}(t)\right]$. (iii) Using the same $t$, sample for every $k \neq m$ a point $r_{k}$ in $d_{k}$ using the kernel $g\left(r_{k}, r_{k}^{\prime}, t\right) /$ $H_{k}(t)$.

The function $g\left(r_{k}, r_{k}^{\prime}, t\right)$ describes the diffusion of a particle started at $r_{k}^{\prime}$ at $t=0 . H_{k}(t)$ is the probability that it is absorbed at the boundary of $d_{k}$ after time $t$ and $-H_{k}^{\prime}(t)$ is the rate of absorption at $t$. Suppose for each $k, t_{k}$ is drawn at random from the probability density function $-H_{k}^{\prime}(t)$. The probability that the smallest of all $t_{k}$ is $t_{m}$ and that $t_{m}$ lies in a unit interval of time near $t$ is

$$
-H_{m}^{\prime}(t) \prod_{k \neq m} H_{k}(t) .
$$

In other words the operation of selecting the smallest of $k$ values $t_{k}$ samples $m$ and $t$ as required for Eq. (3.11).
Sampling $G_{0}\left(R, R^{\prime}\right)$ itself can be done in an analogous way. Of course, all $r_{k}$ lie on the interior of the corresponding domains $d_{k}$. Here a numerical approximation to $\Pi H_{k}(t)$ is used to sample a value of $t$.

In practice, each domain $d_{k}$ was taken to be a sphere of radius $a_{k}$ centered at $r_{k}^{\prime}$. In terms of $z_{k}=\left|r_{k}-r_{k}^{\prime}\right|$ the familiar method of separation of variables and eigenfunction expansion gives

$$
\begin{equation*}
g\left(z_{k}, t\right)=\left(2 a_{k}^{2} z_{k}\right)^{-1} \sum_{j} j \sin \left(\pi j z_{k} / a_{k}\right) e^{-\pi^{2} n^{2} t / a_{k}^{2}} \tag{3.12}
\end{equation*}
$$

We see explicitly that $a_{k}^{3} g$ is the same function of the reduced coordinates $z_{k} / a$ and $t / a_{k}^{2}$. This fact is exploited in the numerical work.
The expansion (3.12), and a complementary one obtained from the Poisson sum rule, which converges rapidly for short times, are the basis for various numerical algorithms used to sample $t_{k}$, $z_{k}$, etc. For the most part the $z_{k}$ are sampled from multivariate normal distributions, which can be done efficiently. Although the procedure may seem somewhat elaborate, the computation time is dominated by the usual calculation of the distances between particles.

## IV. IMPLEMENTATION OF A COMPUTER PROGRAM

We give here some technical details of the computer program in which the ideas outlined in Sec. III have been realized. Readers interested only in the theory may skip this part of the paper.

In any many-body simulation a crucial detail lies in calculating the distances between pairs of particles. In the present calculation this is done for two reasons. First and most important, it is necessary to know for each particle the distance to its nearest neighbor so as to permit the choice of the sphere in which it may move without core overlap. Second, the computation of the value of the trial function $\psi_{J}$ used to accelerate the computation requires the value of $r_{i j}$ for all pairs [cf. Eq. (2.20)]. For the latter purpose $\psi_{J}$ need not be as accurate at large pair separations as needed for good variational calculations. Hence the tabulation of $r_{i j}$ is truncated at a distance where the hyperbolic tangent in (2.20) nearly attains the value 1. The pair function is smoothly extrapolated to 1 at that distance.

The tabulation of the pair distances follows the procedures that have been in use in the Orsay Monte Carlo and molecular dynamics programs for some time. It suffices to say here that tables are
established in which rather near neighbors of each particle are identified. Most of the time (for a crystal, all of the time) distances are computed for pairs only in this table. When the tables are built up or renewed at appropriate intervals, all pairs are examined.

As has been suggested in Sec. III, numerical tables are generated to facilitate sampling at random from the various probability distributions required to select steps from the Cartesian product Green's function. Space limitation precludes a detailed description of the organization of these tables, their use, and the analysis that underlies them. We remark only that care was taken that with the help of these tables, the mappings or inverse mappings based on the Green's function are very rapid and accurate. With respect to the latter, extensive numerical tests showed that in a step drawn from the Green's function as kernel, the error in the mean-square displacement is at most a few parts in $10^{5}$.
The computer program underwent considerable development during the period when it was being used. The part which has changed most is that pertaining to "importance sampling," i.e., the transformation of the dependent variable from $\psi$ to $\psi_{J} \psi$ as indicated in Eqs. (2.8) and following. In fact, in the first version, this was not done although the role of the trial function in forcing convergence of the Green's function development was recognized and included [as in Eq. (2.15)]. We estimate that making the transformation in a tho roughgoing way reduced the computer time required by about a factor of 20 .
In any case it becomes necessary to sample the kernels

$$
\begin{equation*}
\psi_{J}(R)\left[-\nabla_{n} G_{0}\left(R, R_{0}\right) \cdot\left[\nabla_{\psi_{J}}\left(R_{0}\right)\right] / \psi_{J}\left(R_{0}\right) .\right. \tag{4.1}
\end{equation*}
$$

and

$$
\psi_{J}(R) G_{0}\left(R, R_{0}\right) \cdot \nabla u\left(R_{0}\right)
$$

rather than $-\nabla_{n} G_{0}$ and $G_{0}$, respectively. The techniques for doing this have also evolved. At present the method is based upon an expansion of $\psi_{J}(R)$ about $\psi_{J}\left(R_{0}\right)$. To first order

$$
\begin{equation*}
\psi_{J}(R) / \psi_{J}\left(R_{0}\right)=1+\left(R-R_{0}\right)\left[\nabla \psi_{J}\left(R_{0}\right)\right] / \psi_{J}\left(R_{0}\right) \tag{4.2}
\end{equation*}
$$

If we write

$$
\psi_{J}(R)=e^{-u(R)},
$$

then

$$
\begin{equation*}
\psi_{J}(R) / \psi_{J}\left(R_{0}\right)=1-\left(R-R_{0}\right) \cdot \nabla u\left(R_{0}\right) . \tag{4.3}
\end{equation*}
$$

$u(R)$ is commonly called the "pseudopotential"; we may refer to $-\nabla u$ as the "pseudoforce."
If $\psi_{J}$ is set equal to a constant, then for each
sphere the direction in which a particle move is made must be chosen in an isotropic way. The pseudoforce defines a favored direction and a degree of anisotropy for the proposed move. For a system of 256 particles in a crystal phase this elementary use of the pseudoforce has reduced the required computing time by about a factor of 10 . The extra time to compute the pseudoforce is included. It is clear that further improvements, possibly resulting in additional drastic savings, can be made. ${ }^{12}$

An awkward feature of the computational method lies in the necessity of using a trial eigenvalue and the role that it plays in the branching of configurations. It appears to require 100-200 generations for the energy and other quantities to settle down. Since the energy changes by a total of $3-8 \%$ and since the growth of the population in $n$ generations is proportional to the $n$th power of the trial energy, the management of the calculation in the face of statistical uncertainties can be serious. In practice runs are made using from 10 to 80 generations; early in the relaxation process one aims for short runs. At the end of each such run the coordinates specifying the configurations are recorded on magnetic tape and used as input for the subsequent run.

A recent series of runs (crystal, $\rho a^{3}=0.4$ ) is typical. The process was followed for 210 generations from a set of configurations calculated variationally, after which an additional 240 generations were followed during which the calculated parameters were constant within apparent errors ( $<1 \%$ for the energy). A total of 21 h of time on a CDC 6600 was used, about 8 in the early phase. We estimate that about one-third of the total time could have been saved if the generation growth had been observed and managed better. In part, failure to do so lies in the circumstances under which the computer runs were made. It is likely that if the variance which is introduced by the branching in the Green's-function development can be further reduced, then the uncertainties which result from the use of the trial energy will also be reduced.

## V. RESULTS OF THE INTEGRATION OF THE SCHRÖDINGER EQUATION

The numerical results for the energy are given in Table I. The errors quoted are estimates of the standard deviation of the Monte Carlo results of several runs (3-5) in which the properties of the system were found to be constant. In all cases the results are those for a system of 256 particles. For the fluid, a correction to an infinite system is applied as explained in Sec. VI. Nu-
merical values of the radial-distribution function computed for the 256 -body system both by the variational and the Schrödinger integration are given in Appendix A.
The energies are lower than those calculated variationally by a small but significant amount. In the fluid region the rdf shows slightly more structure than the variational prediction. As a consequence the main peak of the structure factor is enhanced relative to the variational prediction.
In summary, the Jastrow wave function is found to be quite good as a first approximation. The small differences will turn out, however, to be of decisive importance in the analysis that follows.

## VI. TAKING THE PHONONS INTO ACCOUNT

The approach we have followed is clearly unable to deal with long-wavelength excitations, because of the limitation due to the size of the box. Since we know the importance of these longwavelength excitations in liquid helium, we have to evaluate their effect. In the framework of the Jastrow approximation function the phonons can be taken into account by adding to the short-range pseudopotential $u_{s}(r)$ of the Jastrow wave function a Reatto-Chester ${ }^{13}$ term

$$
\begin{equation*}
u_{L}(r)=\frac{m c}{\rho \pi^{2} \hbar} \frac{1}{r^{2}+k_{c}^{-2}} \tag{6.1}
\end{equation*}
$$

where $c$ is the velocity of sound and $k_{c}^{-1}$ a wavelength cutoff which should be of the order of a few interparticle distances $(0.25 / \sigma$ is a guess usually met in the literature). The change in the kinetic energy of the hard spheres is the sum of

TABLE I. Energies in units of $\hbar^{2} / m a^{2}$ for the ground state of the quantum hard-sphere fluid and fce solid. For the fluid, $E_{1}$ is the result of the Monte Carlo integration of the Schrödinger equation for a system of 256 particles. The phonon correction to an infinite system is obtained by the method of Sec. VI. For the crystal the results for 256 particles are given with no corrections. Errors are estimates of the standard deviation.

|  |  | Phonon <br> correction |  |  |
| :--- | ---: | ---: | ---: | ---: |
| State | $\rho a^{3}$ | $E_{1}$ | $E_{0}$ |  |
| Fluid | 0.166 | $4.24 \pm 0.05$ | -0.09 | $4.15 \pm 0.05$ |
|  | 0.200 | $5.80 \pm 0.05$ | -0.11 | $5.69 \pm 0.05$ |
|  | 0.244 | $8.28 \pm 0.09$ | -0.14 | $8.14 \pm 0.09$ |
|  | 0.270 | $10.65 \pm 0.07$ | -0.15 | $10.50 \pm 0.07$ |
| fcc | 0.244 |  |  | $8.50 \pm 0.05$ |
| crystal | 0.270 |  |  | $10.12 \pm 0.04$ |
|  | 0.300 |  | $12.27 \pm 0.07$ |  |
|  | 0.400 |  | $21.26 \pm 0.07$ |  |
|  | 0.500 |  | $34.45 \pm 0.25$ |  |

two terms,

$$
\begin{align*}
& \boldsymbol{T}_{1}=\frac{\rho \hbar^{2}}{8 m} \int d \overrightarrow{\mathrm{r}} \nabla^{2} u_{L}(r) g_{s}(r),  \tag{6.2}\\
& T_{2}=\frac{\rho \hbar^{2}}{8 m} \int d \overrightarrow{\mathrm{r}}\left[\nabla^{2} u_{s}(r)+\nabla^{2} u_{L}(r)\right] \delta g(r) . \tag{6.3}
\end{align*}
$$

Here the subscript $s$ refers to quantities calculated with the usual short-range Jastrow function. $\delta g(r)$ is the change in the rdf due to the ReattoChester term.

The difficulty of this variational calculation is due to the long-range character of the ReattoChester function.

It has been proposed, ${ }^{14}$ in order to solve this problem, to use an Ewald-sum technique, as in the classical charged-particle system. It is quite clear that we can thus take correctly into account phonons of wave numbers which may be reached with a finite box and periodic boundary conditions. This sets a limit of $0.6 a^{-1}$ in the case of a 256particle system near the solidification density. If $k_{c}$ is of the order of ( $0.2-0.3$ ) $a^{-1}$ most of the effect will be missed. We can also predict the failure of the Ewald-sum technique for the following reason: In the fluid region the variational and "exact" energies do coincide within about $0.2 \hbar^{2} / m a^{2}$. As a consequence the contribution of the short-wavelength phonons is smaller than $0.2 \hbar^{2} / m a^{2}$ and at the noise level of the standard Monte Carlo computation.

In order to tackle the problem of long-wavelength phonons, we shall resort to a perturbation technique, since, at least if $k_{c}$ is small, we have to deal with a rather weak long-range pseudo-potential in addition to the short-range function $u_{s}(r)$.
Defining

$$
\begin{equation*}
\tilde{u}_{L}(\boldsymbol{k})=\int d \overrightarrow{\mathrm{r}} e^{i \overrightarrow{\mathrm{k}} \cdot \overrightarrow{\mathrm{r}}} u_{L}(r) \tag{6.4}
\end{equation*}
$$

the dominating terms in the perturbation expansion are, as is well known, the ring diagrams formed with $\tilde{u}_{L}(k)$ as bonds. It has been shown ${ }^{15}$ that the proper way of taking into account the effect of the size of the particles involved in the ring is to put at each vertex of the ring diagram the structure factor of the reference system, with no long-range pseudopotential, i.e.,

$$
\begin{equation*}
S_{s}(k)=1+\rho \int d \overrightarrow{\mathrm{r}}\left[g_{s}(r)-1\right] e^{i \overrightarrow{\mathrm{k}} \cdot \overrightarrow{\mathrm{r}}} \tag{6.5}
\end{equation*}
$$

This approach leads to the formula

$$
\begin{equation*}
\delta g(r)=g_{s}(r)\left(e^{-\Gamma(r)}-1\right), \tag{6.6}
\end{equation*}
$$

with

$$
\begin{equation*}
\tilde{\Gamma}(k)=\frac{S_{s}^{2}(k) \tilde{u}_{L}(k)}{1+\tilde{u}_{L}(k) S_{s}(k)} . \tag{6.7}
\end{equation*}
$$

It has been noted by Anderson and Chandler ${ }^{16}$ (AC) that $\Gamma(r)$ and thus $\delta g(r)$ depend crucially on the arbitrary assumption made on the behavior of $u_{L}(r)$ inside the repulsive core (where it has no physical meaning). This dependence appears only because a particular subset of graphs in the perturbation expansion has been selected. AC show that the prescription $\Gamma(r)=0$ inside the repulsive core is very reasonable and leads to excellent results in the case of primitive models of electrolytes as well as in the case of the classical Lennard-Jones liquids.
For $\rho a^{3}=0.234$, we show in Fig. 1 the energy shift as a function of $k_{c}$. It is seen that a minimum is obtained for $k_{c} \simeq 0.3 a^{-1}$, a value which corresponds closely to the intuitive guess made above. The energy is correspondingly lowered by $0.11 \hbar^{2} /$ $m a^{2}$. As this limiting wave vector is substantially smaller than the smallest wave vector considered in the actual "exact" computation ( $2 \pi / L \simeq 0.6 a^{-1}$ as we have seen) we should also apply this phonon correction to the "exact" energies given in Table I.
This correction on the energy, although small. has the effect of displacing the transition parameters of the hard-sphere system. Let us consider first the case of the variational computation. For the solidification density, one finds $\rho a^{3}$ $=0.24 \pm 0.01$ instead of ${ }^{4} \rho a^{3}=0.23 \pm 0.01$. The melting density also rises from $0.25 \pm 0.01$ to $0.26 \pm 0.01$.
We now apply this phonon correction calculated in the Jastrow approximation to the exact results obtained in the paper. This yields the results

FIG. 1. Energy shift due to long-wavelength phonons, in units $\hbar^{2} / m a^{2}$, as a function of the cutoff wave vector $k_{c}$ for the density $\rho a^{3}=0.234$.
obtained in Table I. The final values of the energy of the hard-sphere system are shown in Fig. 2 as a function of $1 / \rho$. A double tangent construction gives the transition parameters. We obtain for the solidification density $\rho a^{3}=0.25 \pm 0.01$, and for the melting density $\rho a^{3}=0.27 \pm 0.01$.

## VII. PERTURBATION EXPANSION AND ITS CONVERGENCE

We shall suppose in the following that the helium atoms interact through a two-body potential $v(r)$. This is not an important restriction since the many-body forces in helium are known to be weak and can be treated as a perturbation. As in the classical theory of liquids ${ }^{6}$ we divide the potential into two parts: a "reference" part $v_{0}(r)$ and a remainder $w(r)$ which will be considered as a perturbation. Let $\epsilon$ be the magnitude of the potential at its minimum and $r_{m}$ be the corresponding abscissa. We write

$$
\begin{array}{rlrlr}
v_{0}(r) & =v(r)+\epsilon & \text { for } r & r \leqslant r_{m} \\
& =0 & & \text { for } r>r_{m} . \tag{7.1}
\end{array}
$$

We then have

$$
\begin{align*}
w(r) & =-\epsilon \text { for } r \leqslant r_{m} \\
& =v(r) \text { for } r>r_{m} . \tag{7.2}
\end{align*}
$$

Let $H_{0}$ be the Hamiltonian of the reference system,

$$
\begin{equation*}
H_{0}=T+V_{0} \tag{7.3}
\end{equation*}
$$

FIG. 2. "Exact" energy per particle as a function of $1 / \rho a^{3}$.
where $V_{0}$ is the potential energy corresponding to the pair potential $v_{0}(r)$. Let $\psi_{0}$ be the normalized wave function of the ground state of the reference system pertaining to the eigenvalue $E_{0}$. We have obviously

$$
\begin{align*}
&\left\langle\psi_{0}\right| H_{0}\left|\psi_{0}\right\rangle+\langle\psi| W|\psi\rangle \\
& \leqslant\langle\psi| \boldsymbol{H}|\psi\rangle \leqslant\left\langle\psi_{0}\right| H_{0}\left|\psi_{0}\right\rangle+\left\langle\psi_{0}\right| W\left|\psi_{0}\right\rangle . \tag{7.4}
\end{align*}
$$

This can be rewritten in terms of $g(r)$, the rdf for the total system, and $g_{0}(r)$, that of the reference system,

$$
\begin{align*}
\frac{E_{0}}{N}+\frac{1}{2} \rho \int g(r) w(r) d \overrightarrow{\mathbf{r}} & \\
& \leqslant \frac{E}{N} \leqslant \frac{E_{0}}{N}+\frac{1}{2} \rho \int g_{0}(r) w(r) d \overrightarrow{\mathbf{r}} \tag{7.5}
\end{align*}
$$

The right-hand side of (7.5) is the energy obtained from first-order perturbation theory. A complete test of this perturbation theory would require the knowledge of the exact solution of the many-body problem both for the reference and the full potential. In view of the success of the Jastrow approximation in the hard-sphere case, we use that approximation consistently in our test of the validity of the first-order perturbation theory.

We have thus performed, in the case of the Lennard-Jones potential at the normal density of liquid helium, a series of Monte Carlo computations with a two-body Jastrow factor of the form ${ }^{7,8}$

$$
f(r)=e^{-(b / r)^{5}}
$$

We choose for the Lennard-Jones potential the constants, ${ }^{17} \epsilon=10.22^{\circ} \mathrm{K}, \sigma=2.556 \AA$, appropriate to $\mathrm{He}^{4}$. The normal density of liquid helium corresponds to $\rho=0.3648 \sigma^{-3}$.

Then the ground state of the total system is obtained as the minimum of $\langle T+V\rangle$ as a function of $b$, the ground state of the reference system as the minimum of $\left\langle T+V_{0}\right\rangle$. In this last case the first-order term is also obtained.
We thus obtain

$$
E / N=(-5.80 \pm 0.08)^{\circ} \mathrm{K}
$$

for

$$
\begin{aligned}
b & =(1.17(2) \pm 0.01) \sigma, \\
E_{0} / N & =(17.90 \pm 0.08)^{\circ} \mathrm{K}
\end{aligned}
$$

for

$$
b=(1.17(6) \pm 0.01) \sigma
$$

and

$$
\langle W\rangle / N=(-23.78 \pm 0.05)^{\circ} \mathrm{K} .
$$

The errors of the Monte Carlo computation remain large even for the rather precise computation reported here. Within these errors it is seen that the minimum of $\left\langle H_{0}\right\rangle$ and $\langle H\rangle$ are obtained for values of $b$ which are very close, as required for validity of the theory.

Using the data of Table II and the set of inequalities (7.5) we can therefore set an upper bound of the order of $0.1^{\circ} \mathrm{K}$ to the sum of higherorder terms in the perturbation theory. We can also state that, owing to the closeness of the upper and lower bounds on the energies, $g_{0}(r)$ and $g(r)$ should be close to each other.

The perturbation theory is therefore seen to work at least as well in the present case as for dense classical liquids. The physical reason for this success is, however, rather different. In the classical case the good convergence of the perturbation is restricted to the dense states. There, owing to the repulsive cores, the particles have little chance to move so that the fluctuations of the perturbing potential remain small. In the quantum fluid, the density is relatively small. The fluctuations are avoided because of the tightness of the wave function: In order to reduce the kinetic energy the particles must keep away from each other as much as possible.

## VIII. TREATMENT OF THE REFERENCE SYSTEM

Our goal is to replace the reference system by a suitably chosen hard-sphere system. In the case of classical liquids this replacement is not entirely simple because the particles tend to crowd near their core, so that some account must be taken of the shape of the repulsion. ${ }^{18}$ Because in the quantum case the particles must stay away from each other, the rdf will be small wherever the repulsive potential is not zero, so that all shape dependence should be negligible. We thus anticipate that the diameter $a$ will be determined as the scattering length $a$ corresponding to $v_{0}(r)$ and that the energy of the total system will be given by the first-order perturbation formula

$$
\begin{equation*}
E=E_{H}+\frac{1}{2} \rho N \int \overrightarrow{d \vec{r}} w(r) g_{H}(r / a) \tag{8.1}
\end{equation*}
$$

where $E_{H}$ and $g_{H}$ are, respectively, the energy and the rdf of the hard-sphere fluid of density $\rho$ and diameter $a$.
Let us consider again the Lennard-Jones potential with the parameters given above. Integration of the Schrödinger equation yields

$$
a=0.8368 \sigma
$$

The normal density of a liquid corresponds to $\rho a^{3}=0.2138$. Using the variational results of Sec. V we obtain

$$
\begin{aligned}
& E_{H} / N=(17.8 \pm 0.1)^{\circ} \mathrm{K} \\
& \langle W\rangle / N=(-23.56 \pm 0.1)^{\circ} \mathrm{K}
\end{aligned}
$$

We therefore obtain for the total energy ( -5.76 $\pm 0.15)^{\circ} \mathrm{K}$. A comparison of these results with the variational results obtained in Sec. VII shows excellent agreement.
We shall now proceed to give some theoretical justification for the basic expression (8.1).
We shall first introduce an approximation for the rdf. Let us write in the hard-sphere case

$$
\begin{equation*}
g_{H}(x)=\psi_{H}^{2}(x) y_{H}(x), \tag{8.2}
\end{equation*}
$$

where $\psi_{H}(x)$ is the solution of the two-body hardsphere problem at zero energy,

$$
\begin{align*}
\psi_{H}(r / a) & =(r-a) / r, \quad r \geqslant a  \tag{8.3}\\
& =0, \quad r<a .
\end{align*}
$$

$y_{H}(r / a)$ then is a smooth function of $r$ at the core. We shall assume that we can write

$$
\begin{equation*}
\left.g_{0}(\boldsymbol{r})=\psi_{0}^{2}(\boldsymbol{r} / \boldsymbol{a}) y_{H}(\boldsymbol{r} / \boldsymbol{a}) \quad \text { (assumption } \mathrm{A}\right), \tag{8.4}
\end{equation*}
$$

where $\psi_{0}(r / a)$ is a function of $r$ which is equal to $\psi_{H}(r / a)$ except near the core. We anticipate that $\psi_{0}(r / a)$ is the zero-energy solution of the twobody Schrödinger equation with the potential $v_{0}(r)$.

Assumption A is justified on physical grounds by the idea that only for close two-body encounters is $g_{0}(r)$ different from the rdf of a hard-sphere fluid with a suitably chosen diameter.

TABLE II. Energies obtained variationally for the reference system (column 4) and for the system with the full LJ potential (column 6). $n$ is the total number of configurations. The statistical error on the kinetic and potential energies is of the order of $0.05^{\circ} \mathrm{K}$. The error on the total energies is about $0.08^{\circ} \mathrm{K}$.

|  | $\langle T\rangle / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $\left\langle\boldsymbol{V}_{0}\right\rangle / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $E_{0} / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $\langle W\rangle / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $E / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $\boldsymbol{n}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| 1.16 | 13.59 | 4.45 | 18.04 | -23.83 | -5.79 | 650000 |
| 1.17 | 13.95 | 4.09 | 18.04 | -23.80 | -5.76 | 650000 |
| 1.18 | 14.30 | 3.60 | 17.90 | -23.76 | -5.86 | 400000 |
| 1.20 | 15.07 | 3.06 | 18.15 | -23.68 | -5.53 | 650000 |

Assumption A is not sufficient to determine the kinetic energy. In order to calculate it we must explicitly use the Jastrow approximation. This requires a new assumption. We shall write for the Jastrow factor $f_{0}(\boldsymbol{r})$,

$$
\begin{equation*}
f_{0}(r)=\psi_{0}(r / a) S_{H}(r / a) \quad(\text { assumption B) }, \tag{8.5}
\end{equation*}
$$

where ${ }^{4}$

$$
\begin{align*}
S_{H}(x) & =\frac{f_{H}(x)}{\psi_{H}(x)} \\
& =\frac{x}{x-1} \tanh \frac{x^{m}-1}{b_{H}^{m}} \tag{8.6}
\end{align*}
$$

$S_{H}(x)$ is a smooth function of $x$ at the core.
We shall now see how these two assumptions are connected. It will turn out that the effective expansion parameter of the development of the reference system around hard spheres (in the Jastrow approximation at least) is

$$
\begin{equation*}
\rho \epsilon^{3}=\rho a^{3} \int \overrightarrow{\mathrm{x}} \Delta(x), \tag{8.7}
\end{equation*}
$$

where

$$
\begin{equation*}
\Delta(x)=\psi_{0}^{2}(x)-\psi_{H}^{2}(x) \tag{8.8}
\end{equation*}
$$

is negligibly small except in the region of the core. For instance, at the normal density of helium ( $\rho_{0}=0.3648 \sigma^{3}$ ), with the above LJ potential it is found that $\rho \epsilon^{3}$ is equal to $0.65 \times 10^{-4}$.

The smallness of this parameter explains why we have replaced in (8.1) the rdf of the reference system, expected to be given by (8.4) in its hardsphere approximation. For the same reason, as sumption B entails assumption A. Let $g_{0}(r)$ be the rdf calculated using assumption $B$. With the help of the superposition approximation, we obtain

$$
\begin{align*}
& \hat{g}_{0}(r)= \psi_{0}^{2}(r / a) y_{H}(r / a) \\
& \times {\left[1+\rho a^{3} \int \overrightarrow{d \mathbf{x}^{\prime}} g_{H}\left(x^{\prime}\right) \Delta\left(x^{\prime}\right)\right.} \\
&\left.\times\left[g_{H}\left(x-x^{\prime}\right)-1\right]+O\left(\rho^{2} \epsilon^{6}\right)\right],  \tag{8.9}\\
& r=x a .
\end{align*}
$$

Using the fact that $\Delta(r)$ is concentrated at the core, we have

$$
\begin{align*}
\delta g_{0}(r) & =\hat{g}_{0}(r)-g_{0}(r) \\
& =\rho \epsilon^{3} g_{0}(r) y_{H}(1) \phi(r / a), \tag{8.10}
\end{align*}
$$

where

$$
\begin{equation*}
\phi(x)=\frac{2 \pi}{x} \int_{\sup \{|x-1|, 0\}}^{x+1} d x^{\prime}\left[g_{H}\left(x^{\prime}\right)-1 \mid x^{\prime}\right. \tag{8.11}
\end{equation*}
$$

We find that at the normal density of liquid helium $\left|\delta g_{0}(r)\right| / g_{0}(r)$ is smaller than $3 \times 10^{-3}$.

Using assumptions A and B , the energy of the reference system can easily be cast in the form

$$
\begin{align*}
E_{0}= & \frac{1}{2} N \rho \int d \overrightarrow{\mathbf{r}}\left(\frac{\hbar^{2}}{4 m} \nabla^{2} \ln f_{0}(\boldsymbol{r})+v_{0}(r)\right) \\
& \times \psi_{0}^{2}(r / a) y_{H}(\boldsymbol{r} / a) \\
= & E_{H}+E_{1}+E_{2} . \tag{8.12}
\end{align*}
$$

There $E_{H}$ is the energy of the hard-sphere system with density $\rho$ and diameter $a$ :

$$
\begin{equation*}
E_{1}=-\frac{N \rho \hbar^{2}}{4 m a^{2}} \int d \vec{x}\left[\nabla^{2} \ln S_{H}(x)\right]\left[\psi_{0}^{2}(x)-\psi_{H}^{2}(x)\right] \tag{8.13}
\end{equation*}
$$

is of order $\rho \epsilon^{3}$ and can be safely neglected.

$$
\begin{equation*}
E_{2}=\frac{1}{2} N \rho a^{3} \int d \overrightarrow{\mathrm{x}} \Phi\left[\psi_{0}\right] y_{H}(r) \tag{8.14}
\end{equation*}
$$

where

$$
\begin{equation*}
\Phi\left[\psi_{0}\right]=v_{0} \psi_{0}^{2}-\left(\hbar^{2} / 2 m\right)\left[\psi_{H}^{2} \nabla^{2} \ln \psi_{H}-\psi_{0}^{2} \nabla^{2} \ln \psi_{0}\right] . \tag{8.15}
\end{equation*}
$$

$\Phi\left[\psi_{0}\right]$ is seen, a posteriori, to be sharply concentrated in the region of the core. We can therefore write

$$
\begin{equation*}
E_{2} \simeq \frac{1}{2} \rho a^{3} y_{H}(1) \int d \overrightarrow{\mathbf{x}} \Phi\left[\psi_{0}\right] \tag{8.16}
\end{equation*}
$$

If we now minimize the energy with respect to $\psi_{0}$, we find that this function obeys the Euler equation:

$$
\begin{equation*}
\left[-\left(\hbar^{2} / m\right) \nabla^{2}+v_{0}\right] \psi_{0}=0 . \tag{8.17}
\end{equation*}
$$

Furthermore, at the minimum, $E_{2}$ as given by (8.16) is seen to vanish. A direct computation shows that, at normal density, $E_{1}+E_{2}$ is smaller than $0.05^{\circ} \mathrm{K}$.
We now see that assumption B has been used as an intermediate step in the reasoning. Its explicit use appears only in the evaluation of correction terms which are shown to be negligible. Furthermore it will be shown in Sec. IX that assumption $B$ is very well justified.

## IX. REMARKS ON THE VARIATIONAL PROBLEM

Assumption B, if taken literally, has the advantage of providing a Jastrow wave function for the reference system which, given the variational solution of the hard-sphere problem, involves no new parameter. In order to put this remark in practical use, we must give an analytical form for $\psi_{0}(x)$. Putting

$$
\begin{equation*}
u_{0}(x)=x \psi_{0}(x) \tag{9.1}
\end{equation*}
$$

we have found the following fit for the solution of the Schrödinger equation (8.17) with the Len-
nard-Jones constants defined above:

$$
\begin{align*}
& u_{0}=\left[c_{0}+c_{1}(x-1)\right] e^{-w\left(1 / x^{5}-1\right)} \text { for } x \leqslant 1,  \tag{9.2}\\
& u_{0}=x-1+c_{0}\left[1+c_{2}(x-1)^{2}\right] e^{-k(x-1)} \text { for } x>1,
\end{align*}
$$

where

$$
\begin{aligned}
& w=8 \pi / 10 \Lambda^{*} a^{5}, \quad \Lambda^{*}=\left(\hbar^{2} / m \sigma^{2} \epsilon\right)^{1 / 2}=2.67, \\
& c_{0}=0.04118, \quad c_{1}=0.0515, \quad c_{2}=-30.18, \\
& k=11.56 .
\end{aligned}
$$

We can use (8.5) with (8.6) and (8.17) to perform a Monte Carlo calculation of the usual type. We have to compute

$$
\begin{equation*}
E_{0}=\left\langle T+V_{0}\right\rangle . \tag{9.3}
\end{equation*}
$$

Using the Schrödinger equation it is easily seen that

$$
\begin{align*}
T(r)+v_{0}(r)= & \frac{v_{0}(r)}{2}+\frac{\hbar^{2}}{2 m a^{2}}\left[\frac{1}{2}\left(\frac{u_{0}^{\prime}}{u_{0}}\right)^{2}-\frac{u_{0}^{\prime}}{u_{0}} \frac{1}{x}\right] \\
& -\frac{\hbar^{2}}{2 m a^{2}} \nabla_{x}^{2} \ln S_{H} \tag{9.4}
\end{align*}
$$

We find, at normal density,

$$
\begin{aligned}
& E_{0} / N=(18.03 \pm 0.1)^{\circ} \mathrm{K}, \\
& W / N=(-23.51 \pm 0.1)^{\circ} \mathrm{K}
\end{aligned}
$$

We thus obtain $E=(-5.5 \pm 0.2)^{\circ} \mathrm{K}$. This should be compared with the value $E=(-5.73 \pm 0.1)^{\circ} \mathrm{K}$ obtained variationally, and with the value $E=(-5.8 \pm 0.2)^{\circ} \mathrm{K}$ obtained from first-order perturbation theory. We see that the agreement is excellent.

In the past, the variational computations of the energy of heliumlike systems have all been performed with Jastrow functions of the form $e^{-(b / r)^{m}},{ }^{7,8}$ or functions very nearly of that form. ${ }^{19,20}$ All the functions hitherto used have the property of tending rather slowly towards 1 for large values of $r$. A Jastrow function of the form (8.5) is very different, and we wish to investigate its use in calculating the energy of the quantum Lennard-

TABLE III. Variational energies for the LJ system using the Jastrow factor defined by Eqs. (9.1) and (9.2). Column 1: equivalent hard-sphere diameter. Jones fluid. It depends on one variational parameter only which is the equivalent hard-sphere diameter $a$. For $\psi_{0}(r / a)$ we shall use the analytical expression provided by Eqs. (9.1) and (9.2). With this Jastrow function we have performed Monte Carlo computations for 256 particles for various values of the diameter. The results are summarized in Table III.
A propos of the energies for the reference system, given in the second column of that table, a remark is in order: In general, for arbitrary values of $a$, the Jastrow function (9.2) is no longer a solution of the Schrödinger equation. The Laplacian of the Jastrow function must therefore be evaluated directly, instead of using (8.17). Because (9.2) gives an excellent fit, this entails no practical difference.

The variational computation yields for the reference system an energy of $17.8^{\circ} \mathrm{K}$, which is consistent with and not significantly below the value $17.9^{\circ} \mathrm{K}$ obtained with the function $e^{-(b / r)^{5}}$. The energy minimum is obtained for $a=0.82(5)$. This is close to (but a little smaller than) the scattering length, especially if one realizes that at the minimum the energy varies but little with $a$. Assumption B of Sec. VIII is well verified.
The total energy per particle is equal to ( -5.82 $\pm 0.1)^{\circ} \mathrm{K}$. This turns out to be little different from the energy obtained with the Jastrow wave function $e^{-(b / r)^{5}}$, i.e., $(-5.73 \pm 0.1)^{\circ} \mathrm{K}$. Taking into account the usual tendency to underestimate the errors in Monte Carlo computations, we do not find convincing evidence in the literature that a lower value of the energy can be obtained with a Jastrow wave function (at least when long-wavelength phonons are not included). The form (9.2)

FIG. 3. Structure factor for the Lennard-Jones system as given by variational computations at the normal density of liquid helium. Solid curve: Jastrow factor $e^{-(b / r)^{5}}$ with $b=1.18$. Full circles: hard-sphere-like Jastrow factor as given by Eqs. (9.1) and (9.2) with $a=0.83$.
for the Jastrow function is sounder than the usual $e^{-(b / r)^{m}}$ because it exhibits hard-sphere features which are the most important characteristics of liquid helium. We compare in Fig. 3 the structure factors obtained with these two different Jastrow factors. The over-all agreement is good. As expected, with a hard-sphere-like Jastrow factor one gets a higher main peak in the structure factor than with a smoother trial function.

## X. RESULTS OF THE PERTURBATION THEORY

We shall apply perturbation theory to the case of the Lennard-Jones potential. Since in that case complete and reliable results exist only for shortrange Jastrow functions, we shall as a first step use, in order to be consistent, the corresponding variational hard-sphere results neglecting phonons in both cases. The corrections will be made afterwards.
We use the values of the variational rdf listed in Appendix A in order to calculate, with the help of formula (8.1), the energy of the quantum fluid composed of Lennard-Jones molecules. This is compared in Table IV with the variational results of Ref. 8 for the liquid, and with those of Hansen and Pollock ${ }^{10}$ for the solid. The statistical errors on the energy and rdf of the hard-sphere gas entail an error on the energy obtained from perturbation theory which is difficult to estimate because there is clearly a correlation between the errors on the zeroth- and first-order terms. For $\rho a^{3}=0.2138$ we have made two independent runs, the results of which are compared in Table IV. The final energies differ by $0.1^{\circ} \mathrm{K}$. The error in the solid region is larger because there we replaced the rdf for distances larger than $2.4 a$ by 1 ; the effect of this cutoff is clearly not negligible.

We expect the perturbation theory to break down for low densities, where one may get large density fluctuations without increasing the kinetic energy much, and in the high-density solid region, where the hard-sphere approximation must break down. There is, in contrast with the classical case, ${ }^{21}$ a large domain of density where the perturbation theory with the hard-sphere approximation works well in the case of the solid. The reason for this success is that in the quantum case solidification occurs at a quite low density because the particles must stay away from the cores of their neighbors, and the details of the repulsion are not seen. As a whole, we do not see in Table IV any clear discrepancy between the perturbation results and the results obtained variationally. There may be an exception to that statement for the lowest liquid density ( $\rho=0.167$ ), where the rather large discrepancy may be due to our neglect of density fluctuations, and for the highest solid density, where the large discrepancy between the perturbation and variational results may be significant. As a whole it appears that the perturbation theory applies in a density domain which is remarkably large.

Now that the validity of the perturbation theory has been checked within the framework of the Jastrow approximation, we shall replace the approximate hard-sphere (HS) results by "exact" ones. There are three kinds of corrections which all tend to lower the energy: (i) The variational HS energies are replaced by exact ones, as computed for 256 -particle systems. This appears to be the leading correction. (ii) Exact instead of variational rdf are used in the computation of the first-order term. This correction is negligible in the solid region and very small (of the order of $0.05^{\circ} \mathrm{K}$ ) in the fluid region. (iii) The phonon

| 0.5 |  |  |  |  |  |

correction is small but not completely negligible. With the value of the HS diameter which has been chosen, and with the Michels constants for the LJ potential, we obtain for the velocity of sound in the hard-sphere system the value $295 \mathrm{~m} / \mathrm{sec}$ for the equilibrium density of liquid helium. This is not far from the experimental value ( $239 \mathrm{~m} / \mathrm{sec}$ ). Owing to the small size of the phonon correction, it is rather irrelevant which value we use.

The perturbation results thus obtained are shown in Table V and compared with the experimental values. ${ }^{22,23}$ It is seen that, within the estimated error, which is by no means small, there is no clear discrepancy except at the highest solid density, where the Lennard-Jones potential clearly gives energies which are too low, as already known from the work of Hansen and Pollock. ${ }^{10}$ We can obtain a confirmation of these results in the following way: As we have seen, the correction to be applied to the variational results is essentially that in the kinetic energy. We can therefore estimate the exact energy by adding to the variational LJ energies a term $\delta E$ equal to the equivalent HS system minus the variational energy of the HS system.

TABLE VI. Smoothed difference $\delta E / N$ between the "exact" energy per particle of the hard-sphere system and its variational estimate. Energies in units of $\hbar^{2} / m a^{2}$.

| $\rho a^{3}$ | $E_{\text {exact }} / N$ | $E_{\mathrm{var}} / N$ | $\delta E / N$ |
| :--- | ---: | ---: | ---: |
| 0.166 | 4.15 | 4.32 | 0.17 |
| 0.2 | 5.69 | 6.01 | 0.32 |
| 0.244 | 8.14 | 8.80 | 0.66 |
| 0.244 | 8.50 | 8.86 | 0.38 |
| 0.27 | 10.12 | 10.50 | 0.38 |
| 0.3 | 12.27 | 12.65 | 0.43 |
| 0.4 | 21.26 | 21.9 | 0.64 |
| 0.5 | 34.45 | 35.5 | 1.05 |

In this process, we use smoother data than in the straight perturbation theory. The LJ variational data are quite precise and smooth, and $\delta E$ can also be smoothed. The value of $\delta E$ which are used are given in Table VI and the energies thus obtained are given in column 5 of Table V . They are entirely compatible with the perturbation energies and with experiment (except at very high density).
We did not try to determine from the above data the transition and equilibrium densities. They are obviously compatible with the experimental data, within a large uncertainty which may amount to $10 \%$.

## XI. HARD-SPHERE MODEL

In the preceding sections, the close relationship between the reference system and the hard-sphere fluid has been exhibited. It has moreover been shown that the attractive forces change the structure only a little. In particular, it has been demonstrated in Sec. IX, on the basis of variational computations, that a hard-sphere-like Jastrow function is perfectly acceptable for the description of the full LJ fluid. Still within the variational framework, we can obtain a further test of the validity of this hard-sphere representation by comparing the off-diagonal long-range order parameter obtained ${ }^{7,8}$ for the LJ fluid at normal density (with the $e^{-(b / r)^{5}}$ Jastrow factor), i.e., $n_{0}=0.105 \pm 0.005$, with the HS variational value at $\rho a^{3}=0.2138$, where we find $n_{0}=0.093 \pm 0.013$. These values are clearly compatible. Last, we may try the solidification criterion used in the classical case ${ }^{24}$ : The real system solidifies when the equivalent HS system does. The solidification density of the HS system in the variational approximation is obtained for $\rho a^{3}=0.23 \pm 0.01$. This gives for the LJ system $\rho \sigma^{3}=0.39 \pm 0.02$, which should be compared with the
value $\rho \sigma^{3}=0.38$ obtained through the variational computation made directly in the LJ system. ${ }^{10}$

Let us now go beyond the Jastrow approximation. In Fig. 4 we show the "exact" $S(k)$ appropriate to the normal density of liquid helium. We take for the full LJ system the same equivalent hard-sphere density $\rho a^{3}=0.2138$ corresponding to a diameter $a=0.8368 \sigma$ as in the case of the reference system. This choice is motivated as follows: We know from the computations of Sec. IX that the attractive forces have the tendency to reduce the equivalent diameter to a value around $a=0.81 \mathrm{\sigma}$. On the other hand, we know that in order to describe real helium more realistic potentials than the usual LJ potential used in this study should be used, e.g., the potential owing to $\mathrm{Beck}^{25}$ or the modified LennardJones potential (LJ2) considered by Hansen and Pollock. ${ }^{10}$ These potentials have a wider core than the LJ potential with Michels constants. They both yield the value $a=0.86 \sigma$ as the equivalent hardsphere diameter for the reference fluid. We thus see that keeping the value $a=0.8368 \sigma$ realizes a compromise between the above two effects.

The determination of the exact $S(k)$ involves some manipulations which should be indicated. For $\rho a^{3}=0.2$, we can compute precisely the difference between the exact and variational rdf. This difference is scaled and added to the variational rdf at $\rho a^{3}=0.2138$. In order to get the Fourier transform of the rdf, we have obtained its value beyond $r=2.4 a$ by using the Ornstein-Zernike relation and the assumption that, for large $r$, the direct correlation function is negligible. ${ }^{8}$ The phonon contribution is then calculated as indicated in Sec. VI, using for the sound velocity the experi-

FIG. 4. Structure factor at the normal density of liquid helium. Solid line: experiment (Ref. 27 and 28). Open circles: "reconstructed" experiment as explained in the text. Full circles: "exact" hard-sphere structure factor.
mental value and for the cutoff wave vector the value $k_{c}=0.3 a^{-1}$ that leads to the energy minimum.

The structure factor thus determined is compared in Fig. 4 to experimental results obtained by x -ray scattering. Hallock's data ${ }^{26}$ have been used for $k<1.1 \AA^{-1}(k a<2.3)$. Achter and Meyer's results ${ }^{27}$ are shown for higher values of $k$. It is seen that at low $k$ our results agree well with those of Hallock although they show the shoulder predicted by Miller, Pines, and Nozieres ${ }^{28}$ a little more. We may note that this shoulder was not observed by Achter and Meyer, whose results may differ from Hallock's by as much as $10 \%$. In the $k$ region corresponding to the rise of the first peak, the experimental and theoretical results agree quite well. The position of the first peak and the zeros in $S(k)-1$ differ markedly. We note, however, that this disagreement is no longer present when one considers the results obtained from neutron scattering by Henshaw. ${ }^{29}$ There, however, the first peak rises to a much higher value than in Fig. 4.

In order to get more insight into the origin of the discrepancy at large $k$, we reexamine the experimental data used in Fig. 4. The rdf obtained from these results by Fourier transform is not strictly zero inside the core. If we correct this rdf by imposing simply that it vanish for $r s a$, the structure factor that we obtain by Fourier transform is no longer identical with the experimental one. We can impose a compatibility with experiment in the low$k$ region (including the first peak) and a strict vanishing of the rdf inside the core if we iterate the procedure described above, based on a succession of Fourier transforms. In this way, a self-consistent structure factor is reconstructed, with admittedly some measure of arbitrariness. The results are shown in Fig. 4. It is seen that the agreement with the hard-sphere structure factor is somewhat improved. We believe the remaining discrepancy to be due more to the errors in the hard-sphere rdf and the experimental structure factor than to a defect in the model.

The exact ODLRO parameter is estimated as $n_{0}=0.095 \pm 0.001$ at $\rho a^{3}=0.2$. It is very different from the recent estimate ${ }^{30}$ of $n_{0}=0.0241 \pm 0.01$ which is obtained indirectly from experiment at $1.2^{\circ} \mathrm{K}$.

Last, we examine the solidification criterion. The freezing density for hard spheres $\rho a^{3}=0.25$ $\pm 0.01$ yields the value $\rho \sigma^{3}=0.427$. At the solidification density, the main peak of the hard-sphere structure factor reaches the value 1.40 , which should be compared to the value 2.85 in the classical case. ${ }^{24}$ A value of the order of 1.40 should therefore be the maximum value reached by the structure factor of liquid helium at very low temperature in the whole fluid range.

## APPENDIX A

We tabulate the radial-distribution function for the hard-sphere Bose system as computed by the Monte Carlo integration of the Schrödinger equation and by the variational method with the Jastrow factor, ${ }^{4}$

$$
f(r)=\tanh \left[\left(r^{m}-1\right) / b^{m}\right] .
$$

Results are given at $\rho a^{3}=0.2,0.244$, and 0.27 for the fluid (Table VII) and at $\rho a^{3}=0.27$ and 0.4 for the crystal (Table VIII). The numbers tabulated as $g$ are, in fact, average values over the interval ending in the $r$. That is,

TABLE VII. Radial-distribution function for fluid states of the hard-sphere boson system calculated by variational method ( $g_{v}$ ) and Schrödinger integration $\left(g_{s}\right)$.

| $r$ | $g_{s}$ | $g_{v}$ | $r$ | $g_{s}$ | $g_{v}$ | $r$ | $g_{s}$ | $g_{v}$ | $r$ | $g_{s}$ | $g_{v}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

$$
g\left(r_{n}\right)=\int_{r_{n-1}}^{r_{n}} r^{2} g(r) d r / \int_{r_{n-1}}^{r_{n}} r^{2} d r .
$$

We estimate the statistical error of the values as less than $2 \%$ except for the first few entries which have errors of $5-10 \%$. A systematic error of a few percent at the peak of $g(r)$ is possible owing to incomplete convergence of the iteration process used in the calculation.

## APPENDIX B

The problem of solid $\mathrm{He}^{3}$ is treated exactly as above. As long as we neglect the (small) exchange
effects, the only difference with $\mathrm{He}^{4}$ lies in the lighter mass of $\mathrm{He}^{3}$. Schiff ${ }^{11}$ has calculated the effective diameter of the reference part of the LJ potential in the $\mathrm{He}^{3}$ case and found the value $0.823 \sigma$. He has shown that, in the variational framework, the perturbation theory works as well as in the solid $\mathrm{He}^{4}$ case. Here we use the results of Schiff, but with "exact" results for the HS boson solid instead of variational results. As above, we give both the results obtained by a straight application of perturbation theory and the estimate obtained from correcting the variational results for the difference between exact and variational HS results.

TABLE VIII. Radial-distribution function for crystal states of the hard-sphere boson system calculated by variational method $\left(g_{v}\right)$ and Schrödinger integration $\left(g_{s}\right)$.

| $r$ | $g_{s}$ | $g_{v}$ | $r$ | $g_{s}$ | $g_{v}$ | $r$ | $g_{s}$ | $g_{v}$ | $r$ | $g_{s}$ | $g_{v}$ |

| 1.85 | 0.786 | 0.753 | 2.70 | 1.342 | 1.376 | 3.55 | 0.892 | 0.890 |  |  |  |

TABLE IY. Results of the perturbation theory applied to $\mathrm{He}^{3}$. Same as in Table V. The results for the liquid state have been obtained using the Wu-Feenberg ansatz.

| $a^{3}$ | $\rho \sigma^{3}$ | $E_{\text {var }} / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $E_{\text {pert }} / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $E_{\text {est }} / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ | $E_{\text {exp }} / N$ <br> $\left({ }^{\circ} \mathrm{K}\right)$ |
| :--- | :---: | :---: | :---: | :---: | ---: |
| 0.167 | 0.283 | -1 | -1.2 | -1.3 | -2.4 |
| 0.2 | 0.341 | 0 | -0.35 | -0.75 | -2.2 |
| 0.2138 | 0.364 | 0.6 |  | -0.4 | -1.8 |
| 0.234 | 0.4 | 2.2 |  | 0.75 |  |
| 0.244 | 0.416 | 3.2 | 0.55 | 1.65 |  |
| 0.244 | 0.416 | 1.5 | $0.2 \pm 0.6$ | $0.1 \pm 0.6$ | -0.4 |
| 0.27 | 0.461 | 3.2 | $1.8 \pm 0.8$ | $1.8 \pm 0.8$ | 1.1 |
| 0.3 | 0.512 | 5.8 | $4.2 \pm 1.0$ | $4.3 \pm 1.0$ | 4.6 |
| 0.35 | 0.597 | 11.7 |  | $9.8 \pm 1.2$ | 11.5 |

Both methods lead to energies which agree, within the rather large errors, with experiment, as in the $\mathrm{He}^{4}$ case.

For the liquid state, the antisymmetry of the wave function must be taken into account. In the absence of exact hard-sphere results in the fermion case, one is led to rely on the Wu-Feenberg approximation:

$$
\psi_{\mathrm{He}}{ }^{3}\left(\overrightarrow{\mathrm{r}}_{1}, \cdots, \overrightarrow{\mathbf{r}}_{N}\right)=\psi_{B}\left(\overrightarrow{\mathrm{r}}_{1}, \cdots, \overrightarrow{\mathbf{r}}_{N}\right) \psi_{F}\left(\overrightarrow{\mathrm{r}}_{1}, \cdots, \overrightarrow{\mathbf{r}}_{N}\right),
$$

where $\psi_{B}$ is the solution of the mass- 3 boson problem and $\psi_{F}$ is the appropriate Slater determinant of plane waves. As Wu and Feenberg ${ }^{31}$ have shown, if the ground-state properties of the boson system are known, the energy of the $\mathrm{He}^{3}$ fluid can be calculated by making a cluster expansion of the determinant. This expansion seems to converge quite well. For the Lennard-Jones potential variational results are available. ${ }^{9}$ In that case, Schiff has shown that the perturbation methods also work quite well. Schiff's results rely on three assumptions: (i) Variational results are used for the hardsphere boson fluid. (ii) The Lennard-Jones potential is a good approximation for the $\mathrm{He}-\mathrm{He}$ interaction. (iii) The Wu-Feenberg ansatz is a good approximation.
Here (Table IX) we correct for (i) by using exact hard-sphere results. We know from the $\mathrm{He}^{4}$ study that the error entailed by the use of the LJ potential is small (less than $0.5^{\circ} \mathrm{K}$ ). The very clear discrepancy revealed in Table IX in the $\mathrm{He}^{3}$ is then largely due to the use of the Wu-Feenberg ansatz, whose effect amounts to an overestimation of the energy by at least $1^{\circ} \mathrm{K}$.

${ }^{12}$ The ratio of the multivariate anisotropic distribution to a distribution isotropic for each sphere may be regarded as a weight factor. This factor times the ratio $\psi_{J}(R) / \psi_{J}\left(R^{\prime}\right)$ is the branching ratio used in a move from point $R^{\prime}$ to point $R$. Clearly it is possible to make this branching factor arbitrarily close to 1 , reducing its contribution to the over-all variance to zero.
