We consider an experimentally realizable model of noninteracting but randomly coupled atoms in a twodimensional optical lattice. By choosing appropriate real or complex-valued random fields and species-dependent energy offsets, this system can be used to analyze effects of disorder in four different symmetry classes: the chiral BDI and AIII and the nonchiral A and AI. These chiral classes are known to support a metallic phase at zero energy, which here, due to the inevitable finite size of the system, should also persist in a neighborhood of nonzero energies. As we discuss, this is of particular interest for experiments involving quenches. Away from the center of the spectrum, we find that excitations appear as domain walls in the cases with time-reversal symmetry or as vortices in the cases where time-reversal symmetry is absent. Therefore, a quench in a system with uniform density would lead to the formation of either vortices or domain walls depending on the symmetry class. For the nonchiral models in classes A and AI, a population imbalance between the two atomic species naturally occurs. In these cases, one of the two species is seen to favor a more uniform density. We also study the onset of localization as the disorder strength is increased for the different classes, and by deriving an effective model for the nonchiral cases we show how their eigenstates remain extended for larger values of the coupling with the disorder when compared to the nonchiral ones.

### **I. INTRODUCTION**

Symmetries play a fundamental role in physics, ranging from predicting planetary motion to understanding interaction among elementary particles. Indeed, properties of quantummechanical systems in equilibrium are often universal and can be characterized according to symmetries [\[1,2\]](#page-8-0). Recently, a more in-depth understanding of the aspects of various lattice models has been advanced thanks to the development of topological insulators [\[3\]](#page-8-0). Not surprisingly, the characteristics of such lattice models rely on the underlying symmetries, i.e., time-reversal, particle-hole, and chirality symmetries. Structuring the models accordingly yields a "periodic table" with ten different symmetry classes [\[4\]](#page-8-0).

Together with the dimensionality, these symmetry classes tell much about the properties of a system. Thus, a question that naturally arises is, Can we identify physical systems that allow for control of symmetry classes? Then, by turning a knob the experimentalist could, in principle, qualitatively alter the system's properties. In this respect, systems of cold atoms loaded into optical lattices are extremely attractive [\[5\]](#page-8-0). These are well isolated from their environments and clean from impurities, and preparation and detection are relatively easy. The lattice geometry and dimensionality can be monitored with great flexibility, and by using multiple atomic electronic states one can realize multispecies models [\[5\]](#page-8-0). Furthermore, cold atomic systems also allow for a systematic study of effects deriving from disorder by handling the type and strength of the disorder with additional laser fields [\[6\]](#page-8-0).

Back in 1958, Anderson predicted that disorder can fully inhibit transport due to disorder-induced coherent scattering

resulting in destructive quantum interferences [\[7\]](#page-8-0). This absence of conductance, following the appearance of spatially localized eigenstates in the system, is the phenomenon of *Anderson localization* or strong localization. In one dimension, arbitrarily weak disorder localizes every eigenstate in the entire spectrum, while in three dimensions there may exist a "mobility edge" separating localized from extended (or metallic) states  $[8]$ . Thus, in three dimensions it is possible to realize a metal-Anderson insulator transition by tuning the disorder strength. In two dimensions, the situation becomes more intriguing because the presence or absence of insulating and/or metallic phases strongly relies on the symmetry classes [\[9\]](#page-8-0). The eigenstates of chiral systems in two dimensions, for example, may become delocalized at the center of the spectrum [\[10\]](#page-8-0). But even if this phenomenon is accepted today, the existence of delocalized states in such systems was long debated [\[11\]](#page-8-0).

In this work we study a cold-atom model which is of easy experimental implementation. We consider two noninteracting atomic species coupled by random fields and confined in an optical lattice. Physically, the coupling amounts to a laser-induced Raman coupling between two internal atomic Zeeman levels. By adjusting the properties of the coupling lasers, i.e., the phase and frequency, the system may fall in four different symmetry classes, where two support a metal-Anderson insulator transition at zero energy. Properties of the eigenstates are explored numerically, and it is found that, depending on the symmetries, the excited states can host domain walls or vortices. The vortices appear in the cases with a complex-valued Raman coupling, i.e., broken time-reversal symmetry. For the system with chiral symmetry, the model can be mapped onto a *random flux model* [\[10,11\]](#page-8-0) in which every lattice plaquette is subject to a (random) synthetic magnetic field. When the chiral symmetry is broken, the two species are reorganized such that one of them carries the

<sup>\*</sup>Corresponding author: fep@thp.uni-koeln.de

<span id="page-1-0"></span>system's kinetic energy, being characterized, therefore, by a smooth density, while the other one shows a vivid structure that follows the random Raman coupling corresponding to lowering the potential energy. This behavior is explained in terms of an effective model valid in the limit of a large population imbalance between the two species.We also discuss the model in light of the Mermin-Wagner theorem [\[12\]](#page-8-0) which impose restrictions on the establishment of long-range order, depending on the symmetries and the dimensions of the system. This is in connection to the phenomenon known as *random-field-induced order* (RFIO) [\[13\]](#page-8-0), in which a particular choice of disorder can be used to lower the symmetries of the clean system and, consequently, to invalidate the premises under which the Mermin-Wagner theorem can be applied, thereby stabilizing long-range order. Despite clear similarities with models studied in the past that have been shown to exhibit RFIO [\[14\]](#page-8-0), we do not find evidence of RFIO in the noninteracting case studied here.

This paper is structured as follows. In the next section we introduce the model system and the corresponding Hamiltonian in a general form. The symmetries and the different classes are presented in Sec. [II C.](#page-2-0) After summarizing known results on the universal properties of the symmetry classes discussed here, in Sec. [III](#page-3-0) we present the numerical results: We characterize the eigenstates in Sec. [III A](#page-3-0) and then the RFIO in Sec. [III C.](#page-7-0) In Sec. [IV](#page-7-0) we give a summary of the results and briefly touch upon the question of how to extend the system to other classes.

## **II. SYSTEM**

The controllability of cold atomic systems together with the possibility to determine at will the disorder properties has made these systems a perfect test bed to study effects like Anderson localization [\[6\]](#page-8-0). In early experiments, one-dimensional (1D) tubes of cold (bosonic) atoms were explored, and either speckle potentials [\[15\]](#page-8-0) or incommensurate optical lattices [\[16\]](#page-8-0) were used to realize disorder (or quasidisorder). In these pioneering cold-atom experiments it was possible to extract both the hindered matter wave spreading and the localization length. The influence of interaction was later probed, and a crossover from localized to delocalized states could be observed [\[17\]](#page-8-0). At a mean-field level, the nonlinearity stemming from the atom-atom interaction effectively couples localized states, leading to a delocalization [\[18\]](#page-8-0). In three dimensions, Mott argued for the presence of a mobility edge separating localized states at the tails of the spectrum, from extended ones at the center [\[19\]](#page-8-0). This has recently been verified using both fermionic [\[20\]](#page-8-0) and bosonic atoms [\[21\]](#page-8-0). In the Bose-Hubbard (BH) model, a suppression of superfluidity has been seen in three dimensions [\[22\]](#page-8-0). Further investigations [\[23\]](#page-8-0) suggested this as a signature of the Bose glass phase predicted years ago for this model [\[24\]](#page-8-0).

In two dimensions, more relevant for this work, the glass phase of the disordered BH model has been explored, along with interaction-driven transitions from a localized phase to a superfluid phase and finally a reentrance into a Mott insulating phase  $[25]$ . The (repulsive) interaction counteracts the disorder-induced localization, and for strong enough interaction the atoms form a disordered Mott-insulator state. For noninteracting gases, the diffusion in a disordered two-

FIG. 1. Schematic plot of the atom-laser  $\Lambda$  coupling configuration. States  $|a\rangle$  and  $|c\rangle$  are dipole coupled by a laser with (spatially dependent) amplitude  $\Omega_1$ , and a second laser couples states  $|b\rangle$  and  $|c\rangle$  with an amplitude  $\Omega_2$ . The atom-laser detuning  $|\Delta| \gg |\Omega_1|, |\Omega_2|,$ such that the excited state  $|c\rangle$  becomes only virtually populated. Thus, it is adiabatically eliminated, resulting in an effective coupling between states  $|a\rangle$  and  $|b\rangle$  with an amplitude  $\Omega = \Omega_1^* \Omega_2 / \Delta$ . Here,  $2\delta$ is the detuning for the emerging two-photon process.

dimensional (2D) optical lattice was measured in Ref. [\[26\]](#page-8-0). By applying the speckle potential with an incident angle the disordered potential shows a different correlation length in the two directions, which leads to anisotropic spreading. In terms of the symmetry classes, this experimental system falls within class AI (see below), in which all the states are known to be localized, and furthermore, this class does not support topological states. Following this rapid progress, we continue by suggesting an experimentally simple model which goes beyond present experiments and show new characteristics.

# **A. Model Hamiltonian**

We consider noninteracting three-level atoms, with internal states labeled *a*, *b*, and *c*, confined to a 2D square optical lattice. The internal electronic states  $|a\rangle$ ,  $|b\rangle$ , and  $|c\rangle$  are Raman coupled with two external lasers, as explained in Fig. 1. By introducing the atomic field operators  $\hat{\Psi}_{\alpha}(\mathbf{x})$  ( $\alpha = a, b, c$ ), which obey the regular bosonic commutations

$$
[\hat{\Psi}_{\alpha}(\mathbf{x}), \hat{\Psi}_{\beta}^{\dagger}(\mathbf{x}')] = \delta_{\alpha\beta}\delta(\mathbf{x} - \mathbf{x}'), \quad [\hat{\Psi}_{\alpha}(\mathbf{x}), \hat{\Psi}_{\beta}(\mathbf{x}')] = 0, \quad (1)
$$

the Hamiltonian is given, in the rotating-wave approximation  $[27]$ , by

$$
\hat{\mathcal{H}} = \int d\mathbf{x} \left\{ \sum_{\alpha=a,b,c} \hat{\Psi}_{\alpha}^{\dagger}(\mathbf{x}) \hat{H} \hat{\Psi}_{\alpha}(\mathbf{x}) + \Delta \hat{\Psi}_{c}^{\dagger}(\mathbf{x}) \hat{\Psi}_{c}(\mathbf{x}) + \delta \hat{\Psi}_{d}^{\dagger}(\mathbf{x}) \hat{\Psi}_{d}(\mathbf{x}) - \delta \hat{\Psi}_{b}^{\dagger}(\mathbf{x}) \hat{\Psi}_{b}(\mathbf{x}) + [\Omega_{1}(\mathbf{x}) \hat{\Psi}_{c}^{\dagger}(\mathbf{x}) \hat{\Psi}_{d}(\mathbf{x}) + \text{H.c.}] + [\Omega_{2}(\mathbf{x}) \hat{\Psi}_{c}^{\dagger}(\mathbf{x}) \hat{\Psi}_{b}(\mathbf{x}) + \text{H.c.}] \right\}.
$$
\n(2)

Here,  $\hat{H} = -\frac{\hbar^2}{2m}(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}) + V_0[\cos^2(kx) + \cos^2(ky)]$  is the 2D lattice Hamiltonian, with *m* being the atomic mass, *k* being the wave vector (the same in both directions), and  $V_0$  being the potential amplitude (also equal for both directions).  $\Delta$ ,  $\delta$ , and  $\Omega_i(\mathbf{x})$  (*i* = 1, 2) are atom-light detunings and drive amplitudes <span id="page-2-0"></span>as explained in Fig. [1,](#page-1-0) and in particular, the two amplitudes  $\Omega_i(\mathbf{x})$  are, in general, complex (which can be controlled by the phases of the lasers).

#### **B. Properties**

We assume the dispersive coupling regime  $|\Delta| \gg |\Omega_1(\mathbf{x})|$ ,  $|\Omega_2(\mathbf{x})|$ ,  $|\delta|$ , meaning that if the internal states of the atoms are initialized in the lower states  $|a\rangle$  and  $|b\rangle$ , the excited state  $|c\rangle$ is only weakly populated and can be integrated out. In this regime, the field

$$
\hat{\Psi}_c(\mathbf{x}) = -\frac{\Omega_1(\mathbf{x})\hat{\Psi}_a(\mathbf{x}) + \Omega_2(\mathbf{x})\hat{\Psi}_b(\mathbf{x})}{\Delta} \tag{3}
$$

is assumed to follow the other two fields adiabatically [\[28\]](#page-8-0). Within this assumption, we derive an effective model for the remaining fields [\[29\]](#page-8-0),

$$
\hat{\mathcal{H}}_{\text{eff}} = \int d\mathbf{x} \left\{ \sum_{\alpha=a,b} \hat{\Psi}_{\alpha}^{\dagger}(\mathbf{x}) \hat{H} \hat{\Psi}_{\alpha}(\mathbf{x}) + \mu_{\alpha}(\mathbf{x}) \hat{\Psi}_{\alpha}^{\dagger}(\mathbf{x}) \hat{\Psi}_{\alpha}(\mathbf{x}) + [\Omega(\mathbf{x}) \hat{\Psi}_{b}^{\dagger}(\mathbf{x}) \hat{\Psi}_{a}(\mathbf{x}) + \text{H.c.}] \right\}.
$$
\n(4)

The "chemical potentials"  $\mu_{\alpha}(\mathbf{x})$  ( $\alpha = a, b$ ) account for the two-photon detuning 2*δ* and the Stark shifts arising from the two lasers  $\Omega_1(\mathbf{x})$  and  $\Omega_2(\mathbf{x})$ . Hereafter we omit the spatial dependence of the chemical potentials as doing so will not change the conclusions, i.e.,  $\mu_{\alpha}(\mathbf{x}) \to \mu_{\alpha}$ . The effective coupling between the two internal atomic levels is given by  $\Omega(\mathbf{x}) = \frac{\Omega_1^*(\mathbf{x})\Omega_2(\mathbf{x})}{\Delta}$ . Disorder in the present model derives from the spatial dependence of  $\Omega(x)$ , which fluctuates in both phase and amplitude from site to site.

We proceed along the standard line [\[5\]](#page-8-0) and expand the field operators in the single-band site-localized Wannier functions  $w_{\alpha i}(\mathbf{x})$ ;  $\hat{\Psi}_{\alpha}(\mathbf{x}) = \sum_{i} \hat{\alpha}_{i} w_{\alpha i}(\mathbf{x})$ , with **i** being the site index, and  $\hat{\alpha}_i$  annihilates an  $\alpha$  (= *a*, *b*) species atom at site **i** =  $(i_x, i_y)$ , respectively. By further imposing the tight-binding approximation, the Hamiltonian becomes

$$
\hat{H}_{\text{eff}} = -t \sum_{\langle ij \rangle} (\hat{a}_i^\dagger \hat{a}_j + \hat{b}_i^\dagger \hat{b}_j) + \sum_i (\mu_a \hat{n}_{ai} + \mu_b \hat{n}_{bi}) + \sum_i h_i (e^{i\varphi_i} \hat{a}_i^\dagger \hat{b}_i + \text{H.c.}).
$$
\n(5)

Here, the first sum includes only nearest-neighbor terms, and we have neglected Raman-induced couplings between atoms in neighboring sites. The atom number operators  $\hat{n}_{a\textbf{i}} = \hat{a}_{\textbf{i}}^{\dagger} \hat{a}_{\textbf{i}}$  and  $\hat{n}_{b\textbf{i}} = \hat{b}_{\textbf{i}}^{\dagger} \hat{b}_{\textbf{i}}$ , and the onsite couplings are  $h_i = \int d\mathbf{x} \, w_{ai}^*(\mathbf{x}) w_{bi}(\mathbf{x}) \Omega(\mathbf{x})$  and  $\varphi_i =$ angle[ $\int d\mathbf{x} w_{ai}^*(\mathbf{x}) w_{bi}(\mathbf{x}) \Omega(\mathbf{x})$ ]. These are random numbers taken from Gaussian distributions with widths *ζ* and *ξ* . Letting  $\zeta = \xi = 0$ , we recover the clean system, and for  $\xi = \infty$ , which will be assumed throughout (unless we consider the real case,  $\xi = 0$ ), the phases  $\varphi_i$  are uniformly distributed over  $2\pi$ . The phase diagram of the clean model has been studied in the past when atom-atom interaction was included [\[30\]](#page-8-0), but the disordered coupled case is, to the best of our knowledge, so far unexplored even for zero interaction.

TABLE I. Classification of Eq.  $(5)$  for different choices of  $h_i$  and  $\mu$  (see text for details).

μ	Class
zero	BDI (chiral orthogonal)
zero	AIII (chiral unitary)
nonzero nonzero	AI (Wigner-Dyson orthogonal) A (Wigner-Dyson unitary)

The Hamiltonian (5) will be the starting point for the analysis in Sec. [III.](#page-3-0) Before presenting the results, however, the various symmetry classes realizable with  $\hat{H}_{\text{eff}}$  are discussed.

# **C. Symmetries**

To date, the internal structure of the atoms plays no particular role in experiments of disorder with systems of cold atoms. Thus, the applied fields are far off resonant from any atomic transitions, and only the resulting Stark shifts generate the disordered potential. It is clear that the coupled system becomes much richer in the sense that a set of different models can be easily monitored by tuning the laser parameters. In particular, in such generalized situations the effective models carry an intrinsic pseudospin degree of freedom. The idea of this section is to present the various possible cases that can be achieved and to relate them to the corresponding symmetry classes. A summary is given in Table I.

# *1. Real-valued disorder and vanishing chemical potential: Class BDI*

The simplest disordered situations appear when the two chemical potentials are equal, i.e., we set  $\mu_a = \mu_b = 0$ , and the disorder is purely real,  $\varphi_i = 0$  ( $h_i$  can still change from site to site). By introducing the notation  $\hat{A}_i = [\hat{a}_i, \hat{b}_i]^t$  the Hamiltonian can be written as

$$
\hat{H}_{\rm BDI} = -t \sum_{\langle ij \rangle} \hat{A}_{i}^{\dagger} \hat{A}_{j} + \sum_{i} h_{i} \hat{A}_{i}^{\dagger} \hat{\sigma}_{x} \hat{A}_{i}, \tag{6}
$$

where  $\hat{\sigma}_x = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$  is the *x*-Pauli matrix. Now, defining

$$
\hat{c}_{\mathbf{i}} = \frac{1}{2}(\hat{a}_{\mathbf{i}} + \hat{b}_{\mathbf{i}}), \quad \hat{d}_{\mathbf{i}} = \frac{1}{2}(\hat{a}_{\mathbf{i}} - \hat{b}_{\mathbf{i}}), \tag{7}
$$

and  $\hat{C}_i = [\hat{c}_i, \hat{d}_i]^t$ , Eq. (6) becomes

$$
\hat{H}_{\rm BDI} = -t \sum_{\langle ij \rangle} \hat{C}_{i}^{\dagger} \hat{C}_{j} + \sum_{i} h_{i} \hat{C}_{i}^{\dagger} \hat{\sigma}_{z} \hat{C}_{i}.
$$
 (8)

In this transformed basis, this model is equivalent to the original Anderson Hamiltonian [\[7\]](#page-8-0) in two dimensions, although here with two copies that experience the random potential with the same magnitude but opposite signs. This system has chiral symmetry [\[31\]](#page-8-0), and therefore, the spectrum is symmetric around zero energy. Specifically, in the representation of the  $\hat{A}_i$  operators introduced above and noticing that the dimension is  $2L^2$ , where *L* is, as before, the size of the lattice in one direction, we have for even *L* that the operator [\[32\]](#page-8-0)

$$
\hat{U} = \text{diag}(+1, -1, +1, \dots, -1|-1, +1, -1, \dots, +1)
$$
\n(9)

<span id="page-3-0"></span>anticommutes with the Hamiltonian. Moreover, since the Hamiltonian is real, it is also time-reversal symmetric. Thus, the model belongs to class BDI of *chiral orthogonal* systems [\[2,4\]](#page-8-0).

# *2. Complex-valued disorder and vanishing chemical potential: Class AIII*

Generalizing the previous case to complex couplings,  $\varphi_i \neq 0$ , the model is written as

$$
\hat{H}_{\text{AIII}} = -t \sum_{\langle ij \rangle} \hat{A}_{i}^{\dagger} \hat{A}_{j} + \sum_{i} h_{i} \hat{A}_{i}^{\dagger} (\cos \varphi_{i} \hat{\sigma}_{x} + \sin \varphi_{i} \hat{\sigma}_{y}) \hat{A}_{i}.
$$
\n(10)

Contrary to the case with real disorder, here, we cannot decouple the two species with a spatially independent transformation like Eq. [\(7\)](#page-2-0). Mixing in the  $\hat{\sigma}_y$  component does not break the chiral symmetry, as can be seen from the fact that  $\hat{\sigma}_z$ anticommutes with  $\hat{\sigma}_x$  and  $\hat{\sigma}_y$ , and the operator of Eq. [\(9\)](#page-2-0) has the form  $\hat{U} = \hat{D} \otimes \hat{\sigma}_z$  with an  $L^2 \times L^2$  matrix  $\hat{D} =$  $diag(+1, -1, +1, \ldots, -1)$ . The Hamiltonian is, however, complex, and time-reversal symmetry is therefore broken. The symmetry class is class AIII of *chiral unitary* systems [\[2,4\]](#page-8-0).

An interesting observation is that by transforming the model with the unitary  $\hat{U}_{\varphi} = \prod_{i} \exp\left[-i\varphi_{i}(\hat{n}_{ai} - \hat{n}_{bi})/2\right]$ , the random phase appears on the tunneling terms:

$$
\hat{H}'_{\text{AIII}} = \hat{U}_{\varphi} \hat{H}_{\text{AIII}} \hat{U}_{\varphi}^{-1} = -\sum_{\langle ij \rangle} \hat{A}_{i}^{\dagger} \hat{t}_{ij} \hat{A}_{j} + \sum_{i} h_{i} \hat{A}_{i}^{\dagger} \hat{\sigma}_{x} \hat{A}_{i}, \quad (11)
$$

with

$$
\hat{t}_{ij} = t \begin{bmatrix} e^{i(\varphi_i - \varphi_j)} & 0\\ 0 & e^{-i(\varphi_i - \varphi_j)} \end{bmatrix} . \tag{12}
$$

This is a version of the random-flux model  $[10,11]$  describing a random flux through any plaquette in the lattice. Thus, the spatially dependent phase  $\varphi(x)$  of the Raman coupling effectively generates a synthetic magnetic field for the neutral atoms [\[33\]](#page-8-0).

#### *3. Real-valued disorder and nonzero chemical potential: Class AI*

Adding a chemical potential to the real-valued disorder case breaks the chiral symmetry, but the time-reversal one remains intact. The resulting Hamiltonian

$$
\hat{H}_{\rm AI} = -t \sum_{\langle ij \rangle} \hat{A}_{\mathbf{i}}^{\dagger} \hat{A}_{\mathbf{j}} + \sum_{\mathbf{i}} \hat{A}_{\mathbf{i}}^{\dagger} (h_{\mathbf{i}} \hat{\sigma}_x + \mu \hat{\sigma}_z) \hat{A}_{\mathbf{i}}, \qquad (13)
$$

where we have introduced the effective chemical potential  $\mu = (\mu_a - \mu_b)/2$  [we have subtracted a trivial term  $(\mu_a + \mu_b)/2 \sum_i \hat{A}_i^{\dagger} \hat{A}_i$  from the Hamiltonian]. With only timereversal symmetry present, the model belongs to class AI of *Wigner-Dyson orthogonal* systems [\[2,4\]](#page-8-0).

# *4. Complex-valued disorder and nonzero chemical potential: Class A*

By breaking both the chiral and the time-reversal symmetries, i.e., by including a chemical potential and considering a complex Raman coupling, respectively, the model belongs to class A of *Wigner-Dyson unitary* systems [\[2,4\]](#page-8-0). The Hamiltonian is then written

$$
\hat{H}_{A} = -t \sum_{\langle ij \rangle} \hat{A}_{i}^{\dagger} \hat{A}_{j} + \sum_{i} h_{i} \hat{A}_{i}^{\dagger} (\cos \varphi_{i} \hat{\sigma}_{x} + \sin \varphi_{i} \hat{\sigma}_{y} + \mu \hat{\sigma}_{z}) \hat{A}_{i}.
$$
\n(14)

The underlying four symmetry classes of our general model Hamiltonian [\(5\)](#page-2-0) are listed in Table [I.](#page-2-0)

# **III. RESULTS AND DISCUSSIONS**

### **A. Universal properties**

Having identified the symmetry classes, it is now possible to directly determine some properties of the different models that can be realized from  $(5)$ . Class AI is trivial in the sense that all states are localized and there is no room for nontrivial topological states, such as delocalized edge states [\[9\]](#page-8-0). In symmetry class A, the states are also all localized, but the model can be potentially topological [\[9\]](#page-8-0). The two other classes, the chiral ones, are more interesting in terms of the localization properties.

Chiral structures arise when a lattice system can be equivalently decomposed into two sublattices. The present model is clearly of this type, as the two species can be thought of as the constituents of a bilayer lattice, with a random tunneling  $h_i$  between the layers. In the usual classification scheme, there are three chiral classes: AIII, BDI, and CII. As mentioned above, in AIII time-reversal symmetry is broken, while in BDI it is preserved, and the time-reversal symmetry operator in this class squares to  $+1$ . Class CII is also time-reversal symmetric, but here, the square of the time-reversal symmetry operator is −1; that is, it is *chiral symplectic* [\[2\]](#page-8-0). The symplectic classes typically contain a spin degree of freedom, and will not be of importance here. One can imagine, however, that by using four species (four different electronic Zeeman levels) this class could also be realized with our model.

Although it has been shown that weak localization is absent in all orders in perturbation theory in chiral systems [\[34\]](#page-9-0), recent studies support the possibility of a metal-insulator transition at the center of the spectrum (for energies  $E \sim 0$ ) [\[35\]](#page-9-0) as a function of the disorder strength. We thus expect a diverging localization length *λ* for not too strong values of the disorder as the energy approaches zero in the chiral cases. In particular, for Gaussian disorder, a renormalization-group analysis gives the localization length [\[9\]](#page-8-0)

$$
\lambda(E) \propto e^{g^{-1}|\ln(E/\Delta)|^{1/2}},\tag{15}
$$

where  $g^{-1}$  is proportional to the conductance and  $\Delta$  is the bandwidth (of the clean system). It follows that for any finite energy *E* the system is localized, although the localization length can get very long (in comparison to the system size here denoted as *L*). According to expression (15), the system can be metallic in a strict sense only for  $E \equiv 0$ , which implies that for finite systems the total number of sites has to be odd. Nevertheless, when the localization length  $\lambda \gg L$ , more states at the center of the spectrum will always appear metallic in this case. In the infinite system, the analysis via the effective nonlinear  $\sigma$  model [\[9\]](#page-8-0) from which Eq. (15) is derived hints that, indeed, the  $E = 0$  state should always be delocalized (metallic). However, Eq.  $(15)$  can also be obtained from a <span id="page-4-0"></span>modified action, including higher-order terms, which shows that the  $E = 0$  state can be localized even for the chiral classes. This allows, therefore, for a metal-insulator transition. This transition is of the Kosterlitz-Thouless type and has a topological origin in terms of creation of vortex excitations which are responsible for the insulating phase [\[35\]](#page-9-0).

Chirality is, however, broken as soon as  $\mu \neq 0$ , and the properties of the system are determined by class A or AI. This explains, at least qualitatively, why the states have to be localized for the nonchiral cases considered in this work.

## **B. Numerical results**

As we have seen, we have at our disposal a system Hamiltonian [\(5\)](#page-2-0) where the parameters can be tuned such that four different symmetry classes can be explored. The great flexibility of the model compared to earlier studies of localization in cold-atom settings is the multispecies structure. Thus, in the limit of large chemical potential  $\mu = |\mu_a - \mu_b|/2$ (when one species is almost completely unpopulated) we recover the standard scenario of the Anderson model which has served as a theoretical model of most disordered cold-atom experiments  $[6,15,16,21]$ . We should mention that even in the absence of interactions, as is the model studied here, the conclusions drawn from the numerical results should be taken with care; the system is unavoidably finite, and as soon as the localization length becomes comparable to the system size, boundary effects play an important role. For this reason, the metal-insulator transition, conjectured to happen for  $E = 0$ , has not been verified numerically, for example.

#### *1. Localization properties*

A measure of localization is the inverse partition ratio [\[9\]](#page-8-0)

$$
I(E) = \sum_{\mathbf{i}, \mathbf{j}} |\psi_E(\mathbf{i}, \mathbf{j})|^4,\tag{16}
$$

where  $\psi_E(\mathbf{i}, \mathbf{j})$  is an eigenstate with energy *E*. This is considered in the real-space basis;  $I = N^{-1}$  for a maximally delocalized state, with *N* being the dimension of the Hilbert space, and  $I = 1$  for a maximally localized state. We conclude therefore that if  $I \sim N^{-1}$ , the localization length exceeds the system size *L* (which in our case is the number of sites in one of the directions), and we expect *I* to drop as we approach the negative tail of the spectrum. As taken here, *I* is the second power of the particle density, i.e.,  $\sum_{i,j} \rho_E^q(i,j)$ , with  $\rho_E(\mathbf{i}, \mathbf{j}) = |\psi_E(\mathbf{i}, \mathbf{j})|^2$  and  $q = 2$ . Other powers of *q* might also be relevant in connection with multifractal properties of the wave function, which have been thoroughly discussed in terms of the Anderson metal-insulator transition [\[9](#page-8-0)[,36\]](#page-9-0). In general, for given *q* one finds a scaling  $L^{\tau(q)}$ , where  $\tau(q)$  is a *q*- and dimension-dependent exponent, but such considerations have been left out of the present study.

Figure 2 shows *I* for the ground state of the four different symmetry classes as a function of the disorder strength *ζ* . By comparing the models preserving or not preserving timereversal symmetry and chiral with nonchiral ones, that is, BDI with AI and AIII with A, we notice that in the nonchiral classes A and AI, localization sets in later than in the chiral classes BDI and AIII in terms of the disorder strength. This result can

FIG. 2. (Color online) The inverse partition ratio *I* (16) for the ground state of the Hamiltonian [\(5\)](#page-2-0) averaged over 100 disorder realizations in a  $30 \times 30$  lattice. This size of the lattice is chosen from its relevance for experiments, and throughout this work we use periodic boundary conditions. The parameters are  $t = 1$ ,  $\mu =$  $(\mu_a - \mu_b)/2 = 2$ , and  $\xi = \infty$ , and the dotted lines display *I* for the species *b* atoms (clearly, in the chiral classes *I* are identical for species *a* and *b*). As is seen, localization sets in at weaker disorder strengths for the chiral models in the ground state and also for the low-lying excitations (not shown). As explained in the text, this result can be understood from an effective model for the nonchiral classes, which contains an inherent long-range (exponential) hopping.

be understood by considering Hamiltonian [\(5\)](#page-2-0) in the regime of  $|\mu| \gg |t|$ ,  $|h_i|$  such that the two species can be effectively decoupled. In doing so and integrating out over one of the species, the effective Hamiltonian describing the other one contains a tunneling term that is long range. More precisely, the equations of motion for the atomic operators, given  $(5)$ , obey

$$
\partial_t \hat{a}_{\mathbf{i}} = -ih_{\mathbf{i}} \hat{b}_{\mathbf{i}} - i \mu_a \hat{a}_{\mathbf{i}} + it \sum_{\mathbf{j}} \hat{a}_{\mathbf{j}},
$$
  

$$
\partial_t \hat{b}_{\mathbf{i}} = -ih_{\mathbf{i}} \hat{a}_{\mathbf{i}} - i \mu_b \hat{b}_{\mathbf{i}} + it \sum_{\mathbf{j}} \hat{b}_{\mathbf{j}}.
$$
 (17)

Here, the sum  $\sum_{j}$  is over the nearest neighbors to site **i**. Let us assume that  $\mu_a$  has the largest amplitude of all the parameters, and in this situations we set  $\partial_t \hat{a}_i = 0$ . In vector notation, the steady-state solution for species *a* can be written  $\hat{\mathbf{a}} = \mathbf{M}^{-1} \mathbf{h} \hat{\mathbf{b}}$ , with **h** being a diagonal matrix with diagonal elements *h***<sup>i</sup>** and **M** being a tight-binding matrix with −*t* as the tunneling strength and  $\mu_a$  on the diagonal. Inserting the steady-state solution of  $\hat{a}_i$  into the second equation in (17), it directly follows that the species *a* atoms induce an effective longrange hopping of the species *b* ones. If  $|\mu_a| < |t|$ , the effective hopping has infinite range, while for  $|\mu_a| > |t|$  it falls off as  $(t/\mu_a)^{-|\mathbf{i}-\mathbf{j}|}$ . Notice, however, that this procedure is consistent only with the second case  $(|\mu_a| > |t|)$  since it relies on the adiabatic assumption  $\partial_t \hat{a}_i \equiv 0$ . An alternative derivation using the path-integral formalism of the above result can be found in Ref. [\[37\]](#page-9-0). The effective long-range hopping counteracts localization, and since the hopping is exponential in this model provided that  $|\mu_a| > |t|$ , we still expect localization to set in but for stronger disorder [\[38\]](#page-9-0).

<span id="page-5-0"></span>

FIG. 3. (Color online) The inverse partition ratio  $I(E)$  [\(16\)](#page-4-0) as a function of the energy. Like in Fig. [2,](#page-4-0) *I* for the species *b* atoms are marked by dotted lines. As argued in Sec. [III A,](#page-3-0) the localization length grows as the energy  $|E|$  is decreased. The flattening of *I* is a result of the localization length *λ*, which becomes comparable to or longer than the system size  $L (L = 30$  for the lattice used here). The parameters are the same as those of Fig. [2,](#page-4-0) with the disorder strength  $h = 10$ ; that is, the low-energy states are well localized.

We have just shown that for nonchiral classes it is possible to think of the second species as generating an effective longrange hopping. But what about the chiral classes? For class BDI, direct inspection of Eq. [\(8\)](#page-2-0) shows that there exists a simple (disorder-independent) localized basis where the model is, indeed, of short-range character in terms of hopping. For class AIII this is not as clear, however, since there is neither spatially independent transformation decoupling the species in this case nor a scale separation allowing for the derivation of an effective model.

Let us now turn to localization of the excited states. As we discussed in the previous section, field-theory methods have shown that the localization length  $\lambda$  may diverge at  $E = 0$  in the chiral classes. For small but nonzero  $|E|$ ,  $\lambda$  is always finite, such that the states are localized, although possibly with a long localization length. A numerical check of Eq. [\(15\)](#page-3-0) would require a system size *L* far beyond what is computationally achieved for our system. Indeed, as we see, even for energies not too close to  $E = 0$  the localization length  $\lambda \sim L$ . When this happens,  $I \sim N^{-1}$ . The energy dependence of *I* for the four classes is displayed in Fig. 3. The ground and first excited states are clearly localized, but localization is quickly lost as the energy increases. The delocalized states appear more pronounced in the A and AIII models in which time-reversal symmetry is broken. In these cases, the localization length becomes comparable to the system size already for the 100th excited state (the total number of states is 1800). Closer to  $E = 0$ , *I* increases again, in contrast to what is analytically predicted in  $(15)$ . We should point out, however, that Eq.  $(15)$ is obtained from an effective field theory that is valid only in the vicinity of  $E = 0$  and for infinite systems. As for the ground state (see Fig. [2\)](#page-4-0), localization is more pronounced in the models with chiral symmetry. It is tempting to argue that this is again a result deriving from the effective long-range hopping in these models. While this might be true, it should be noted that the population imbalance between the species

is decreased for higher energies (still in the lower half of the spectrum), and for states at the center of the spectrum the two species are approximately equally populated.

### *2. Properties of excited states*

Many fewer analytical results are available to describe the system away from the center of the spectrum. In systems of cold atoms, with high control of state preparation and of system parameters, it is possible to study out-of-equilibrium dynamics following a quantum quench (see, for example,  $[39]$ ). By preparing an initial, nonstationary state with a given energy  $\varepsilon > E_0$ , where  $E_0$  is the system ground-state energy, and by properly adjusting the quench, the "energy window" scanned by the initial state could be made narrow  $[40]$ , and thereby properties of the excited states could be probed.

The last term with the Raman coupling in Eq. [\(5\)](#page-2-0) favors an on-site phase locking between the two species that is determined by the field phase  $\varphi_i$ . Thus, if we are interested in the ground state and label it as

$$
|\psi_0\rangle = \begin{bmatrix} c_{ai} \\ c_{bi} \end{bmatrix},\tag{18}
$$

where  $c_{\alpha i}$  ( $\alpha = a, b$ ) is a vector indexed by the site subscript **i**, then it follows that the energy of the coupling term is minimized whenever  $\phi_i \equiv \text{angle}[c_{ai}^*c_{bi}] = -\varphi_i + (2n+1)\pi$ for any integer *n*. In the classes with time-reversal symmetry, BDI and AI,  $\varphi_i$  is zero or  $\pi$ , and the relative phase  $\varphi_i$  is an integer multiple of  $\pi$  at every site. Thus, the coefficients  $c_{ai}$ and  $c_{bi}$  will be real but may change sign (which also follows from the fact that the Hamiltonian is real and symmetric). Furthermore, in the chiral class BDI,  $\phi_i$  is independent of the site index **i**, and according to Eq. [\(8\)](#page-2-0), the eigenstates are found in either the *c* or the *d* subspaces. In the other two classes, AIII and A, the phase  $\varphi_i$  can be anything, and consequently, so can the relative phase  $\phi_i$ . Of course, the above picture is much simplified; whenever the phase  $\phi_i$  varies, there is an additional cost of kinetic energy (this will be further discussed in the next section). Nevertheless, by combining the knowledge of the kinetic and coupling terms it is possible to determine qualitative properties of the excitations in the different models.

In the classes with time-reversal symmetry, the Hamiltonian is real, and the eigenstates can always be chosen to be real. In other words, we can restrict the relative phase  $\phi_i$  to only integer multiples of  $\pi$ . The kinetic term is minimized if  $\phi_i = 0$ or  $\phi_i = \pi$  for all **i**'s. In class BDI this means that  $\phi_i$  has to be constant throughout the lattice, as a consequence of the decoupling of the species. This does not mean, however, that the phases of the individual species, i.e., of  $c_{a\mathbf{i}}$  and  $c_{b\mathbf{i}}$ , do not change between zero and *π*. Whenever this occurs, it creates a domain wall in the wave function of the species in question. This implies an additional kinetic-energy cost which is proportional to the length of the domain wall. Thus, we expect the domain wall to become longer for more excited states. This holds true only for not too highly excited states, as we explain below.

For classes AIII and A, the Hamiltonian is Hermitian, and therefore, its eigenstates are, in general, complex valued. Due to the kinetic-energy cost, we expect the phase of the wave functions to vary smoothly between nearby sites. However,

FIG. 4. (Color online) The individual phase for species *a* (i.e., the phase of the coefficients  $c_{a\textbf{i}}$ ) for the 20th excited state for classes (a) BDI and (b) AIII and for a single disorder realization. In BDI the Hamiltonian is real, and the only allowed excitations are domain walls, while in AIII the eigenstates are complex and vortices are typically formed (see circles demonstrating the winding of a vortex and an antivortex). The parameters are  $t = 1$ ,  $\mu = 0$ ,  $\zeta = 0.4$ , and  $\xi = \infty$  in a 40 × 40 lattice.

since the phase is defined modulo  $2\pi$ , the single-valuedness of the wave function is still preserved for the  $2\pi$  phase jumps or in the presence of vortices (except at the vortex core were the phase is ill defined and the density vanishes). The phase may thus contain branch cuts with a singularity at the ends of the cut, which reflects the vanishing density and the presence of vortices. In analogy with the cases with domain walls, we expect a larger number of vortices to appear higher up in the spectrum. In addition, since we consider finite lattices with periodic boundary conditions, any branch cut has two ends (unless it closes itself), and as a result a vortex is always accompanied by an antivortex. However, if the state is localized, the vortex and the antivortex might not both be within the region of nonzero particle density. The implication for experiments is the possibility of having only one of the vortices detected.

These conclusions are confirmed in Fig. 4, which shows one example of a single species' phase for classes BDI and AIII. The first case displays a domain-wall structure, while the appearance of vortices characterizes the second case. Under periodic boundary conditions, the domain walls are forced to close. We have indeed seen that the number of vortices and the length of the domain wall depend on the excitation energy as expected (we focus on energies  $E < 0$ ). We did not find, however, any particular relation that describes the increase in the number of vortices or domain walls as one goes up in the spectrum. Notice, in addition, that this increase in the number of vortices and in the length of the domain walls will only continue until roughly the center of the spectrum. As mentioned above, this follows from the fact that in the chiral classes an eigenstate  $\psi_E$  with energy *E* has a companion state  $\psi_{-E} = \hat{U} \psi_E$  with energy  $-E$ , where  $\hat{U}$  is the operator given in Eq. [\(9\)](#page-2-0). This operator shifts the sign of the state on every second site. Therefore, if, say, the phase of  $\psi_{-E}$  is smooth and positive (or negative), the phase of  $\psi_E$  will have a checkerboard structure. In class AIII we have also checked that all the vortices are characterized by a winding number of 1 and that no vortices with higher angular momentum are formed.

In experiments, we expect the vortices or domain walls to appear after a quench in the system. The vortices should be visible via time-of-flight and absorption detection techniques

FIG. 5. (Color online) (a) and (b) The densities and (c) and (d) the phases for the ground-state wave function in the nonchiral class A. As explained in the main text, the dominant species experiences a weaker effective disorder, and its density thereby has a smooth envelope, and its phase become constant, while the other species feels a strong effective disorder and its wave function then adjusts accordingly. The parameters are the same as for Fig. 4, except  $\mu = 0.4$ .

like in standard experiments [\[41\]](#page-9-0). In order to single out vortices in only one of the atomic species, one can also envision statedependent detection. Likewise, the domain walls could be probed with the same methods; in a time-of-flight detection, a domain wall will, for example, be manifested as a zero-density cut in the momentum distribution.

For the above discussion of excited states we considered the chiral classes for which species *a* and *b* are equally populated. For the nonchiral classes, A and AI, this equal balance is lost, and for the low-lying energy states the species with the smallest chemical potential (we have defined the chemical potential as a positive energy cost) will dominate. As can be understood from the equations of motion  $(17)$ , this imbalance has a direct consequence on the structure of the states. If, say,  $\mu_a > \mu_b \geq 0$ and as long as the energy is not too big, mainly species *b* will be populated;  $||\hat{a}_i|| < ||\hat{b}_i||$ . Since the amount of disorder felt by one species is related to the population of the states of the other species, it follows that the atom of the *b* type will experience a weak disorder, while the atoms populating the species *a* states experience a strong disorder (in comparison to the tunneling part). In Eq.  $(17)$  this is seen from the fact that the first terms on the right-hand side are large in the first equation and small in the second equation. As a consequence, the wave function for species *b* will minimize the kinetic energy, and its density will be smooth. The wave function for species *a*, on the other hand, will minimize the disordered part, and the density and phase will show large fluctuations. This is displayed in Fig. 5, where we plot the ground-state densities and phases of both species. Higher up in the spectrum, the species with the higher chemical potential get more populated, and excitations then appear to partly excite the "internal" structure characterized by the two species. Finally, the situation is reversed in the highest excited states, and the population predominantly occupies the species *a* states. In addition, in the same way as for the chiral

<span id="page-7-0"></span>classes, the excitations in the classes where chiral symmetry is broken will also appear in the form of vortices and/or domain walls.

## **C. Random-field-induced order vs localization**

The phenomenon known as the random-field-induced order refers to the ability of certain systems to order only in the presence of a random field of a certain kind. This is the case when a clean system with a continuous symmetry in two dimensions, for example, is forbidden to order due to the restrictions of the Mermin-Wagner theorem [\[12\]](#page-8-0), and then, after inclusion of a random field with discrete symmetry, the system does not fulfill the assumptions under which the theorem is valid, such that order is, in principle, not precluded. This has been proven to happen in the classical *XY* model [\[13\]](#page-8-0) and has also been suggested as the mechanism of order in graphene quantum Hall ferromagnets [\[42\]](#page-9-0).

In the RFIO, order appears in a particular way: In the ferromagnetic *XY* model in two dimensions, for example, the inclusion of a random field in the *x* component of the spin will induce a ferromagnetic state with long-range order, but in the direction perpendicular to that of the field. In this case, the expectation value is finite for magnetization in the *y* component. This can be understood from an intuitive argument, that the system minimizes the energetic cost of the random field by orienting all the spins in a direction in which the field exerts minimal influence, therefore the perpendicular choice [\[42\]](#page-9-0). But despite the activity during the last years in the study of RFIO, the mechanisms allowing for such phenomena are still not fully understood. A step in this direction, however, has been taken in [\[13\]](#page-8-0), where the occurrence of RFIO in the 2D *XY* model has been suggested in connection with the Anderson localization of spin waves.

This phenomenon has also been shown to happen in interacting systems of two-species Bose-Einstein condensates that are randomly coupled by a real-valued Raman field [\[14\]](#page-8-0). Here, RFIO appears as a  $\pi/2$  phase locking between the two species, and an experimental setup for observation has been proposed. Motivated by this, we have investigated Eq. [\(5\)](#page-2-0) in the context of the RFIO. The advantage of the noninteracting system over the interacting one is the possibility of a direct check of localization properties in all the excited states. Therefore, in analogy to the system studied in  $[14]$ , we expected RFIO to appear as a phase locking between the two species in the system of class BDI, and following this reasoning, localization of the excitations should exhibit a different behavior from what was observed in the system of class AIII, where the random Raman coupling only magnifies effects of the continuous symmetry.

As we discussed in Sec. [III B 2,](#page-5-0) all the states of the chiral class BDI have a homogeneous phase locking, whereas this does not happens in class AIII. This phase locking, however, does not seem to be a manifestation of the RFIO. First, because Eq. [\(8\)](#page-2-0) is always real, there is no reason for the appearance of a  $\pi/2$  relative phase. Second, because the relative phase is always locked (at random) at zero or  $\pi$ , a  $\pi/2$  relative phase would be only the result of averaging and therefore would not be relevant for experiments with single disorder realizations. In addition, since all low-lying states are localized in both

class BDI and class AIII, the existence of phase coherence in BDI does not seem to have any relation to the localization of the excitations. This means that even if the homogeneous phase could be a manifestation of the RFIO, which appears in a particular and still unidentified way for the system discussed here [see Eq. (5) in [\[14\]](#page-8-0)], it would nevertheless be unrelated to the localization of the low-lying excited states in this case.

The close relation between the present lattice model and the continuum model of Ref. [\[14\]](#page-8-0) and the fact that we do not find the expected signatures of RFIO suggest that interaction may play a crucial role for the appearance of RFIO. This would have direct consequences on the hypothesis that a better understanding of localization of the excitations could also explain the origin of RFIO. In fact, the mechanisms behind localization in single-particle or interacting many-particle systems are very different. Anderson localization can be understood from interfering loops in configuration space, and in particular, the loops may be very long. In an interacting system, the destructive interference processes occur instead in a hypercubic lattice, and the loops are typically extremely short [\[43\]](#page-9-0). Our results illustrate once again [\[13\]](#page-8-0) that the mechanisms allowing for the phenomenon of RFIO constitute a very interesting open question.

## **IV. CONCLUSION**

In this work we studied a model consisting of two species in a square optical lattice. The two species represent internal atomic Zeeman levels that are Raman coupled with an amplitude *h***<sup>i</sup>** which randomly varies between the sites. The disorder resulting from the Raman coupling tends to localize the eigenstates of the system. However, the properties of the states depend strongly on the symmetry class of the model. In particular we showed that with this simple model it is possible to realize four different symmetry classes. In terms of the localization, two of them, the chiral ones, are especially interesting since they may support a transition to a metallic phase in the center of the spectrum. Strictly speaking, the metallic state should only appear at zero energy, but since the system always has a finite size, a metallic-looking phase should also appear at nonzero energies. Experimentally, such extended states could be studied after a quench where an initially localized state is prepared with an energy close to zero; if the system is metallic, then one should see an everlasting diffusion of the density, while in the Anderson insulating phase the diffusion is rapidly hindered following a short expansion.

Properties of the symmetry classes are also reflected in the sort of excitations. We found that excitations can be characterized as either domain walls or vortices depending on whether the Hamiltonian is purely real or complex. It should be noticed that these results only occur due to the two-species structure of the problem and that similar excitations cannot occur in models with only one species. We also argued that both the vortices and the domain walls should be verifiable in time-of-flight measurements following a quench of the system, and we concluded with a discussion on the phenomenon of the RFIO.

With the newly developed transport experiments with cold atoms [\[44\]](#page-9-0), using two atomic reservoirs with different chemical potentials, one should be able to explore the unique

<span id="page-8-0"></span>properties of chiral models in the vicinity of  $E = 0$ . In particular, the scattering of the particle current as a function of energy should behave qualitatively different for chiral and nonchiral models at  $E = 0$  [\[45\]](#page-9-0). This might become even more relevant for topological models, for example, a 1D system hosting Majorana modes [\[46\]](#page-9-0) that has gained enormous attention lately.

As a final remark, we notice that the present model could be easily extended to other situations, for example, to include more species (internal electronic levels), different lattice geometries and dimensions, and atom-atom interaction. These ideas could also be explored to engineer systems in class CII by using four-level atoms, were the levels are coupled to yield two species, *a* and *b*, both with an intrinsic spin-1*/*2 structure. Probably most interesting, however, would be to

consider the present model in the presence of interactions. How to characterize interacting systems in the topological periodic table is a very open question, and here, experiments might provide valuable information for understanding the new physics.

### **ACKNOWLEDGMENTS**

D. Bagrets and A. Altland are thanked for helpful discussions about the chiral symmetry classes. M. Lewenstein is thanked for bringing up the idea about RFIO in the present model. The authors acknowledge financial support from VR-Vetenskapsrådet (the Swedish Research Council). J.L. acknowledges KAW (the Knut and Alice Wallenberg Foundation), and F.P. thanks ICFO, where part of this research was developed, for its hospitality.
