(Received 5 September 2017; published 29 January 2018)

We use a slave-rotor approach within a mean-field theory to study the competition of metallic, Mott-insulating, and superconducting phases of spin-3*/*2 fermions subjected to a periodic optical lattice potential. In addition to the metallic, the Mott-insulating, and the superconducting phases that are associated with the gauge symmetry breaking of the spinon field, we identify an emerging superconducting phase that breaks both roton and spinon field gauge symmetries. This superconducting phase emerges as a result of the competition between spin-0 singlet and spin-2 quintet interaction channels naturally available for spin-3*/*2 systems. The two superconducting phases can be distinguished from each other by quasiparticle weight. We further discuss the properties of these phases for both two-dimensional square and three-dimensional cubic lattices at zero and finite temperatures.

I. INTRODUCTION

Recent extraordinary progress achieved in trapping and manipulating ultracold atomic gases provides a wonderful opportunity for exploring quantum many-body physics. Ultracold atomic systems are now considered as one of the most promising and efficient playgrounds for studying condensed matter and nuclear physics phenomena [\[1\]](#page-7-0). Recent developments in laser technology and experimental advancements allow one to have unprecedented control over various experimental parameters [\[2\]](#page-7-0). Effective spatial dimensionality, lattice structure, and lattice geometry can be tuned by adjusting the laser intensity, phase, and wavelength. The interaction between the atoms can be controlled dramatically by adjusting the twobody scattering length through magnetically tuned Feshbach resonance. Through the first generation of experiments with ultracold bosons and fermions in optical lattices, it has been well established that these systems can exhibit a variety of interesting phenomena [\[3–8\]](#page-7-0). The growing availability of multicomponent degenerate fermionic atoms, such as ⁶Li $[9-11]$, 40 K [\[12\]](#page-7-0), 135 Ba and 137 Ba [\[13\]](#page-7-0), and 173 Yb [\[14\]](#page-7-0) provides a controllable platform to study higher spin, strongly correlated physics that features novel phenomena.

Among multicomponent ultracold gases, high spin fermions such as spin- $3/2$ ^{132}Cs , ^{9}Ba , ^{135}Ba , and ^{201}Hg attracted much attention due to the rich collective phenomena they can exhibit [\[15–26\]](#page-7-0). Spin-3*/*2 systems are expected to show emerging behavior due to the competing parameters, such as total spin-0 singlet and spin-2 quintet scattering lengths. The total spin-1 and spin-3 channels are prohibited due to the Pauli exclusion principle. In addition, the strong quantum fluctuations due to the enlarged $SO(5)$ or $Sp(4)$ symmetry is expected to play a bigger role in these systems [\[27,28\]](#page-7-0). In particular, when these spin-3*/*2 atoms are subjected to a periodic lattice potential, they can show novel collective behavior that is not obvious in spin-1*/*2 electronic systems. For example, on-site four-particle clustering instabilities can leads to quintet Cooper pairing favored by the spin-2 interaction channel [\[29–34\]](#page-7-0). When the total spin-0 interaction channel is strongly positive, the system can leads to a Mott-insulating state with a fixed number of atoms on each lattice site. It is the purpose of this paper to study the competition and phase transitions among metal, Mott-insulating, and singlet Cooper pairing states of neutral spin-3*/*2 fermions subjected to a two-dimensional square lattice and a three-dimensional cubic lattice. In order to do so, we use a slave-rotor approach that allows us to handle the intermediate-coupling regime where the charge fluctuations are strong [\[35\]](#page-7-0). In the slaverotor representation, the particle operator is decomposed into a roton-bosonic field and a spinon-fermionic field. While the roton caries the charge degrees of freedom, the spinon caries the spin degrees of freedom. In this approach, the metal and Mott-insulating phases are characterized by breaking of global U(1) gauge symmetry associated with the charge degrees of freedom. In general, the superconducting phase is characterized by breaking of global U(1) symmetry associated with the spinon degrees of freedom.

In addition to the obvious metal, Mott-insulator, and conventional (in the sense that one gauge symmetry is broken) superconducting phases arising from the competing interactions, we find an emerging superconducting phase where both global symmetries associated with charge and spin degrees of freedom are broken. This superconducting phase is differentiated from the conventional superconducting phase due to the nonzero quasiparticle weight. Notice that we use the condensed matter terminology, but our metal and superconducting phases are neutral for atoms in optical lattices. Further, we investigate each of these emerging phases at both zero temperature and finite temperature by calculating various physical quantities.

The paper is organized as follows. In Sec. [II,](#page-1-0) we introduce a spin-3*/*2 model Hamiltonian for atoms on an optical lattice. The model is a generalized Hubbard model based on microscopic *s*-wave atom-atom interactions. In Sec. III, we introduce the slave-rotor approach and convert our model Hamiltonian into a coupled rotor-spinon Hamiltonian. In Sec. [IV,](#page-2-0) a decoupling scheme is introduced to decouple the rotor part and the spinon part of the Hamiltonian. In Secs. [V](#page-2-0) and [VI,](#page-3-0) we use a mean-field treatment to solve the rotor and spinon sectors of the Hamiltonian. In Secs. [VII](#page-3-0) and [VIII,](#page-5-0) we discuss our zero-temperature and finite-temperature formalism and their results. In Sec. [IX,](#page-5-0) we summarize and discuss our results.

II. MODEL HAMILTONIAN

We start with the generic form of the spin-3*/*2 neutralparticle Hamiltonian of the lattice model [\[27\]](#page-7-0)

$$
H = -t \sum_{\langle ij \rangle} (c_{i\sigma}^{\dagger} c_{j\sigma} + \text{H.c.}) - \mu \sum_{i\sigma} c_{i\sigma}^{\dagger} c_{i\sigma} + U_0 \sum_{i} P_{00}^{\dagger}(i)
$$

$$
\times P_{00}(i) + U_2 \sum_{i,m=\pm 2,\pm 1,0} P_{2m}^{\dagger}(i) P_{2m}(i), \tag{1}
$$

where $P_{Fm}^{\dagger}(i) = \sum_{\alpha\beta} \langle F, m | \alpha, \beta \rangle c_{i\alpha}^{\dagger} c_{i\beta}^{\dagger}$ are the singlet (*F* = $0,m = 0$) and quintet $(F = 2,m)$ pairing operators and $c_{i,\sigma}^{\dagger}$ is the fermionic creation operator at site i , in one of the hyperfine spin states $\sigma = \pm 1/2, \pm 3/2$. Here

$$
U_s = \int d\vec{r} d\vec{r}' w^* (\vec{r} - \vec{R}_i) w^* (\vec{r}' - \vec{R}_i)
$$

× $g_s w (\vec{r}' - \vec{R}_i) w (\vec{r} - \vec{R}_i)$ (2)

is the interaction parameter for the total spin $S = 0$ and $S = 2$ channels with the contact interaction in free space $g_s = 4\pi \hbar^2 a_s/m$ and localized Wannier functions $w(\vec{r} - \vec{R}_i)$ at \dot{R}_i , where a_s is the *s*-wave scattering length for the total spin-*S* channel. At half filling (i.e., on average one atom per site), the particle-hole symmetry ensures the chemical potential $\mu = (U_0 + 5U_2)/4$ [\[27\]](#page-7-0). Here we assume that the atoms can hop between nearest neighbors with hopping amplitude *t*, where $\langle ij \rangle$ stands for the sum over only nearest neighbors.

For the purpose of studying the phase transition of metallic, insulating, and superconducting phases, it is convenient to rewrite the Hamiltonian in terms of the spin-3*/*2 on-site singlet operator $P_i^{\dagger} \equiv P_{00}^{\dagger}(i) = 1/\sqrt{2}(c_{i,3/2}^{\dagger}c_{i,-3/2}^{\dagger} - c_{i,1/2}^{\dagger}c_{i,-1/2}^{\dagger})$ and the on-site density operator $n_i = \sum_{\sigma} c_{i\sigma}^{\dagger} c_{i\sigma}$ [\[36\]](#page-7-0),

$$
H = -t \sum_{\langle ij \rangle} (c_{i\sigma}^{\dagger} c_{j\sigma} + \text{H.c.}) - \mu_0 \sum_{i\sigma} c_{i\sigma}^{\dagger} c_{i\sigma}
$$

$$
+ \frac{U}{2} \sum_{i} \left(\sum_{\sigma} c_{i\sigma}^{\dagger} c_{i\sigma} - 4/2 \right)^2 + V \sum_{i} P_{i}^{\dagger} P_{i}. \quad (3)
$$

Here $U = 2U_2$ and $V = U_0 - U_2$ with the shifted chemical potential μ_0 given by $(U_0 - U_2)/4$ at half filling. This model has an exact SO(5) symmetry which reduces to an SU(4) symmetry at $U_0 = U_2$ [\[16,27\]](#page-7-0). Notice that at this SU(4) symmetric limit, the chemical potential at half filling reaches zero. Each major terms in the model competes for metallic, Mott-insulating, and singlet pairing states. At the SU(4) limit and for interactions that are weak compared to the tunneling energy $U \ll t$, atoms can gain kinetic energy by hopping through the lattice. In the opposite limit where $U \gg t$, the repulsion is greater than

the gain in kinetic energy, thus the atoms will localize at lattice sites, resulting in a Mott insulator. For $V < 0$, the model naturally favors the singlet pairing state while the first two terms compete for metallic and Mott-insulating states, respectively. In addition to the singlet pairing, as discussed in Ref. [\[25\]](#page-7-0), multiparticle clustering of spin-3*/*2 atoms can lead to quintet pairing states with a total spin 2. The quintet pairing requires a negative quintet interaction parameter *U*2. Here we consider a positive U_2 that supports Mott-insulating states, therefore we can safely neglect the possible quintet pairing in the model.

For deep optical lattices, one can approximate the Wannier functions by the Gaussian ground state in the local oscillator potential and find that the tunneling amplitude $t \propto$ $E_r V_r^{3/4} e^{-2\sqrt{V_r}}$ is exponentially sensitive to the laser intensity $V_0 = E_r V_r$ that was used to create the optical lattice; here E_r is the recoil energy [\[37\]](#page-7-0). The interaction term $U_s \propto a_s E_r V_r^{3/4}$ is linearly sensitive to scattering lengths and relatively weakly sensitive to the laser intensity. As a result, the model is highly tunable in experimental setups in optical lattice environments.

III. SLAVE-ROTOR APPROACH

Slave-particle approaches are proven to be simple and computationally inexpensive approaches to study strongly correlated effects in many-particle systems and these approaches are capable of accounting for particle correlations beyond standard mean-field theories. The first slave-particle approach was proposed to study the Mott-insulator–metal transitions [\[38\]](#page-7-0). There are several advantages of using slaveparticle approaches over other mean-field theories and variational methods. While most variational approaches are valid only at zero temperature, the slave-particle approaches are applicable at both zero and finite temperatures. Unlike other mean-field theories, quantum fluctuations can be taken into account by the Stratonovich-Hubbard transformation within the slave-particle formalism [\[39\]](#page-7-0). Further, it has been shown that slave-particle approaches are equivalent to a statistically consistent Gutzwiller approximation [\[40–42\]](#page-7-0). Here we use the slave-rotor approach as it is convenient for many component systems [\[35\]](#page-7-0). The method is simply to introduce an auxiliary boson to represent the local degrees of freedom in the correlated system. The metallic solution will be described as a correlated Fermi liquid. In the slave-rotor approach, the original local Fock space of the problem is mapped onto a larger local Fock space that contains as many fermions degrees of freedom as the original one and the same number of spin-3*/*2 local quantum variables, one for each fermion. While a new pseudofermion variable describes the itinerant quasiparticle fraction of the atom, the auxiliary boson describes its localized fraction.

The slave-rotor approach was first introduced by Florens and Georges for the Hubbard model to study the metal–Mottinsulator transition [\[35\]](#page-7-0). Later this approach was applied to magnetic systems to study spin liquid phases [\[43–48\]](#page-7-0). In this approach, the particle operator is decoupled into fermion and bosonic rotors that carry the spin and the charge degrees of freedom, respectively. First, the particle operator $c_{i\sigma}$ that annihilates an atom with spin σ at site *i* is expressed as a product

$$
c_{i\sigma} = e^{-i\theta_i} f_{i\sigma}, \qquad (4)
$$

where the auxiliary fermion $f_{i\sigma}$ annihilates a spinon with spin σ and the local phase degree of freedom θ_i conjugates to the total (neutral) charge through the angular momentum operator $L_i = -i\partial/\partial\theta_i,$

$$
[\theta_i, L_j] = i\delta_{ij}.
$$
 (5)

In this representation, while the rotor operator $e^{-i\theta_i}$ reduces the site occupation by one unit, the eigenvalues of the L_i correspond to the possible number of atoms on the lattice site. Notice that the term angular momentum is used due to the conservation of the O(2) variable $\theta_i \in [0, 2\pi]$ but has nothing to do with the physical angular momentum of the atoms. Using the fact that rotons and spinons commute, one can show that the number operator of the physical particles coincides with that of the spinon,

$$
n_{i\sigma} = c_{i\sigma}^{\dagger} c_{i\sigma} = f_{i\sigma}^{\dagger} f_{i\sigma} = n_{i\sigma}^f.
$$
 (6)

As the eigenvalues of the angular momentum operator $l \in Z$ can have any integer values, one must impose a constraint to truncate the enlarged Hilbert space to remove unphysical states,

$$
L_i = \sum_{\sigma} n_{i\sigma}^f - 1. \tag{7}
$$

This constraint connects the charge and spin degrees of freedom and can be taken into account by introducing a Lagrange multiplier in the formalism. Notice that the angular momentum operator *Li* measures the particle number at each site relative to the half filling. In terms of new variables, our Hamiltonian in Eq. (3) becomes

$$
H = -t \sum_{\langle ij \rangle} f_{i\sigma}^{\dagger} f_{j\sigma} e^{i(\theta_i - \theta_j)} - (\mu_0 + h) \sum_{i\sigma} f_{i\sigma}^{\dagger} f_{i\sigma}
$$

$$
+ \frac{U}{2} \sum_{i} L_i^2 + +V \sum_{i} P_i^{\dagger} P_i, \tag{8}
$$

where pairing operators in the last term now has the form $P_i^{\dagger} = 1/\sqrt{2}(f_{i,3/2}^{\dagger}f_{i,-3/2}^{\dagger} - f_{i,1/2}^{\dagger}f_{i,-1/2}^{\dagger})e^{2i\theta_i}$. Notice that the constraint is treated on average so that the Lagrange multiplier *h* is site independent. Even though one interaction term in the $S = 2$ channel simply becomes the kinetic energy for the rotons, the pairing interaction term is still quartic and the hopping term now becomes quartic in spinon and rotor operators as well. In the following section, we make further approximations to the quartic terms to get a manageable theory.

IV. DECOUPLING SPINON AND ROTORS

For spin-3*/*2 atoms on square or cubic lattices at half filling, we plan to decouple the Hamiltonian in Eq. (8) by using a mean-field description. First, we decouple the hopping term so that the Hamiltonian *H* becomes the sum of independent spinon and rotor parts: $H \rightarrow H_f + H_\theta$. This will lead to the H_{θ} part being an interacting quantum *XY* model and the H_f part being an interacting *f* -particle spinon part. We will then make a second mean-field treatment for each part of the Hamiltonian to convert them into effectively noninteracting ones. At half filling, particle-hole symmetry requires the Lagrange

multiplier $h = 0$ and $\mu_0 = (U_0 - U_2)/4$. We introduce three mean fields as follows:

$$
\Delta = \frac{|V|}{2} \langle f_{i,3/2}^{\dagger} f_{i,-3/2}^{\dagger} - f_{i,1/2}^{\dagger} f_{i,-1/2}^{\dagger} \rangle_{f},
$$
(9)

$$
Q_{\theta} = \sum_{\sigma} \langle f_{i\sigma}^{\dagger} f_{j\sigma} \rangle_{f}, \qquad (10)
$$

$$
Q_f = \langle e^{i(\theta_i - \theta_j)} \rangle_\theta, \tag{11}
$$

where *i* and *j* are nearest-neighbor sites. The subscript *f* or *θ* means that the quantum and thermal expectation values must be taken with respect to the spinon and roton sectors, respectively. Here we make the assumptions that these expectation values are real and independent of bond directions. One can relax these assumptions and treat the orbital current around a plaquette. After performing the decoupling scheme, the spinon and rotor parts of the Hamiltonian become

$$
H_f = -tQ_f \sum_{\langle ij \rangle,\sigma} (f_{i\sigma}^{\dagger} f_{j\sigma} + \text{H.c.}) - \mu_0 \sum_{i\sigma} f_{i\sigma}^{\dagger} f_{i\sigma}
$$

+ $\Delta \sum_{i} (f_{i,3/2}^{\dagger} f_{i,-3/2}^{\dagger} - f_{i,1/2}^{\dagger} f_{i,-1/2}^{\dagger} + \text{H.c.}), (12)$

$$
H_{\theta} = -tQ_{\theta} \sum_{\langle ij \rangle} (X_i^{\dagger} X_j + \text{H.c.}) - \lambda \sum_{i} X_i^{\dagger} X_i
$$

- $\frac{1}{2U} \sum_{i} (i \partial_{\tau} X_i^{\dagger}) (-i \partial_{\tau} X_i),$ (13)

where $X_i = e^{i\theta_i}$ and λ is the Lagrange multiplier to impose the condition $|X_i|^2 = 1$. At the operator level, the Hamiltonian is now decoupled and while the spinon part is quadratic, the rotor part is naturally interacting. While the mean-field parameter Q_f renormalizes the hopping term and is related to the effective mass $m^* = mQ_f$, the expectation value of the pairing operator Δ represents the pairing of spinons.

V. MEAN-FIELD TREATMENT OF THE SPINON PART

The spinon part can easily be diagonalized in the momentum space. Performing a Fourier transform in momentum space and then the usual Bogoliubov transformation, the spinon Hamiltonian has the form

$$
H_f = \sum_{k,l} \Lambda_l(k) \eta_{k,l}^\dagger \eta_{k,l} + \frac{1}{2} \sum_{k,l} \left[A_{kk}^l - \Lambda_l(k) \right], \quad (14)
$$

where $\eta_{k,l}$ is a four-component vector representing quasispinons and $\Lambda_l(k) = \pm \sqrt{\epsilon_k^2 + \Delta^2}$ (twice) are the eigenvalues with $l = 1,2,3,4$. Here $A_{kk'}^l$ is a 4 × 4 diagonal matrix with the diagonal element $\epsilon_k = -Q_f \gamma_k - \mu_0$, where $\gamma_k =$ 2*t* \sum_{α} cos k_{α} with $\alpha = x, y, z$, and the lattice momentum is rescaled with the lattice constant. The quantum and thermal expectation values of Eq. (9) with respect to the Hamiltonian H_f lead to the gap equation

$$
\frac{4}{V} = -\frac{1}{N_s} \sum_{k} \frac{\tanh(\beta E_k/2)}{E_k},\tag{15}
$$

where $E_k = \sqrt{\epsilon_k^2 + \Delta^2}$ with the total number of lattice sites *Ns* and dimensionless inverse temperature *β*. Summing over nearest neighbors and then calculating the expectation value in Eq. [\(10\)](#page-2-0) with respect to H_f gives

$$
\eta t Q_{\theta} = \frac{1}{N_s} \sum_{k,\sigma} \gamma_k n_k, \qquad (16)
$$

where η is the number of nearest neighbors and the average occupation n_k is given by

$$
n_k = \frac{1}{2} - \frac{\epsilon_k}{2E_k} \tanh(\beta E_k/2). \tag{17}
$$

The two self-consistent equations derived in Eqs. (15) and (16) must be solved with Eq. [\(11\)](#page-2-0), which can be written as $Q_f =$ $\langle X_i^{\dagger} X_j \rangle_{\theta}$.

VI. MEAN-FIELD TREATMENT OF THE ROTON PART

The calculation of Q_f requires special attention as X bosons can undergo Bose-Einstein condensation. The metallic (or band-insulating) phase corresponds to the ordering of rotors and thus spontaneously breaks the O(2) symmetry. The rotor disordered phase corresponds to the Mott-insulating phase given that the system is nonsuperfluid. Note that the metal to Mott insulator transition is driven by spontaneous global U(1) symmetry associated with the charge degrees of freedom. However, the Mott transition emerging from the slave-rotor approach does not break any spin rotational symmetry, thus the transition is into a nonmagnetic phase.

The final self-consistent equation can easily be calculated using a functional integral approach to the roton part of the Hamiltonian with the constraint equation $|X_i|^2 = 1$. Introducing the rotor Green's function $G_{\theta}(k,\tau) = \langle X_k(\tau)X_k^{\dagger}(0) \rangle$, the constraint equation becomes

$$
\frac{1}{N_s} \sum_{k} \frac{1}{\beta} \sum_{n} G_{\theta}(k, i\nu_n) = 1,
$$
\n(18)

where $v_n = 2n\pi/\beta$ are the bosonic Matsubara frequencies. In a coherent-state path-integral representation, the rotor Green's function can be written as

$$
G_{\theta}(k,\tau) = \frac{\int \prod_{ki} \frac{dX_{ki}dX_{ki}^*}{2\pi i} X(\tau) X_k^*(0) e^{-S_{\theta}}}{\int \prod_{ki} \frac{dX_{ki}dX_{ki}^*}{2\pi i} e^{-S_{\theta}}},
$$
(19)

where the time index *i* labeling runs from 0 to ∞ , corresponding to $\tau = 0$ and $\tau = \beta$, respectively. The action in the momentum space associated with the rotor part of the Hamiltonian is given by

$$
S_{\theta} = \int_0^{\beta} d\tau \sum_k X_k^* \bigg(-\frac{1}{2U} \partial_{\tau}^2 - \lambda - Q_{\theta} \gamma_k \bigg) X_k. \tag{20}
$$

Following the standard path-integral formalism, the rotor Green's function for the nonzero wave vector is given by

$$
G_{\theta}(k, i\nu_n) = \left[\nu_n^2/U + \lambda - Q_{\theta}\gamma_k\right]^{-1}.
$$
 (21)

Note that, following Ref. [\[35\]](#page-7-0), a renormalization of $U \rightarrow U/2$ has been performed to preserve the exact atomic limit. Then

writing

1

$$
\frac{1}{\beta} \sum_{n} G_{\theta}(k, i\nu_{n}) = \frac{U}{\beta} \sum_{n} \frac{1}{i\nu_{n} + \sqrt{U(\lambda - Q_{\theta}\gamma_{k})}}
$$

$$
\times \frac{1}{-i\nu_{n} + \sqrt{U(\lambda - Q_{\theta}\gamma_{k})}}
$$
(22)

and performing a suitable contour integration, we find

$$
\frac{1}{\beta} \sum_{n} G_{\theta}(k, i\nu_{n}) = \frac{U}{2\sqrt{U(\lambda - Q_{\theta}\gamma_{k})}}
$$

$$
\times \coth\left(\frac{\beta}{2}\sqrt{U(\lambda - Q_{\theta}\gamma_{k})}\right). (23)
$$

Combining this with Eq. (18) and separating the $k = 0$ term leads to the constraint equation

$$
1 = Z + \frac{1}{2N_s} \sum_{k \neq 0} \sqrt{\frac{U}{\lambda - Q_\theta \gamma_k}}
$$

$$
\times \coth\left(\frac{\beta}{2} \sqrt{U(\lambda - Q_\theta \gamma_k)}\right), \tag{24}
$$

where $0 \leqslant Z \leqslant 1$ is the rotor condensate amplitude which represents the quasiparticle weight. As the rotor condensation indicates the transition into the metallic phase, a nonzero quasiparticle weight *Z* represents the metallic state. In the noninteracting limit $Z \rightarrow 1$. Finally, summing over nearest neighbors of Eq. [\(11\)](#page-2-0) and transforming into Fourier space leads to

$$
\eta t Q_f = \eta t Z + \frac{1}{N_s} \sum_{k \neq 0} \frac{\gamma_k}{\beta} \sum_n G_\theta(k, i\nu_n). \tag{25}
$$

Completing the contour integration, our final self-consistent equation becomes

$$
\eta t Q_f = \eta t Z - \frac{1}{2N_s} \sum_{k \neq 0} \gamma_k \sqrt{\frac{U}{\lambda - Q_\theta \gamma_k}}
$$

$$
\times \coth\left(\frac{\beta}{2} \sqrt{U(\lambda - Q_\theta \gamma_k)}\right). \tag{26}
$$

This Q_f is the mass enhancement factor of the quasiparticle, thus it is proportional to the effective mass of the quasiparticle $m^* = Q_f m$, where *m* is the bare mass of the free atoms. As the second term in Eq. (26) is negative, mass enhancement is always greater than the quasiparticle weight, $Q_f > Z$ at the saddle point level, and remains finite even away from the metallic phase where *Z* vanishes.

VII. ZERO-TEMPERATURE FORMALISM AND QUANTUM PHASE TRANSITIONS

For spin-3*/*2 atoms on a *d*-dimensional lattice at zero temperature, four self-consistent equations can be largely simplified. First, by introducing the *d*-dimensional density of states $D(\epsilon) = \frac{1}{N_s} \int \frac{d^d k}{(2\pi)^d} \delta(\epsilon + \gamma_k)$ and setting energy units to

FIG. 1. Zero-temperature phase diagram showing four different phases: M, metallic phase; MI, Mott-insulating phase; Z-SC, superconducting phase with nonzero quasiparticle weight; and SC, superconducting phase with zero quasiparticle weight. (a) Phase diagram for the two-dimensional square lattice. (b) Phase diagram for the three-dimensional cubic lattice. The metal phase is characterized by a global U(1) symmetry-broken state associated with the rotor degrees of freedom and both superconducting phases (SC and Z-SC) are characterized by the global U(1) symmetry-broken states associated with the spinon degrees of freedom. The Z-SC phase shows additional U(1) symmetry breaking associated with the rotor sector.

be $t = 1$, our self-consistent equations become

$$
\frac{4}{V} = -\int d\epsilon \, D(\epsilon) \frac{1}{\sqrt{(Q_f \epsilon - \mu_0)^2 + \Delta^2}},\tag{27}
$$

$$
\eta Q_{\theta} = -\int d\epsilon \ D(\epsilon)\epsilon \left(\frac{1}{2} - \frac{Q_f \epsilon - \mu_0}{2\sqrt{(Q_f \epsilon - \mu_0)^2 + \Delta^2}}\right), \tag{28}
$$

$$
1 = Z + \frac{1}{2} \int d\epsilon \, D(\epsilon) \sqrt{\frac{U}{\lambda + Q_{\theta} \epsilon}}, \tag{29}
$$

and

$$
\eta Q_f = \eta Z - \frac{1}{2} \int d\epsilon \, D(\epsilon) \epsilon \sqrt{\frac{U}{\lambda + Q_\theta \epsilon}},\tag{30}
$$

where the nearest-neighbor coordination number is *η* and these self-consistent equations are valid only at zero temperature for a half-filled system whose chemical potential is given by $\mu_0 = (U_0 - U_2)/4.$

Obviously, the superconducting phase is characterized by the nonzero singlet pairing order parameter Δ . The gap equation gives nonzero solutions for the pairing order parameter for all $V < 0$, thus the superconducting transition line in U_0 - U_2 parameter space is given by the equation $U_0 = U_2$. This is the SU(4) symmetric line which can be alternatively represented by $\mu_0 = 0$. In the metallic phase rotors are condensed so that the nonzero value of the condensate amplitude or the quasiparticle weight *Z* signifies the metallic state. In the metallic phase, a macroscopic fraction of rotors occupies the lowest energy $E_l = -\eta t Q_\theta$ and the Lagrange multiplier or the rotor chemical potential $\lambda = -E_l \equiv \eta t Q_\theta$ remains constant. The quantum phase transition from the metallic state to the Mott-insulating state is characterized by the vanishing quasiparticle weight *Z*. In the Mott-insulating phase the quasiparticle weight *Z* is zero and the rotor chemical potential $\lambda > \eta t Q_{\theta}$ needs to be determined self-consistently. The metal-insulator transition line can be determined by setting $\Delta = 0$, $Z = 0$, and $\lambda = \eta t Q_{\theta}$ in self-consistent equations presented above.

For a two-dimensional square lattice, the density of states can be approximated by a closed form using the elliptic integral of the first kind $K: D(\epsilon) = \frac{1}{2\pi^2} K(1 - \epsilon^2/16)$ for $-4t \leq \epsilon \leq$

4*t* and zero otherwise. Therefore, for both metal and Mottinsulating phases, where $\Delta = 0$, Q_{θ} has an analytical form. Evaluating the integral in Eq. (28) for a two-dimensional square lattice, we find

$$
Q_{\theta} = \frac{1}{2\pi^2} K \left(1 - \mu_0^2 / 16 \right) \left[16 - \mu_0^2 \right]. \tag{31}
$$

Note that the chemical potential $\mu_0 = (U_0 - U_2)/4$ at half filling, thus *Qθ* depends on the interaction parameters. This is in contrast to the regular Hubbard model with spin-1*/*2 particles where $Q_{\theta} = 4/\pi^2$ is independent of the interac-tion [\[49\]](#page-7-0). Here, at the SU(4) limit where $\mu_0 = 0$, we find $Q_\theta =$ $8/\pi^2$, where the extra factor 2 comes from the extra spin for the spin-3*/*2 system. For a three-dimensional cubic lattice, we numerically evaluate the Q_{θ} value. Rearranging Eq. (30), we find a self-consistent equation for the critical U_2 value for the metal-insulator transition

$$
U_2^{CMI} = 16Q_\theta^C \left\{ \int \frac{d\epsilon \ D(\epsilon)}{\sqrt{1 + \epsilon/4}} \right\}^{-2},\tag{32}
$$

where $Q_{\theta}^C = Q_{\theta}(U_2 = U_2^{CMI})$ depends on the critical interaction through the chemical potential.

Zero-temperature phase diagrams for both square and cubic lattices in the U_0 - U_2 plane are given in Fig. 1. There are four different phases at half filling: a metallic phase (M) at smaller values of $U_2 < U_0$, a Mott-insulating phase (MI) at larger values of $U_2 < U_0$, and two distinct superconducting phases (Z-SC and SC) for larger values of $U_2 > U_0$. In the Z-SC phase quasiparticle weight *Z* is nonzero and it reaches zero at the SC–Z-SC boundary breaking the O(2) rotor symmetry. The boundary of the Z-SC and SC phases is determined by solving our self-consistent equations with the conditions $Z = 0$ and $\lambda = \eta t Q_{\theta}$. With our numerical calculations, we find that Q_f remains constant along the Z-SC–SC boundary, giving $Q_f \approx$ 0.255 for a two-dimensional square lattice and $Q_f \approx 0.104$ for a three-dimensional cubic lattice. This is an emergent Z-SC phase in which both U(1) symmetries associated with the rotor degrees of freedom and spinon degrees of freedom are broken.

FIG. 2. Zero-temperature physical properties as a function of U_2 at (a) $U_0 = 6t$ and (b) $U_0 = 2t$. (a) The quasiparticle weight *Z* (green line) continuously and monotonically decreases from unity to zero, showing the metal to Mott insulator transition at $U_2 \approx 3.8t$. For $3.8t \le U_2 \le 6t$, both the quasiparticle weight and the pairing order parameter remain zero, showing the Mott-insulating phase. For $U_2 > 6t$, the singlet pairing order parameter Δ (blue line) becomes finite, indicating the Mott insulator to superconductor transition. (b) Only the metallic phase exists for low values of U_2 showing nonzero *Z* and zero Δ . For $2t \le U_2 \le 3.3t$, the existence of the Z-SC phase is evident as both *Z* and Δ have nonzero values. Notice for both cases that, while Q_θ (gray line) is continuous at each phase boundary, Q_f shows discontinuities. For clarity, the pairing order parameter Δ has been increased by a factor of 5 in these figures.

For the two-dimensional square lattice, the quasiparticle weight *Z*, the mass enhancement Q_f , the average kinetic energy of the spinons Q_{θ} , and the pairing order parameter Δ are shown at fixed values of $U_0 = 6t$ and $U_0 = 2t$ in Fig. 2. As can be seen from Fig. $2(a)$, the quasiparticle weight is unity at a noninteracting level of rotors and then reaches zero at the metal-insulator boundary. Meantime, the superconducting order parameter picks a finite value at the insulatorsuperconductor boundary and increases as one increases the interaction parameter U_2 beyond U_0 . Both the quasiparticle weight and superconducting order parameter remain at zero in the intermediate Mott-insulating phase. Figure $2(b)$ shows the variation of parameters across the quantum phase transition from metallic to Z-SC to SC phases. For a fixed value of $U_0 = 2t$, the metallic phase exists for low values of $U_2 \le 2$, indicating a nonzero quasiparticle weight *Z* and zero pairing order parameter Δ . For intermediate values of U_2 , both the quasiparticle weight and pairing order parameter become nonzero and thus represent the Z-SC phase. As can be seen from Fig. $2(b)$ in the SC phase, while the quasiparticle weight vanishes, the pairing order parameter remains nonzero beyond $U_2 \approx 3.3t$. Notice that both the mass enhancement and average kinetic energy of the rotons are nonzero across all quantum phase transitions; however, Q_f shows small discontinuities at the quantum phase transitions. This zero-temperature discontinuity of the mass enhancement factor Q_f is an artifact of the mean-field theory and it can be recovered by adding fluctuations over the mean fields, as discussed in Sec. IX.

VIII. FINITE-TEMPERATURE PHASE TRANSITIONS

For two-dimensional fermions on a lattice, the finitetemperature phase transitions are absent, but one can expect to have crossovers. For three-dimensional fermions on a lattice, the finite-temperature phase transitions are not forbidden. We numerically solve the finite-temperature self-consistent equations for the cubic lattice. As a demonstration, we show some

finite-temperature properties of the metallic phase and Z-SC phase in Fig. [3.](#page-6-0) Figure $3(a)$ shows the temperature dependence of the quasiparticle weight Z, the mass enhancement factor Q_f , and the average kinetic energy Q_{θ} in the metallic phase where the interaction parameters are fixed at $U_2 = 2t$ and $U_0 = 4t$. Unlike the zero-temperature metal–Mott-insulator transition, the finite-temperature metal-insulator phase transition is found to be of first order, thus *Z* shows a discontinuity at the transition. However, we find that Q_f and Q_θ remain continuous at the transition. Figure $3(b)$ shows the temperature dependence of the singlet pairing order parameters Δ , Q_f , and Q_θ for the interaction parameters $U_2 = 1.5t$ and $U_0 = 0.5t$. The ground state for these interaction parameters is the Z-SC phase where both the singlet pairing order parameter Δ and the quasiparticle weight *Z* are nonzero. The continuously vanishing singlet order parameter at a high temperature indicates the secondorder thermal transition from the Z-SC phase.

IX. DISCUSSION AND CONCLUSION

As discussed above, all zero-temperature quantum phase transitions are second order; however, we find a discontinuity in the mass enhancement factor Q_f when the transition is into a Mott-insulating phase. On the other hand, while the finitetemperature thermal phase transition into the Mott-insulating phase is first order, we do not find any discontinuity in the mass enhancement factor. In our approach, the zero-temperature Mott transition is continuous, thus one expects continuous destruction of the metallic Fermi surface. This would lead to a metal having instabilities toward a magnetic Mott insulator due to the Fermi surface nesting, though we have not considered any symmetry-breaking insulating states in our approach.

The two superconducting phases discussed above are distinguished for two main reasons. In the Z-SC phase, both the rotor and the pair of spinons are in the condensate. As a result, the broken U(1) gauge symmetry in the rotor sector gives a nonzero quasiparticle weight similar to that of the metallic

FIG. 3. Finite-temperature properties of (a) the metallic phase and (b) the Z-SC phase of fermions in a three-dimensional cubic lattice. (a) Quasiparticle weight *Z* as a function of temperature $k_B T/t$ in the metallic phase. The interaction parameters were chosen as $U_2 = 2t$ and $U_0 = 4t$. The quasiparticle weight (green line) monotonically decreases from the ground-state metallic phase to the Mott-insulating phase at $k_B T/t \approx 0.58t$. Notice that the finite-temperature metal-insulator transition is first order, showing a discontinuity of *Z* at the transition. At the transition, both Q_θ and Q_f are finite and continuous. (b) Superconducting order parameter Δ as a function of temperature $k_B T/t$ in the Z-SC phase close to the Z-SC–SC boundary. The interaction parameters were chosen as $U_2 = 1.5t$ and $U_0 = 0.5t$. While Δ continuously decreases (blue line) from a finite value to zero, showing a second-order thermal phase transition, both Q_f and Q_θ values remain almost constant as a function of temperature.

phase. In the SC phase, the rotors give a nonzero charge gap $\delta_c = 2\sqrt{U(\lambda - \eta t Q_\theta)}$, similar to that of the Mott-insulating phase.

In the present work, we have decoupled the rotor and spinon parts of the Hamiltonian using a mean-field theory. We do not expect the inclusion of fluctuation to alter the qualitative features. However, the physical observable can be slightly different once the direct coupling between the rotors and spinons is restored. Fluctuations can easily be included by going beyond the saddle-point approximation. From the transition from the metal phase or the Z-SC phase, the quasiparticle weight vanishes, however the effective spinon hopping tQ_f is finite. As a result, the effective mass does not diverge at these transitions. We believe this is an artifact of our mean-field theory. In the presence of fluctuation of a gauge field, the zero-sound Goldstone mode will combine with a gauge boson through the Anderson-Higgs mechanism. We believe that this would recover our metal phase as a proper Fermi liquid phase with a diverging Fermi liquid mass [\[50\]](#page-7-0). In addition to the mean-field approximation, we treat our constraint globally and assume that all parameters are bond independent. We do not expect these approximations to change any qualitative features, especially for the square and cubic lattices discussed.

On the experimental side, spin-3*/*2 alkaline-earth atoms, such as 135 Ba and 137 Ba, can be promising candidates for observing the Z-SC emerging phase. Even though the full spectrum of scattering lengths is not available yet, it is predicted that both scattering lengths a_0 and a_2 should have similar values [\[25,51\]](#page-7-0). Therefore, we believe experiments can find a suitable parameter window in the phase diagram to observe the Z-SC phase even if scattering lengths cannot be independently tuned. On the other hand, the pairing phenomena and the emerging phase discussed here are much more general concepts associated with many-body systems. Thus, the Z-SC phase must exist in other manybody systems where competing interactions are taking place. One such example is spin-3*/*2 rare-earth-based half-Heusler semimetals [\[52–](#page-7-0)[57\]](#page-8-0). Another promising electronic compound is rubidium-doped fullerids [\[58\]](#page-8-0). Though on-site interaction is repulsive, the effective negative Hund coupling due to phonon screening effects can lead to a pairing of electrons [\[59,60\]](#page-8-0). Indeed, a recent experiment finds a phase referred to as a Jahn-Teller metal in rubidium-doped fullerids [\[58\]](#page-8-0). Perhaps the superconducting critical temperature enhancement close to the tricritical point of a paramagnetic metal, a paramagnetic insulator, and a superconducting phases indicates the Z-SC phase in this rubidiumdoped fullerid compound [\[61\]](#page-8-0).

The superfluid density, charge gap, and quasiparticle weight all can be measured with currently available experimental techniques in cold gas experiments. For example, the momentum distribution of the atoms can be probed by the absorption imaging after a period of ballistic expansion or in trap *in situ* imaging [\[6\]](#page-7-0). The charge gap can be detected by measuring the fraction of atoms residing in a lattice site [\[5\]](#page-7-0). The superconducting order can be probed by the momentumresolved Bragg spectroscopy [\[62\]](#page-8-0). In addition, the periodic forcing can also be used as a detection and manipulation tool for many-body states of ultracold atomic quantum gases in optical lattices [\[63\]](#page-8-0). Though we neglected it in this study, the underlying harmonic trapping potential present in all cold gas experiments causes the density to monotonically vary across the lattice. As a result, the edge of the trap will not be at half filling. As the metallic phase is favorable over the Mottinsulating phase away from half filling, we expect the metallic phase to dominate over the Mott-insulating phase in the phase diagram.

In conclusion, we have studied the competition of emerging phases of spin-3*/*2 fermions subjected to a periodic lattice potential using a slave-rotor approach. In addition to the well-known Fermi liquid metallic phase, Mott-insulating

phase, and singlet pairing superconducting phase, we discovered the possibility of having an emerging superconducting phase due the competing interactions. The superconducting phase is characterized by the global U(1) broken symmetries with respect to both roton and spinon fields. Experimentally, this phase can be differentiated from the regular superconducting phase by its nonzero quasiparticle weight. Further, we have calculated properties of these phases for fermions in both a two-dimensional square lattice and three-dimensional cubic lattice geometries at zero and finite temperatures.
