(Received 7 March 2018; published 14 November 2018)

Ionization can serve as a universal probe of excited-state dynamics in molecules, such as internal conversion, dissociation, and isomerization. These processes are of fundamental importance to a wide array of dynamics in biology, chemistry, and physics. In recent years, there has been significant debate about the relative merits of strong-field ionization (SFI), which involves multiphoton absorption, versus weak-field ionization (WFI), where a single photon is absorbed, as probes of these dynamics. SFI is advantageous because it uses wavelengths that are relatively easy to generate, and one can always ionize the molecule with sufficient intensity. However, for SFI it is difficult to calculate observables, such as the time-dependent ion yield, since the calculation of the ionization dynamics including multiphoton processes is computationally expensive and difficult to carry out for many molecular geometries. WFI has the advantage that calculations of observables are tractable. However, the generation and implementation of the appropriate wavelengths (photon energies) can be challenging, and the fixed energy of the probe can lead to technical complications in following the dynamics from excited states back down to the ground state. Here we present a quantitative comparison of the two approaches for following the excited-state dynamics of two molecules, diiodomethane and uracil. The combination of internal conversion and dissociation in these molecules provides an ideal comparison of WFI and SFI as a probe. We compare the measurements with calculations of the dynamics. Our work indicates that while SFI and WFI provide qualitatively similar information about the excited-state dynamics, only WFI results can be compared quantitatively with present-day calculations.

I. INTRODUCTION

Photoinduced excited-state molecular dynamics play a central role in many fundamental processes in nature. Many different approaches have been developed in order to follow these dynamics in real time. While the dream of time-resolved measurements is to make "molecular movies", it is very rare that one can directly measure a molecular structure or wave function amplitude as a function of time. Rather, the most insight is typically gained by comparing experiment with theoretical calculations of observables in order to verify the calculations and then generating the "molecular movie" from calculations. Thus, an important criterion in evaluating different measurement approaches is how easily they can be compared with theoretical calculations of the measured observable. Each time-resolved experimental approach has advantages and disadvantages. For example, ultrafast electron diffraction $[1–5]$ holds the promise of providing direct structural information as a function of time but suffers from orientational averaging over the sample, repulsion between the electrons in a short pulse, and the group velocity mismatch between electrons and light. Ultrafast x-ray diffraction [\[6–9\]](#page-7-0) overcomes the last two disadvantages of electron diffraction but suffers from low scattering cross sections, and requires a large number of photons in the probe pulse—typically only

available at free electron laser light sources. Optical spectroscopy approaches such as transient absorption [\[10–](#page-7-0)[14\]](#page-8-0) can provide high time resolution with a compact apparatus, but require detailed knowledge of the potential energy surfaces (electronic energies as a function of nuclear coordinates) and transition dipole moments along the reaction coordinate in order to be interpreted. Time-resolved ionization spectroscopy [\[15–20\]](#page-8-0) offers the advantage over optical spectroscopies that it is always possible to ionize, regardless of the character of the excited state. The near-threshold ionization of valence electrons from excited states (for which the cross section is large) can be accomplished either in the weak-field regime, with the absorption of a single ultraviolet (UV) or vacuum ultraviolet (VUV) photon (∼6–10 eV), or in the strong-field regime, with the absorption of multiple low-energy nearinfrared photons $(\sim 1-3$ eV) [\[19–25\]](#page-8-0).

Here we compare weak-field ionization (WFI) with strongfield ionization (SFI) as probes of excited-state molecular dynamics. We consider two different kinds of excited-state dynamics, internal conversion and dissociation, in two different molecules, and we compare the measurements directly with high-level dynamics calculations in order to assess the relative strengths and weaknesses of the two approaches. While earlier work found significant differences between multiphoton ionization with a 1.55-eV probe and single-photon ionization with a 14-eV probe [\[28\]](#page-8-0), we find that WFI near threshold and SFI provide qualitatively similar results (see below), although only WFI can be compared quantitatively with calculations of the excited-state dynamics. It can be shown analytically that the first-order one-photon ionization probability is directly proportional to the norm of the Dyson orbital formed by projecting the $N - 1$ electron wave function of the final (ionic) state onto the *N* electron wave function of the initial (neutral) state of the molecule [\[29,30\]](#page-8-0):

$$
\phi^D = \sqrt{N} \int \psi_i^N(r_1, \dots, r_N) \psi_f^{N-1}(r_2, \dots, r_N) dr_2 \dots dr_N,
$$
\n(1)

where ψ_i^N is the initial, *N*-electron wave function of the neutral, and ψ_f^{N-1} is the final, $N-1$ electron wave function of the ion. The integral is over $N-1$ dimensions, leaving a one-electron function or orbital for ϕ^D . The total ion yield for each molecular geometry produced by a dynamics calculation can be expressed in terms of this Dyson orbital as

$$
\text{Ion yield} \propto |\langle \psi_{k}^{e} | \hat{\epsilon} \cdot \mathbf{r} | \phi^{D} \rangle|^{2} \langle \phi^{D} | \phi^{D} \rangle, \tag{2}
$$

where $\hat{\epsilon}$ is the polarization direction of the light, **r** is the position operator, ψ_k^e is the free (continuum) electron wave function with momentum *k*, and $\langle \phi^D | \phi^D \rangle$ is the Dyson norm. For SFI, perturbation theory cannot be used, and there is no analog for the Dyson norm as a good predictor of the population distribution across the ionic states. Because of this, strong-field ionization requires computationally costly calculations to determine the ionization rate as a function of molecular geometry.

II. RESULTS

We carry out our comparison of WFI and SFI by following dissociation in diiodomethane, $CH₂I₂$, and internal conversion in uracil. The excited-state dynamics of both diiodomethane and uracil have been the subject of intense theoretical and experimental studies [18,26,27,31-49]. Figure 1 shows onedimensional representations (cartoons) of the relevant potential energy surfaces for both molecules. In $CH₂I₂$ [Fig. 1(a)], earlier studies concluded that after being pumped with UV light at 260 nm, the molecule undergoes direct dissociation [\[48\]](#page-8-0), producing $CH₂I$ and I fragments. For uracil [Fig. 1(b)], excitation with a pump pulse centered at 260 nm promotes the molecule to the first bright excited state, S_2 , which is predominantly of $\pi \pi^*$ character near the ground-state minimum (Franck-Condon point). From *S*2, the molecule can undergo radiationless decay via two seams of conical intersections, S_2/S_1 and S_1/S_0 . It is generally accepted that there is population trapping on S_1 , while the extent of trapping on S_2 depends on the barrier on that surface. A cartoon illustrating uracil's relaxation dynamics can be seen in Fig. 1(b). While intersystem crossing has been found to play a role in the relaxation dynamics of uracil [\[42\]](#page-8-0), triplet states are not shown in the cartoon for the sake of simplicity.

In conjunction with a time-of-flight mass spectrometer (TOFMS), we make use of ultrafast UV (260 nm, 4.8 eV) and vacuum-UV (VUV) pulses (156 nm, 7.95 eV) to perform pump-probe ion yield measurements. The ultrafast UV and

FIG. 1. Cartoons showing the excited-state dynamics in (a) $CH₂I₂$ after UV absorption [\[26\]](#page-8-0) and (b) uracil after UV absorption [\[27\]](#page-8-0). The different ionization probes for WFI (solid magenta line) and SFI (dashed red line) are also indicated.

VUV pulses are generated from a Ti:sapphire laser system (1.3 mJ, 1 kHz, 30 fs, 780 nm, 1.55 eV). The impulse response function (IRF) of our experimental apparatus, limited largely by our pump and probe pulse durations, is characterized by performing VUV-pump UV-probe experiments on ethylene. Ethylene undergoes rapid internal conversion after being pumped in the VUV $[50,51]$, and hence it can be used to extract the IRF of our system. The IRF for our apparatus is about 100 fs, although the uracil measurements were carried out before the most recent upgrade and had an IRF of about 200 fs. Gas-phase diiodomethane is injected as an effusive molecular beam at 25 ◦C. Gas-phase uracil molecules are injected into the vacuum chamber as an effusive molecular beam with an oven at 200 ◦C. More details about the experimental setup and a schematic of the system can be found in Ref. [\[52\]](#page-8-0).

For WFI UV-VUV pump-probe measurements performed on diiodomethane, $CH₂I₂$, we observed transient ion yields for the parent ion, $CH_2I_2^+$, and the fragment ion, CH_2I^+ . The total energy available following the absorption of one photon from each of the pump and probe pulses is 12.75 eV. The observation of the parent and this fragment ion are consistent with previous measurements [\[53–56\]](#page-8-0), where the appearance energies (AE) of $CH_2I_2^+$ and CH_2I^+ are about 9.46 and 10.49 eV respectively.

The total ion yield pump-probe signal for $CH₂I₂$ (both SFI and WFI) can be seen in Fig. $2(a)$ plotted on the same graph. Negative time delays are shaded gray, because we want to focus our attention on positive time delays where the UV pump precedes the VUV probe. Both methods reveal a very fast ∼50-fs decay, but the SFI measurements show a longer component to the decay (∼500 fs). Since the excited state dynamics in both experiments are identical, the differences in the measured signals must be due to differences in the interaction between the molecules and the probe pulse; i.e., the difference in the measurements comes from the different sensitivities that WFI and SFI have to the excited-state dynamics. We believe that this longer decay in the SFI

FIG. 2. (a) Weak-field UV-VUV and strong-field UV-IR total ion yield pump-probe measurement on diiodomethane. (b) Weakfield UV-VUV and strong-field UV-IR total ion yield pump-probe measurement on uracil.

 $CH₂I₂$ pump-probe signal is due to a multiphoton resonance which enhances the ion yield as the molecule dissociates $[19-25,28]$. As the wave packet dissociates on the neutral excited state, the molecular structure can be such that *n* photons (*n<V*ion*/*h*ν*) from the strong-field probe can come into resonance with an intermediate state, between the excited state and the continuum, increasing the ionization rate. This interpretation is consistent with earlier measurements of multiphoton resonances in strong-field ionization of halogenated methane molecules [\[20\]](#page-8-0). Since one does not know *a priori* (i.e., without carrying out detailed electronic structure calculations for different molecular geometries) whether resonances will modify the ion signal versus structure or configuration for SFI, one cannot know whether the SFI signal versus time is directly connected to changes in molecular geometry or distorted by the intermediate dynamic resonances that occur.

In the uracil UV-VUV WFI pump-probe experiments, we measured the parent ion, $C_4H_4N_2O_2^+$, and the fragment ion with mass 69 in atomic mass units (AMU) in the TOFMS. These observations are consistent with photon impact AE $(9.15 \pm 0.03 \text{ eV}$ for the parent ion and $10.95 \pm 0.05 \text{ eV}$ for the fragment ion, $C_3H_3NO^+$ (mass 69 AMU) [\[57\]](#page-8-0)). The appearance energies of other fragments are all greater than 12*.*75 eV.

The total ion pump-probe signal for WFI UV-VUV pumpprobe experiments and SFI UV-IR pump-probe experiments on uracil can be seen in Fig. $2(b)$. For SFI, we find that the exact structure of the pump-probe signal can vary with the intensity of the probe, which highlights one of the major difficulties with working with the SFI as a probing mechanism (a more detailed discussion of this can be found in Appendix [A\)](#page-3-0).

By analyzing the WFI and SFI results on uracil and performing χ^2 fitting, it became clear that the pump-probe signals consist of two decay timescales, one short and one long (details of this fitting can be seen in Appendix [A.3\)](#page-4-0). The SFI and WFI signals have similar long decay timescales, but they differ significantly for the shorter timescales. The SFI yield has a much sharper peak at zero time delay than the WFI yield. As in the case of $CH₂I₂$, given the same dynamics excited by the pump pulse, the difference in signal must derive from differences in the sensitivity of the two probes. The sharp peak near zero delay in the SFI data could be due to multiple effects: an enhancement in the multiphoton ionization yield due to the overlap of the pump and probe pulses, a distortion of the potential energy surfaces by the strong field of the probe pulse, or the greater sensitivity of the SFI yield to wave-packet motion away from the FC region. In any case, it is clear that SFI exaggerates or distorts the motion of the wave packet near the FC region.

Figure 2 illustrates one of the difficulties in only looking at decay constants to compare an experiment to theory. The SFI measurements cannot be fit to a single exponential decay in either of the two cases we consider here. Comparing one decay time from a multiparameter fit with several decay components to theory can be very misleading because the fit parameters can be coupled and the relative importance of a given decay time can depend sensitively on the details of the fitting procedure. As a result, we argue that the best test of quantitative agreement between a particular theory and experiment is to plot the experiment and theory together on the same graph.

The differences between WFI and SFI as a probe of excited-state dynamics are highlighted by comparing theory and experiment. For both molecules, we carried out trajectory surface hopping calculations of the dynamics, using the SHARC $[58-60]$ and NEWTON-X $[61,62]$ packages. The ionization yield as a function of delay was based upon the excited state populations as a function of time, with Dyson norms calculated in addition for the case of $CH₂I₂$.

For $CH₂I₂$ the calculations were done with SHARC based on MS-CASPT2 (multi-state complete active space perturbation theory second order) level of theory [\[63\]](#page-9-0) and coupled with Dyson norm calculations [\[64\]](#page-9-0) in order to carry out a thorough comparison to the experimental results. The convolution of the calculations with the IRF of our apparatus, acquired from the ethylene VUV-UV pump-probe scans, is required to accurately compare the experimental results to the theory (further details in Appendix [B\)](#page-6-0). The results of this analysis can be seen in Fig. $3(a)$.

For uracil, CASPT2 analytic gradients are not available and numerical gradients would be computationally prohibitive. Therefore, dynamics were carried out on potentials calculated at the complete active space self-consistent field (CASSCF) and multireference configuration interaction with single excitations (MRCIS) levels of theory using the COLUMBUS 7.0 and NEWTON-X packages [\[65–67\]](#page-9-0). CASSCF dynamics calculations were performed to track the dynamics for 1 ps, and MRCIS dynamics calculations, due to the greater computational complexity, were carried out for only 500 fs. MRCIS is a higher level of theory than CASSCF and is used to check the validity of the CASSCF calculations. To compare these results to the UV-VUV pump-probe signal, we look

FIG. 3. (a) $CH₂I₂$ WFI UV-VUV pump-probe total ion yield data (green triangle), CASPT2 dynamics with Dyson norms calculation for CH_2I_2 (dot-dashed line), IRF of our apparatus (dotted line), and convolution of the calculation and the IRF of the system (solid line). (b) Uracil WFI UV-VUV pump-probe total ion yield data (upward facing green triangle), CASSCF calculation for uracil (black dot-dashed line), impulse response function (IRF) of our apparatus (black dotted line), convolution of the CASSCF calculation and the IRF of the system (solid black line), MRCIS calculation for uracil (gold dot-dashed line), and convolution of the MRCIS calculation and the IRF of the system (solid gold line).

at the total ion yield and assume that the total excited-state populations $(S_1$ and S_2) are ionized, taking the S_1 and S_2 populations as the total ion signal. Dyson norms are not used for the uracil calculations, because they do not appear to have significant variation for different geometries along *S*¹ and *S*2. In earlier work, we studied the variation in the Dyson norms for ionization of uracil from S_1 and S_2 [\[27\]](#page-8-0). Our calculations indicated that there were no dramatic differences in the Dyson norms on these states in moving between the *S*² minimum, the *S*¹ minimum, and the *S*1*/S*² CI geometries. Since only these two states are involved in the dynamics and there is not much variation in the Dyson norms from these two states, we did not calculate them at each point in the trajectories. Again, the results of the computation were convolved with the IRF of the system for an accurate comparison to the experiment. The results of this analysis can be seen in Fig. 3(b). The agreement between the experimental WFI data and the MRCIS and CASSCF calculations is quite good (details of the uracil calculations can be found in Appendix \overline{B}). A more detailed analysis of the excited-state dynamics calculations for both uracil and $CH₂I₂$ is the subject of forthcoming papers.

III. DISCUSSION AND CONCLUSION

The agreement between the WFI experimental data and the calculations highlights a key difference between SFI and WFI. Even though SFI and WFI are both able to provide a qualitative picture of the relaxation dynamics, there are still quantitative differences for both molecules. By qualitative agreement, we mean that the decay curves look similar (i.e., exponential or multiexponential behavior), yield timescales of the same order of magnitude, and show similar trends (i.e., the ionization yield for uracil has a long tail for both SFI and WFI whereas the WFI and SFI ion yields for $CH₂I₂$ do not). However, in order to test the validity of a calculation or discriminate between two different theories, quantitative agreement is required. We argue that the best test of quantitative agreement is to plot experimental and theoretical results together on the same graph. A direct comparison between SFI measurements and calculations of the excited-state dynamics is impossible without explicit calculations of the SFI dynamics, which are computationally expensive and unfeasible for the timescales involved in the excited-state dynamics probed here. The qualitative agreement between WFI and SFI measurements of the excited-state dynamics illustrates the fact that both ion yields contain similar information on the excited-state dynamics. The quantitative agreement between the WFI measurements and calculations, however, allows one to interpret and understand the dynamics at a level of detail not possible with SFI.

We gratefully acknowledge support from the Department of Energy under Awards No. DEFG02-08ER15983 and No. DEFG02-08ER15984 for the weak field ionization measurements as well as the National Science Foundation under Award No. 1505679 for the strong field ionization measurements. This project was partly supported by the Government of Hungary and the European Regional Development Fund under Grant No. VEKOP-2.3.2-16-2017-00015. The computational results presented have been achieved in part using the Vienna Scientific Cluster (VSC). Part of the computational work used the Extreme Science and Engineering Discovery Environment (XSEDE), which is supported by National Science Foundation Grant No. ACI-1548562.

APPENDIX A: FITTING DETAILS

1. Fitting function details

The dichroic mirror which combines the UV pump pulse and VUV probe pulse does not act as a perfect filter for the residual UV used to generate the VUV, and a fraction (between 5 and 10%) of this UV is reflected and generates a UV-UV pump-probe background signal in the uracil data. The UV-UV pump-probe signal has to be filtered out from the UV-VUV pump-probe signal (the details into separating the two signals can be seen in the next section). The fitting function for the uracil weak-field data is

$$
f(t) = e^{-\frac{(t-t_0)^2}{2\sigma^2}} \otimes \left[\Theta(t-t_0) \left(A_1 e^{-\frac{(t-t_0)}{\tau_1}} + A_2 e^{-\frac{(t-t_0)}{\tau_2}} + A_3 \right) \right] + e^{-\frac{(t-t_0)^2}{2\sigma^2}} \otimes \left[\Theta(t-t_0') \left(A' e^{-\frac{(t-t_0')}{\tau'}} \right) \right]. \tag{A1}
$$

This fitting function for the weak-field data has two main components: The first component is the UV-VUV pumpprobe signal, and the second is the UV-UV pump-probe signal. We assume that our UV and VUV pulses are Gaussian in time, so that our apparatus's impulse response time, σ , is dictated by our pulse durations. Therefore, σ is essentially the convolution of our pump and probe pulse durations. t_0 corresponds to time zero (where the UV and VUV pulses are overlapped). t'_0 represents the time zero for the two UV pulses, i.e., where the two UV pulses are overlapped, and σ' is the time resolution of the UV-UV signal in our apparatus. σ' is essentially the convolution of the two UV pulse durations. *A* and τ' are the amplitude and decay constant for the molecular decay. Θ is the Heaviside step function and is used to ensure that the molecular dynamics cannot initiate until the excited state is populated.

The UV-VUV fit also consists of two exponential decays and a constant. A_1 and τ_1 characterize the amplitude and decay constant for the first decay. A_2 and τ_2 are the amplitude and decay constant of the second decay. The constant, *A*3, represents the population that has a decay constant on the order of nanoseconds, so on our timescales it manifests itself as a constant.

In the weak-field data, there is a plateau in both the parent and the fragment ion data. By a plateau, we mean that the ion yield from before time zero is lower than the ion yield at long time delays (if the molecule were relaxing back to its ground state, we would expect these levels to be equal on either side of time zero). As mentioned before, this plateau is encapsulated in the fit as *A*3. Longer delay scans of 20 ps were taken for uracil and it was found that after 7 ps the ion yield shows no more significant decay and that the yield reaches a plateau.

The fitting function for the weak-field $CH₂I₂$ data and for the strong-field $CH₂I₂$ parent ion data is

$$
f(t) = e^{-\frac{(t-t_0)^2}{2\sigma^2}} \otimes [\Theta(t-t_0)(A_1 e^{-\frac{(t-t_0)}{\tau_1}})]. \quad (A2)
$$

The fitting function for the strong-field $CH₂I⁺$ fragment ion data is

$$
f(t) = e^{-\frac{(t-t_0)^2}{2\sigma^2}}
$$

$$
\otimes \left[\Theta(t-t_0)\left(A_1e^{-\frac{(t-t_0)}{\tau_1}} + A_2e^{-\frac{(t-t_0)}{\tau_2}}\right)\right].
$$
 (A3)

2. UV-UV pump-probe peak subtraction

After the VUV is generated in an argon gas cell, the VUVpulse passes through a 500- μ m-thick CaF₂ window into an interaction chamber, which is maintained at a pressure of 10^{-7} Torr. The VUV pulse first passes under the repeller plates of our TOFMS. It is then reflected by a dichroic mirror of radius of curvature $R = 268$ mm. The mirror has a high reflectivity coating of *>*90% at 0◦ for 156- to 160-nm light and *<*10% reflectivity for 260 and 800 nm. This enables the residual UV and IR radiation left over from VUV generation to be separated from the VUV.

While less than 10% of the UV is reflected by the dichroic mirror, it is enough UV to also generate multiphoton absorption and leads to a UV pump–UV probe signal. The group velocity difference between the UV and VUV passing through the 500- μ m-thick CaF₂ window leads to a 1-ps delay between the VUV and the UV pulses reflected by the dichroic mirror. UV-UV background scans are taken to subtract the UV-UV signal from the UV-VUV signal.

FIG. 4. The green diamonds are the raw data collected for the parent ion that contain both the UV-VUV and UV-UV pump-probe signals. The red solid curve is the full fit given by Eq. [\(1\)](#page-1-0). The dashed cyan curve is the UV-VUV fit component. The purple dash-dotted curve is the UV-UV fit component. The inset plot is contains UV-UV pump-probe data taken without any VUV present. The light blue diamonds are the UV-UV pump-probe data and the dash-dotted purple line is the fit to the UV-UV data.

In order to properly look at the UV-VUV pump-probe dynamics, the UV-UV pump-probe signal must be separated from the UV-VUV pump-probe signal. In Fig. 4, the green diamonds represent the raw uracil parent ion yield. It is evident that there are two peaks. The first peak, at 0 fs, is the UV-VUV pump-probe signal, and the second peak, at \sim 1000 fs, is the UV-UV pump-probe signal.

Background pump-probe scans were performed with only the UV in the chamber in order to characterize the background signal, which can be seen in the inset of Fig. 4. From these background scans, it is possible to extract t_0^{\prime} , σ^{\prime} , and τ^{\prime} to use in Eq. [\(1\)](#page-1-0), which are then fixed when doing the fitting of the combined UV-VUV and UV-UV pump-probe scan.

In Fig. 4, the red curve is the complete fit, shown in Eq. (1) , with both the UV-VUV and UV-UV pump-probe components. The purple dash-dotted curve in the main plot of Fig. 4 is the fit to the UV-UV pump-probe component and is the same as the purple dash-dotted line in the inset (except for the amplitude factor A'). The cyan dashed curve is the UV-VUV pump-probe fit. Characterizing the UV-UV background signal independently of the VUV signal enables fitting to the UV-UV pump-probe data, and then it is possible to subtract the UV-UV contribution from the raw data and generate the plots in Fig. $2(a)$ in the main text.

No UV-UV pump-probe peak subtraction is needed for the weak-field $CH₂I₂$ data, because the molecular dynamics are very fast and the dynamics are completed before the UV probe pulse comes with a 1-ps delay relative to the VUV probe pulse.

3. CH2I2 and uracil fitting results

WFI UV-VUV pump-probe scans for the parent and the fragment ions together with fits can be seen in Fig. $5(a)$. The SFI results and fitting of $CH₂I₂$ can be seen in Fig. $5(b)$. χ^2 fitting is performed to determine the decay constants. Each pump-probe scan is fit to an exponential or a sum of two exponentials convolved with the IRF of our apparatus (Gaussian). The minimum number of exponentials are used that give a fit where $\chi_v^2 \sim 1$.

The results of the fitting of the parent ion for both SFI and WFI give consistent decay constants, but some discrepancy between the yields for the two methods appears in the

FIG. 5. (a) Weak field ion yields vs UV pump VUV probe delay for CH2I2. (b) Strong field ion yields vs UV pump IR probe delay for CH_2I_2 . Yields are shown for both the parent and the CH_2I^+ fragment.

fragment ion data. Both methods reveal a very fast ∼50-fs decay, but the SFI data also show a longer component to the decay with $\tau = 380$ fs.

The parent and fragment ion yields along with fits for WFI UV-VUV pump-probe experiments on uracil can be seen in Fig. $6(a)$. In uracil, error bars for a fit parameter in the WFI scans are determined by the range over which χ^2 changes by

FIG. 6. (a) Weak field ion yields vs UV pump VUV probe delay for uracil. (b) Strong field ion yields vs UV pump IR probe delay for uracil. Yields are shown for both the parent and mass 69 fragment ion.

FIG. 7. Uracil decay constants extracted from strong-fieldionization experiments with varying probe intensities in order to determine the systematic errors in the experiment, so error bars can be set on our decay constants.

1 from its minimum value. For SFI, we found that the variation in decay times for different pump probe scans was larger than the uncertainty determined from a given fit. Therefore, the error bars were determined by performing the measurement multiple times and refitting the data, with the standard deviation from the mean for the multiple measurements taken as the error bar.

For the parent ion, $C_4H_4N_2O_2^+$, the shorter decay, $\tau_1 =$ 325 ± 50 fs, is consistent with either a rapid motion away from the Frank-Condon region or a portion of the wave packet making a rapid nonadiabatic transition to S_1 or S_0 . The longer decay constant, $\tau_2 = 2045 \pm 260$ fs, suggests that a portion of the wave packet is trapped in a minimum for several picoseconds. For the fragment ion, $C_3H_3NO^+$, time constants of $\tau_1 = 455 \pm 100$ fs and $\tau_2 = 3250 \pm 150$ fs were extracted. The SFI results and fitting can be seen in Fig. $6(b)$. For the parent ion, $\tau_1 = 65 \pm 10$ fs and $\tau_2 = 2450 \pm 130$ fs. For the fragment ion, $\tau_1 = 80 \pm 20$ fs and $\tau_2 = 3030 \pm 140$ fs.

4. Error bar determination for uracil strong-field-ionization measurements

The strong-field-ionization results for uracil are sensitive to systematic effects (such as the laser intensity of the strong field probe), and these systematic effects appear to be the main source of error in the fitting for these experiments. To account for these in the calculation of uncertainties in the strong-field uracil data, four different data sets with varying probe intensity were analyzed. Each data set was individually fitted. The results of this fitting can be seen in Fig. 7 for both the parent and the fragment ion decay constants. The mean, μ , and the mean plus and minus the standard deviation, σ , are also plotted. Unlike in the weak-field experiments, the error extracted from the individual data sets from $\Delta \chi^2 = 1$ is much smaller than the variation in the decay constants from data set to data set. This indicates that the dominant source of error in these experiments is systematic.

5. Time resolution check for comparison of CH₂I₂ calculations to the experimental data

In order to compare the CASPT2 dynamics and Dyson norm calculation on diiodomethane with the experimental data, we had to convolve the calculation with the temporal

FIG. 8. Scaling the CASPT2 dynamics and Dyson norm calculation on diiodomethane and convolving with a 100-fs FWHM Gaussian to check the comparison between theory and experiment.

response of our system (which is 100 fs). As a test of whether this convolution obscures the underlying molecular dynamics, we compare the experimental measurements with calculations where we stretched or contracted the dynamics by factors of 1.5 and 2 prior to the convolution. We plot the stretched and contracted calculations together with the data in Fig. 8. It is clear from the figure that the measurements agree well with the original calculation data, while disagreeing with the stretched or contracted data. This indicates that the measurement contains more information than just an upper bound on the dynamics or timescale.

APPENDIX B: CALCULATION DETAILS

1. CH2I2 calculation details

In order to carry out the excited-state dynamics simulations for $CH₂I₂$, we used SHARC (Surface Hopping including Arbitrary Couplings) [\[58–60\]](#page-8-0) interfaced with MOLCAS 8.0 [\[68\]](#page-9-0). The electronic structure calculations of the neutral molecule were performed with MS-CASPT2(12,8)/ano-rccvdzp (multi-state complete active space perturbation theory second order) based on SA(5/4)-CASSCF(12,8) (complete active space self-consistent field with 12 electrons in 8 orbitals and state-averaging including either 5 singlet or 4 triplet states) calculations. The IPEA shift was set to zero, as this was found to improve the results in combination with the small double-*ζ* basis set [\[69\]](#page-9-0). However, to avoid intruder states and ensure a stable propagation in the dynamics simulations, an imaginary shift of 0.3 hartree was added [\[70\]](#page-9-0). In order to account for scalar-relativistic effects, the second-order Douglas-Kroll-Hess (DKH) Hamiltonian [\[71\]](#page-9-0) was employed while spin-orbit couplings (SOCs) were computed with the RASSI [\[72\]](#page-9-0) and AMFI [\[73\]](#page-9-0) formalisms. The dynamics were run employing the velocity-Verlet algorithm with a time step of 0.5 fs for the nuclear dynamics and a time step of 0.02 fs for the propagation of the electronic wave function, using the local diabatization formalism [\[74\]](#page-9-0). Energy conservation during a surface hop was ensured by scaling of the full velocity vectors, since the nonadiabatic coupling vectors are not available for our level of theory. We employed an energy-based decoherence correction with a parameter of 0.1 hartree [\[75\]](#page-9-0). The initial geometries and velocities for the trajectories were sampled from a Wigner distribution of the harmonic ground-state potential. In this way, 1000 geometries were produced and a single-point calculation at the MS-CASPT2(12,8) level of theory was performed at each of these

FIG. 9. Theoretical absorption spectra of uracil simulated at the CASSCF(12,9)/cc-pVDZ level (solid blue line centered around 6.5 eV) and MRCIS/CASSCF(12,9)/cc-pVDZ level (solid red line centered around 5.8 eV).

to obtain the state energies and oscillator strengths. The initial excited states were selected stochastically [\[76\]](#page-9-0), restricting the excitation energy window between 4.775 and 4.825 eV. The ionization probability along the trajectories was obtained in an approximate manner from Dyson norm calculations [\[64\]](#page-9-0) using our WFOVERLAP code [\[77\]](#page-9-0) in a postprocessing step. The necessary wave functions of the neutral and ionized molecule were obtained at steps of 2.5 fs along the precomputed trajectories from MS-CASPT2(12,8)/ano-rcc-vdzp or MS-CASPT2(11,8)/ano-rcc-vdzp calculations including altogether 5 singlets, 9 doublets, 4 triplets, and 4 quartets as well as all possible SOCs.

2. Uracil calculation details

The ground state of the biologically relevant tautomer of uracil was optimized at DFT level using the B3LYP functional and 6-31G(d) basis set using the GAUSSIAN09 package [\[78\]](#page-9-0). The frequencies and normal modes were calculated at the same level of theory. A sampling was performed using a harmonic oscillator Wigner distribution in NEWTON-X [\[61,62\]](#page-8-0) to generate 500 initial conditions (nuclear coordinates and velocities) based on the optimized geometry and the normal modes from the previous calculation. The S_1 ($n\pi^*$) and S_2 $(\pi \pi^*)$ excited states of uracil for the 500 geometries were calculated at both the complete active space self-consistent field (CASSCF) and multireference configuration interaction with singles (MRCIS) levels using cc-pVDZ basis set with an active space of 12 electrons in 9 orbitals. Three states were averaged at the CASSCF level. The vertical excitation energies and oscillator strengths were used to calculate the absorption cross sections to simulate the first absorption band of uracil in both CASSCF and MRCIS methods. The temperature was considered to be 298 K. A Lorentzian line shape and a phenomenological broadening (*δ*) value of 0.1 eV were employed. Figure 9 shows the theoretical absorption spectra of uracil at both the CASSCF and MRCIS level.

We performed nonadiabatic excited-state dynamics simulations using trajectory surface hopping in NEWTON-X on CASSCF(12,9)/cc-pVDZ and MRCIS/CASSCF(12,9)/ccpVDZ potential energy surfaces calculated using the COLUM-BUS 7.0 package [\[65–67\]](#page-9-0). The experimentally measured first absorption peak for uracil in the gas phase is at 5.08 eV [\[42\]](#page-8-0). The first absorption peak is at 6.60 and 5.90 eV for CASSCF and MRCIS levels, respectively. The pump pulse generated in our experiment is at 4.77 eV, which is 0.31 eV lower than the experimental maximum. So, 0.31 eV is subtracted from the peak of the theoretical spectra at both levels of theory to estimate the center of the pump pulse. The excitation windows were considered to be 6.29 ± 0.15 eV and 5.59 ± 0.15 eV at CASSCF and MRCIS level, respectively, selecting 71 and 73 initial conditions for the aforementioned levels of theory, to be propagated starting from the S_2 state, as it is the first bright state in uracil. The fewest switches surface hopping (FSSH) algorithm was used to take into account nonadiabatic events among *S*2, *S*1, and *S*⁰ states. The FSSH algorithm was corrected for decoherence effects using the approach of nonlinear decay of mixing by Zhu *et al.* [\[79\]](#page-9-0) and Granucci *et al.* [\[75\]](#page-9-0), keeping the parameter $\alpha = 0.1$ hartree. The velocity verlet algorithm was used to integrate Newton's equations of motion with a time step of 0.5 fs and the semiclassical Schrödinger equation was integrated using fifth-order Butcher's algorithm with a time step of 0.025 fs. The simulations were performed for 1000 fs at the CASSCF level and 500 fs at the MRCIS level using XSEDEs computational resources [\[80\]](#page-9-0).

APPENDIX C: EVIDENCE FOR PROBING EXCITED-STATE DYNAMICS

We calculated the Frank-Condon (FC) factors of the ground and the excited states in uracil in order to show that with our VUV probe we can only ionize population in *S*¹ and S_2 , and we cannot see any ionization from S_0 , even if we assume we have a "hot" ground state. This illustrates why a VUV probe is needed in order to do a proper weak-field pump-probe experiment.

EZSPECTRUM 3.0 [\[81\]](#page-9-0) was used to calculate FC overlaps using the Duschinsky rotations approximation. We define the FC factors as $|\langle \psi_{v_{\text{final}}} | \psi_{v_{\text{initial}}} \rangle|^2$, where $\psi_{v_{\text{initial}}}$ and $\psi_{v_{\text{final}}}$ are the initial and final vibrational states. The S_0 and D_0 minima were optimized at the B3LYP/6-31G(d) and UB3LYP/6-31G(d) levels of theory, respectively. Frequencies and normal modes were calculated at the same level of theory and used for the FC overlap calculations. In order to obtain the correct character for the D_1 minimum, we had to use TDDFT/TDA/CAM-B3LYP/6-31G(d) level, since the B3LYP functional did not give the correct character. For consistency, the S_1 minimum was also obtained at the same level of theory. Frequencies

FIG. 10. FC factors between (a) S_0 and D_0 and (b) S_1 and D_1 . The UV and VUV photon energies are labeled and are indicated by the blue (4.8 eV) and magenta (7.95 eV) vertical lines, respectively.

and normal modes were calculated at the TDDFT/TDA/CAM-B3LYP/6-31G(d) level of theory for the S_1 and D_1 minima and were used in the FC overlap calculations. The minima and normal modes were calculated with Q-CHEM package [\[82\]](#page-9-0).

FC factors were calculated between S_0 and D_0 and between S_1 and D_1 . The results can be see in Fig. 10, where the UV and VUV photon energies are also indicated. In Fig. 10(a), it is clear that the UV and VUV photon energies are not energetically capable of ionizing from S_0 to D_0 , even if the ground state were vibrationally hot. Figure $10(b)$ shows the FC factors between S_1 and D_1 which indicate that the UV photon energy is insufficient to ionize from *S*¹ without excess vibrational energy, making it a poor probe of *S*1. In contrast, the VUV photon has more than enough energy to ionize S_1 to *D*¹ from its lowest vibrational level and is a good probe of *S*1. The VUV photon is in a unique position to enable us to fully probe any dynamics in *S*1, but is still "blind" to ground-state dynamics.
