(Received 30 May 2018; published 5 November 2018)

We present a numerical study of the interaction quench dynamics in a superfluid ultracold Fermi gas confined in a three-dimensional cigar-shaped harmonic trap. In the present paper, we investigate the amplitude mode of the superfluid order parameter after interaction quenches, which start deep in the BCS phase and end in the BCS-BEC-crossover regime. To this end, we exploit the Bogoliubov–de Gennes formalism, which takes the confinement potential explicitly into account and provides a microscopic fully coherent description of the system. We find an anharmonic nonlinear oscillation of the modulus of the superfluid order parameter, i.e., of the Higgs mode. This oscillation persists for large times with only a small amplitude modulation being visible. We connect the frequency and the mean value of this oscillation with the breaking of Cooper pairs in the superfluid phase. Additionally, we demonstrate that the occurrence of this persistent oscillation is connected to the onset of chaotic dynamics in our model. Finally, we calculate an interaction quench phase diagram of the Higgs mode for quenches on the BCS side of the BCS-BEC crossover and discuss its properties as a function of the aspect ratio of the cigar-shaped trap.

I. INTRODUCTION

Exploring collective excitations of quantum many-body systems provides key insights in order to gain a deeper understanding of the quantum nature of such systems. The nature of such collective excitations changes dramatically in the context of a spontaneously broken continuous symmetry like the U(1) symmetry present in solid-state physics, i.e., in superconducting and superfluid systems, as well as in the standard model of particle physics [\[1,2\]](#page-7-0). The spontaneous symmetry breaking (SSB) of the U(1) symmetry leads to the emergence of two fundamental collective modes: the massive (Higgs) amplitude mode and the massless (Goldstone) phase mode [\[2–4\]](#page-7-0). These collective modes are important probes of the many-body system.

Ultracold Fermi gases provide an ideal test bed to investigate the collective modes of superfluid systems, because they ensure a very high controllability of most relevant system parameters [\[5,6\]](#page-7-0). Using a Feshbach resonance [\[7\]](#page-7-0), the interactions in an ultracold Fermi gas can be tuned. A weak attractive interaction leads to a Bardeen-Cooper-Schrieffer (BCS) superfluid state and in the case of a strong attractive interaction the fermionic constituents form dimers which condensate in a Bose-Einstein condensate (BEC). Those two regimes are connected by the continuous BCS-BEC crossover [\[8\]](#page-7-0). With this control of the interaction, an excitation of the system may be evoked by changing the interaction strength instantaneously, i.e., on a timescale much faster than the characteristic timescales of the dynamics. Such an interaction quench can be exploited to obtain direct access to the collective modes of the system. The experimental implementation, however, remains challenging. It has been proposed to be done either by a radio-frequency (rf) flip of one spin state of the superfluid

to another spin state (cf. Ref. [\[9\]](#page-7-0)), which exhibits a different interaction strength due to the Feshbach resonance, or an optical control of a Feshbach resonance [\[10\]](#page-7-0).

Evidence of the Higgs mode has been found in various condensed matter and quantum gas systems, namely in charge density wave compounds $[11-16]$ $[11-16]$ and materials $[17-19]$, in NbN, Nb_{1−*x*}Ti_{*x*}N, and NbSe₂ superconductors [\[20–25\]](#page-8-0), in quantum antiferromagnets $[26-28]$, in the superfluid ³He [\[29,30\]](#page-8-0), in an ultracold bosonic gas in a two-dimensional (2D) optical lattice $[31,32]$, and recently in a ⁶Li Fermi gas by modulation spectroscopy [\[33\]](#page-8-0). However, a time-resolved detection of the nonadiabatic regime in the Higgs mode, as has been predicted [\[34,35\]](#page-8-0) and achieved in superconducting samples [\[20–22\]](#page-8-0), has not been reported so far for ultracold Fermi gases. Nevertheless, there are numerous theoretical studies devoted to the Higgs mode in ultracold Fermi gases and various superconducting systems [\[36–59\]](#page-8-0).

The topics covered in these studies include (i) a damped oscillation of the order parameter [\[36\]](#page-8-0), (ii) the dynamical vanishing of the order parameter [\[37,38\]](#page-8-0), (iii) relaxation and per-sistent oscillations of the order parameter [\[38–40\]](#page-8-0), (iv) spectroscopic signatures of nonequilibrium pairing in fermionic condensates [\[41\]](#page-8-0), (v) collective excitations in confined systems [\[42–47\]](#page-8-0) and in a 2D system [\[48\]](#page-8-0), (vi) an entire quantum quench phase diagram of the superfluid condensate [\[49,50\]](#page-8-0), (vii) collective modes in strongly disordered superconductors [\[51\]](#page-8-0), (viii) the Higgs mechanism and the stability of the BCS mean-field theory in the weak coupling limit [\[52\]](#page-8-0), (ix) the influence of phonon-mediated interactions $[53]$, (x) the Higgs mode in a moving condensate [\[54\]](#page-8-0), (xi) collective modes in a two-band BCS superconductor [\[55\]](#page-8-0), and (xii) the modes in the Fulde-Ferrell-Larkin-Ovchinnikov (FFLO) state [\[56–59\]](#page-8-0).

The general picture which emerges from the theory work is that the perturbation of a 3D system of interacting fermions leads to a variety of dynamical phases with properties quite distinct from the equilibrium ones. A classification of the nonequilibrium behavior arising from different excitations of the BCS state has been established for a three-dimensional homogeneous Fermi gas by calculating a quantum quench phase diagram, which has revealed three distinct phases [\[49\]](#page-8-0). In "phase I", the superfluid order parameter vanishes dynamically [\[37,38,49\]](#page-8-0), in "phase II", a damped oscillation with a $t^{-1/2}$ behavior was found [\[36,49\]](#page-8-0), and "phase III" is characterized by a persistent oscillation with a constant amplitude [\[38–40,49\]](#page-8-0). Furthermore, studies in nanostructured superconducting BCS systems where quantum confinement may strongly influence the superconducting pairing [\[60–66\]](#page-8-0) show an alteration of the damping in phase II depending on the geometry [\[43,44\]](#page-8-0) while in an inhomogeneous Fermi gas with a harmonic confinement in one dimension and a box potential in the other two dimensions the homogeneous behavior has been confirmed [\[45\]](#page-8-0).

In our previous articles, we have studied the dynamical phases I and II for a Fermi gas in a three-dimensional harmonic trap and we have found a confinement-induced fragmentation of the Higgs mode in phase II [\[46\]](#page-8-0) and an alteration of the dynamical vanishing in phase I due to the confinement [\[47\]](#page-8-0). In this paper, we continue investigating the impact of the confinement potential on the Higgs mode of a superfluid order parameter and present a numerical study of the dynamical phase III as well as a quench phase diagram in a cigar-shaped ultracold Fermi gas with a harmonic confinement.

The paper is organized as follows: Section \overline{II} introduces the model system and we will briefly sketch the used Bogoliubov– de Gennes formalism. In Sec. [III,](#page-2-0) we will analyze the persistent dynamics for interaction quenches starting deep in the BCS phase and ending in the BCS-BEC crossover regime. Finally, in Sec. [IV](#page-5-0) we discuss the interaction quench phase diagram of an inhomogeneous Fermi gas on the BCS side of the BCS-BEC crossover. Here, we focus on the dependence on the aspect ratio of our cigar-shaped harmonic trap. In Sec. [V,](#page-7-0) we provide a brief summary of the results obtained in the paper.

II. THEORETICAL MODEL

In our model, we consider an ultracold Fermi gas composed of fermionic ⁶Li atoms in two different internal spin states (labeled by \uparrow and \downarrow) with a balanced population, i.e., $N_{\uparrow} = N_{\downarrow} = N/2$. We choose a cigar-shaped harmonic confinement potential with an aspect ratio $r = f_{\perp}/f_{\parallel} \gg 1$ where *f*⊥ (*f*_|) is the radial (longitudinal) trap frequency. Further, we assume an attractive interaction between fermions of different spins with zero range such that its strength can be characterized by a single parameter, the so-called scattering length *a*. This is commonly done for *s*-wave scattering processes in ultracold gases and results in an effective contact potential $V_{\text{int}} = (4\pi \hbar a/m_0) \delta(\mathbf{r}) = g \delta(\mathbf{r})$, where m_0 is the mass of ⁶Li. Our treatment here is restricted to negative scattering lengths, i.e., to the BCS side of the BCS-BEC crossover. We aim at describing the superfluid phase which evolves in such an ultracold Fermi gas by means of the Bogoliubov–de Gennes (BdG) formalism.

In the following, we will sketch the formalism briefly; for a detailed discussion, we refer the reader to Refs. [\[46,67,68\]](#page-8-0). We start from the usual Hamiltonian for a contact interaction written in terms of the field operators. Then, we introduce the superfluid order parameter by applying a BCS-like mean-field approximation which yields the BdG Hamiltonian

$$
H_{\text{BdG}} = \sum_{\sigma} \int d^3 r \, \Psi_{\sigma}^{\dagger}(\mathbf{r}) H_0 \Psi_{\sigma}(\mathbf{r}) + \int d^3 r \, \Delta^*(\mathbf{r}) \Psi_{\downarrow}(\mathbf{r}) \Psi_{\uparrow}(\mathbf{r}) + \text{H.c.}, \qquad (1)
$$

where H_0 is the one-particle Hamiltonian including the kinetic energy of the bare atoms and the confinement potential. Then, the superfluid order parameter is defined by

$$
\Delta(\mathbf{r}) = g \langle \Psi_{\downarrow}(\mathbf{r}) \Psi_{\uparrow}(\mathbf{r}) \rangle. \tag{2}
$$

Here, $\Psi_{\sigma}(\mathbf{r})$ is a field operator annihilating an atom with spin *σ* at position **r**. In order to diagonalize the Hamiltonian in Eq. (1) and obtain the ground-state order parameter of the system, we introduce Bogoliubov's quasiparticles:

$$
\gamma_{na}^{\dagger} = \int u_n(\mathbf{r}) \Psi_{\uparrow}^{\dagger}(\mathbf{r}) + v_n(\mathbf{r}) \Psi_{\downarrow}(\mathbf{r}) d^3 r, \tag{3}
$$

$$
\gamma_{nb}^{\dagger} = \int u_n(\mathbf{r}) \Psi_{\downarrow}^{\dagger}(\mathbf{r}) - v_n(\mathbf{r}) \Psi_{\uparrow}(\mathbf{r}) d^3 r. \tag{4}
$$

The indices a/b result from the two spin species and $u_n(\mathbf{r})$ and $v_n(\mathbf{r})$ are the eigenfunctions of the corresponding eigenvalue problem of the Hamiltonian in Eq. (1) , the so-called BdG equation. Exploiting Anderson's approximation, which only considers pairing in time-reversed states [\[69\]](#page-8-0), we obtain the BdG eigenenergies $E_n = \sqrt{\varepsilon_n^2 + \Delta_n^2}$, where ε_n are the eigenenergies of the atoms in the trap and $\Delta_n = \langle n | \Delta(r) | n \rangle$. Here, we use $\Delta(\mathbf{r}) = \sum_{n} u_n(\mathbf{r}) v_n(\mathbf{r})$ and the eigenstates of the confinement potential $|m\rangle$. From the solution of the BdG equation, we obtain the well-known self-consistency equations for the order parameter and the chemical potential μ where the latter is determined by a given particle number *N*. We regularize and solve the obtained self-consistency equations numerically for $T = 0$ K, which yields the BdG eigenenergies and eigenfunctions. Here, the numerical cutoff is chosen such that all states with energies up to twice the Fermi energy E_F are considered. By inverting Bogoliubov's transformation, we obtain $\Delta(\mathbf{r})$ according to Eq. (2).

In order to excite a nonequilibrium state of the system, we consider an instantaneous change, i.e., a quench, of the scattering length $a_i \rightarrow a_f$. We assume that the change of the scattering length takes place on a timescale much faster than typical system reaction times. Thus, the density $n(\mathbf{r}) =$ $\langle \Psi_{\uparrow}^{\dagger} \Psi_{\uparrow} \rangle + \langle \Psi_{\downarrow}^{\dagger} \Psi_{\downarrow} \rangle$ immediately after the quench is the same as before, i.e., the system is in a nonequilibrium state with respect to the new interaction strength. In order to evaluate the subsequent dynamics, it is convenient to express the ground state of the initial system in terms of the eigenfunctions corresponding to the final ground state. This yields occupations $x_{ml} = \langle \gamma_{ma}^{\dagger} \gamma_{la} \rangle = \langle \gamma_{mb}^{\dagger} \gamma_{lb} \rangle$ and coherences $y_{ml} =$ $\langle \gamma_{ma}^{\dagger} \gamma_{lb}^{\dagger} \rangle = \langle \gamma_{lb} \gamma_{ma} \rangle^*$ of the density matrix instantaneously after the quench. However, an interaction quench does only introduce excitations which are diagonal, i.e., $x_{ml} =: x_m \delta_{ml}$ and $y_{ml} =: y_m \delta_{ml}$. These excitations provide the initial values for our nonadiabatic dynamics.

In the next step, we make use of Heisenberg's equation of motion and obtain coupled ordinary differential equations for the occupations and coherences. We solve these equations numerically and finally invert Bogoliubov's transformation in order to obtain the superfluid order parameter

$$
\Delta(\mathbf{r}, t) = g \sum_{n} 2 v_n(\mathbf{r}) u_n(\mathbf{r}) \left[x_n(t) - \frac{1}{2} \right]
$$

$$
+ u_n^2(\mathbf{r}) y_n^*(t) - v_n^2(\mathbf{r}) y_n(t). \tag{5}
$$

in terms of the occupations and coherences. This formalism provides the coherent quantum mechanical dynamics of an ultracold Fermi gas confined in a cigar-shaped harmonic trap in mean-field approximation. The numerical solution of the present formalism relies on Anderson's approximation and we will address its implications in the following.

Anderson's approximation applied to the BdG formalism results in an identical self-consistency equation for the ground state of the system as a multiband BCS Hamiltonian which only includes intraband Cooper pairing with zero center-ofmass momentum [\[70\]](#page-8-0). It was shown that also in the case of a confined system these states provide the most significant contribution to the Cooper pairing due to the interaction matrix elements involved [\[46,71\]](#page-8-0). Hence, the BdG formalism in Anderson's approximation realizes the extension to a confined system of the reduced BCS Hamiltonian, which has been employed to study the dynamical phases after an interaction quench before (see, e.g., Ref. [\[49\]](#page-8-0)).

In a confined system, Anderson's approximation has been discussed as well as numerically tested for systems with various geometries both in equilibrium and nonequilibrium. The studies include superconducting nanowires in the weakly interacting regime [\[60,63–65\]](#page-8-0) and cigar-shaped ultracold Fermi gases in the weakly interacting regime [\[71\]](#page-8-0) as well as in the BCS-BEC-crossover region [\[72\]](#page-9-0). These studies have observed slight quantitative deviations due to Anderson's approximation, which increase with increasing interaction strength. However, for both the weakly as well as the strongly interacting regime, no qualitative deviations in the properties of the superfluid ground state have been found.

The validity of Anderson's approximation in the dynamical case has been discussed in Ref. [\[43\]](#page-8-0) and is expected to hold if the excitation does not introduce further inhomogeneities, which is the case for all investigated interaction quenches. Furthermore, the order parameter dynamics in Anderson's approximation has been investigated numerically for quenches leading to phase II dynamics by solving the full BdG equation, which is, however, extremely demanding in terms of numerical resources. Therefore, those calculations can only be carried out for systems with a very small number of states [\[72\]](#page-9-0). In this previously published study, the initial and the final systems were both either situated in the BCS regime or in the BCS-BEC-crossover region. In both cases, the dynamics in Anderson's approximation have been found to be qualitatively correct with only slight quantitative deviations when compared to the solution of the full BdG equation [\[72\]](#page-9-0). Based on these findings, also the dynamics after quenches which lead to phase III dynamics are expected to be described qualitatively

FIG. 1. Spatiotemporal dynamics of the modulus of the order parameter after a sudden change of the scattering length from $1/(k_F a_i) = -2.0$ to $1/(k_F a_f) = -0.5$ and an aspect ratio of $r = 20$. $\tau_{trap} = h/\delta E = 1/(2f_{\parallel}) \approx 4.2$ ms is the characteristic timescale of the trap [\[46\]](#page-8-0).

correctly since both the initial and the final ground states as well as the dynamical approach have been shown to yield qualitatively correct results in Anderson's approximation.

III. PERSISTENT OSCILLATIONS IN THE INTERACTION QUENCH DYNAMICS

In this section, we will investigate interaction quenches which start in the BCS regime $[1/(k_F a_i) < -1]$ and end in the BCS-BEC crossover region $[-1] < 1/(k_F a_f) < 0$. Here, we follow the usual characterization of the coupling strength of the system in terms of $1/(k_F a)$, where we obtain $k_F =$ $\sqrt{(2m_0E_F)/\hbar^2}$ from the Fermi energy E_F by the dispersion relation of free atoms. In the following, we will discuss the spatiotemporal dynamics of the order parameter $\Delta(\mathbf{r},t)$ of an ultracold Fermi gas after such a quench.

In Fig. 1, we show the spatiotemporal dynamics of the order parameter after an interaction quench starting from an initial coupling of $1/(k_F a_i) = -2.0$ to a final coupling of $1/(k_f a_f) = -0.5$. We choose an aspect ratio of $r = 20$ with $f_{\parallel} = 120$ Hz. Furthermore, to ensure the comparability of the different systems considered in this paper, we choose a constant system parameter $s = E_F/(hf_{\perp}) = 5.5$ for all calculations with *h* being Planck's constant. This parameter characterizes the band structure which results from the cigar-shaped trap and the value of $s = 5.5$ is chosen such that the system size is small enough for a systematic numerical analysis and at the same time the quantum-size oscillations occurring for small systems are avoided [\[71\]](#page-8-0). In such a case, the results can easily be scaled to a larger system size by making use of the scaling relations which we discussed in Ref. [\[47\]](#page-8-0). Furthermore, the parameters chosen here are exemplary for strong quenches from the BCS regime toward the BCS-BEC crossover, as we will see later from the phase diagrams in Sec. [IV.](#page-5-0)

Figure $1(a)$ shows the order parameter instantaneously after the quench at $t = 0 \tau_{trap}$; i.e., the excitations introduced by the quench are already included. The striped distribution of $\Delta(\mathbf{r})$ —which is typical for the BCS regime—corresponds to the order parameter of the initial system scaled by a factor of a_f/a_i . In the subsequent dynamics in Fig. [1\(b\),](#page-2-0) we observe an increase of the order parameter which affects the whole trap and which finds its maximum at $t = 0.043 \tau_{trap}$, shown in Fig. $1(c)$. This rise in the order parameter is symmetrical with respect to the trap center and the striped structure in the initial distribution transforms into a monotonic distribution with a maximum in the center of the trap. This spatial distribution is characteristic in the BCS-BEC-crossover regime and results from the order parameter in the ground state of the final system. Figure $1(d)$ shows the succeeding minimum at $t =$ $0.083 \tau_{trap}$. Here, again the whole trap is affected and the order parameter is slightly larger than in the initial frame while it recovers its striped structure.

Overall, we find an oscillation that affects the whole trap while the spatial distribution of the gap oscillates between the distribution given by the ground states of the initial and of the final system, respectively. Hence, in this case the modulus of the spatially averaged order parameter correctly provides all information necessary, i.e., the frequency and amplitude of the oscillation for a detailed investigation. Hence, we introduce the spatially averaged order parameter

$$
\overline{\Delta}(t) = \left| \frac{1}{V} \int d^3 r \Delta(\mathbf{r}, t) \right|, \tag{6}
$$

where we set the volume to $V = [\hbar/(m_0\pi)]^{3/2} f_{\perp}^{-1} f_{\parallel}^{-1/2}$.

The time evolution of the modulus of the spatially averaged order parameter $\Delta(t)$ is shown in Fig. 2(a) normalized to the spatially averaged order parameter in the initial system Δ_i . We find an oscillation around the mean value Δ_{∞} (black dashed line), which is reduced compared to the ground-state value of the final system $\overline{\Delta}_f$ (solid red line). After a small initial damping, the oscillation persists for several τ_{trap} . Only a modulation of the amplitude is visible, opposed to the homogeneous case where the persistent oscillation features a constant amplitude [\[39,49\]](#page-8-0).

By investigating the Fourier transform of the order parameter, we observe that the persistent oscillation shows a pronounced nonlinear character: In Fig. $2(b)$, we show the Fourier spectrum of $\overline{\Delta}(t)$, which shows one dominant feature at $f_{\text{Higgs}} = 14.2(2 f_{\parallel})$ being smaller than twice the smallest Bogoliubov eigenenergies $2E_{min}/h = 22(2f_{\parallel})$ (red crosses). In contrast, in the linear case the spectrum is composed of a series of peaks given by twice the quasiparticle energies. This leads to linear dephasing dynamics of the Higgs mode which break down after τ_{trap} [\[46\]](#page-8-0). Hence, the absence of the breakdown in the persistent oscillation is a consequence of the nonlinear character. Additionally, we observe a further contribution in the spectrum around $28.5(2f_{\parallel})$, which corresponds to the second harmonic of the dominant frequency, indicating that the oscillation of $\Delta(t)$ is anharmonic. In order to illustrate this, we depict in Fig. $2(c)$ the phase space of the oscillation, i.e., $d/dt(\overline{\Delta})$ versus $\overline{\Delta}$, each being normalized to their corresponding maximum value. In this phase space, we find a trajectory, which is egg shaped. This demonstrates

FIG. 2. Amplitude mode of the spatially averaged order parameter after an interaction quench from $1/(k_F a_i) = -2.0$ to $1/(k_F a_i) =$ −0.5 with identical parameters as in Fig. [1:](#page-2-0) $r = 20$, $f_{\parallel} = 120$ Hz, and *s* = 5*.*5. (a) Time evolution of the spatially averaged order parameter $\overline{\Delta}(t)$ normalized to the spatially averaged order parameter in the ground state of the initial system $\overline{\Delta}_i$. $\overline{\Delta}_f$ is the spatially averaged order parameter of the final system in its ground state (red line) and Δ_{∞} is the mean value over the whole calculation time (black dashed line). (b) Fourier transformation of the signal in panel (a). E_k are the Bogoliubov quasiparticle eigenenergies (red crosses). (c) Phase space representation of the signal in panel (a) normalized to the corresponding maximum values.

the anharmonic character of the oscillation in accordance with what has been found in phase III in the homogeneous system $[49]$.

Summarizing, we observe an anharmonic nonlinear oscillation that persists after τ_{trap} where the amplitude is modulated. In the next step, we will investigate the origin of the frequency of the oscillation and of the reduction of the mean value in more detail and we will demonstrate that those two are interconnected.

An excitation of Bogoliubov quasiparticles in the BCS phase reduces the modulus of the order parameter [\[73\]](#page-9-0). This can be understood by considering that the population of Bogoliubov's quasiparticles x_k corresponds to the breaking of Cooper pairs. Bearing in mind that $|\Delta(\mathbf{r})|^2$ is proportional to the Cooper pair density [\[74\]](#page-9-0), it becomes apparent that such an excitation also reduces the modulus of the spatially averaged order parameter $\overline{\Delta}$ which sets the mean value of the oscillation. Furthermore, from dynamical studies in homogeneous systems it is known that the frequency of the Higgs mode, i.e., the oscillation frequencies of the modulus of the order parameter, is determined by the mean value of the modulus of the order parameter itself [\[34,35,49\]](#page-8-0). Hence, on the one hand a reduction of $\overline{\Delta}$ due to excitations leads to a reduction of the mean value Δ_{∞} and on the other hand it implies a reduction

FIG. 3. Frequency of the Higgs mode f_{Higgs} normalized to twice the smallest BdG quasiparticle energy 2*E*min (blue circles) and mean value Δ_{∞} of $\Delta(t)$ normalized to the ground-state value $\overline{\Delta}_{f}$ (orange pluses) for various quench strengths characterized by $1/(k_F a_i)$. The final coupling is $1/(k_F a_f) = -0.5$ and all other parameters are identical to Figs. [1](#page-2-0) and [2.](#page-3-0) The roman numerals mark phase II and phase III, respectively.

of *f*Higgs. Indeed, from our numerical data we do not only extract that this is the case. We also find that the reduction of f_{Higgs} is approximately given by the reduction of Δ_{∞} for all investigated quenches, as we show in Fig. 3.

Figure 3 shows the frequency of the Higgs mode f_{Higgs} normalized to twice the smallest BdG quasiparticle energy $2E_{\text{min}}$ (blue circles) for $r = 20$, and $\Delta_{\infty}/\overline{\Delta}_f$ for $r = 20$ (blue boxes) and $r = 50$ (orange crosses) as a function of $1/(k_F a_i)$, i.e., of the quench strength. Here, we choose the remaining parameters identical to Figs. [1](#page-2-0) and [2.](#page-3-0) We choose the normalization such that both quantities (f_{Higgs} and Δ_{∞}) are normalized to the value they take in the case of a linear dynamics induced by a weak quench. Both quantities in Fig. 3 decrease in the same nonlinear fashion when increasing the quench strength, i.e., when choosing a smaller initial coupling $1/(k_F a_i)$. From our data, we confirm that this close interconnection between f_{Higgs} and Δ_{∞} applies for all considered quenches and aspect ratios. This clearly shows a connection between both quantities. Furthermore, comparing $\Delta_{\infty}/\overline{\Delta}_f$ for $r = 20$ and $r = 50$ in Fig. 3 reveals that the decrease with increasing quench strength is independent of the aspect ratio *r*. In accordance with our preceding discussion, the reduction of Δ_{∞}/Δ_f is controlled by the initial quasiparticle occupations introduced at the time of the quench, which is confirmed by the numerical data. These initial quasiparticle occupations only depend on the quench strength but not on the aspect ratio *r* in the case of a constant system parameter *s*.

Overall, we have demonstrated that the decrease of f_{Higgs} and Δ_{∞} with increasing quench strength in the inhomogeneous system is caused by the breaking of Cooper pairs due to the creation of quasiparticle occupations. These excitations are introduced by the interaction quench and their occupation increases with the quench strength [\[47\]](#page-8-0) which leads to the observed reduction of f_{Higgs} and Δ_{∞} . In the next step, we will analyze the nonlinear nature of the oscillation further and we will show that our model system shows a chaotic signature when entering phase III of the quench dynamics.

In order to test whether the dynamics of the system is chaotic, we introduce a small perturbation and calculate the difference between the perturbed and unperturbed trajectory in phase space, which is in this case defined by the

FIG. 4. Temporal evolution of the logarithm of the relative difference in phase space $\ln(\Vert z'-z\Vert/\Vert z\Vert)$ between the two trajectories *z* and *z'*. The black line shows a linear fit for $t < 51 \tau_{trap}$ from which we extract the largest Lyapunov exponent $x_{Ly}^{(1)}$. The parameters are identical to those in Figs. [1](#page-2-0) and [2.](#page-3-0)

occupations and coherences. To this end, we add a randomized perturbation $\eta_k^{x/y}$ to the unperturbed initial values and we obtain the perturbed initial values $x'_k|_{t=0} = x_k|_{t=0} + \eta^x_k$ and $y'_k|_{t=0} = y_k|_{t=0} + \eta_k^y$. In the next step, we calculate the resulting trajectory $z' := z'(x'_1, \ldots, x'_{N_c}, y'_1, \ldots, y'_{N_c})$ together with the unperturbed trajectory $z := z(x_1, \ldots, x_{N_c}, y_1, \ldots, y_{N_c})$. Here, N_c is the number of states in the calculation set by the numerical cutoff. In order to measure the difference between these two trajectories in phase space, we use the norm [\[75\]](#page-9-0)

$$
||z|| = \frac{1}{N_c} \sqrt{\sum_{k} (|x_k|^2 + |y_k|^2)}.
$$
 (7)

For our numerical calculation, we choose all perturbations $\eta_k^{x/y}$ to be within the same order of magnitude and we ensure that the initial relative distance in phase space is small, i.e., $||z' - z||/||z|| \lesssim 10^{-8}$. With this choice, we ensure that the numerical errors per time step in our calculations, which we estimated to be on the order of 1×10^{-13} , are kept orders of magnitude smaller than the perturbation which provides reliable data [\[76\]](#page-9-0).

In Fig. 4, we illustrate the temporal evolution of the logarithm of the relative difference in phase space $\ln(\Vert z' - z \Vert / \Vert z \Vert)$ between the two trajectories. We find that $\ln(\Vert z' - z \Vert / \Vert z \Vert)$ oscillates with an underlying linear increase for $t < 55 \tau_{trap}$ which saturates for larger times. The saturation sets in at $\ln(\Vert z' - z \Vert / \Vert z \Vert) \approx 1$ which corresponds to a situation where the difference in phase space is equal to the norm of the trajectory itself. By this, the possibility of dealing with unbound trajectories is ruled out since $\ln(\Vert z \Vert)$ is bounded. Such a behavior is commonly considered as the signature of systems which exhibit chaos. In this case, the exponent of the exponential increase of $|z' - z| / |z|$ is the so-called first Lyapunov exponent $x_{Ly}^{(1)}$ which determines the behavior of the systems dynamics. We extract the Lyapunov exponent from the linear fit shown in Fig. 4 as $x_{Ly}^{(1)} \approx 0.38/\tau_{trap}$.

These results raise the question of whether the positive Lyapunov exponent indicating signatures of chaos is related to the confinement potential. To answer this question, we have performed corresponding calculations for a Fermi gas within the homogeneous BCS model, which revealed the

FIG. 5. Interaction quench phase diagrams of $\Delta_{\infty}/\overline{\Delta}_f$ for aspect ratios of $r = 20, 30, 40, 50,$ a longitudinal trap frequency of $f_{\parallel} = 120$ Hz, and a system parameter of $s = 5.5$. The dynamical phases I, II, and III are marked as I, II, and III, respectively.

same behavior. This demonstrates that signatures of chaos are characteristic for the phase III behavior both in homogeoeus and in confined Fermi gases.

Summarizing, we have analyzed the dynamics after an interaction quench from the deep BCS regime to the BCS-BEC-crossover region, i.e., the dynamical phase III. After the quench, we observe an anharmonic nonlinear oscillation where both the frequency and the mean value are reduced due to the breaking of Cooper pairs which is induced by the excitation of quasiparticles at the time of the quench. This oscillation is very robust with respect to the confinement potential and persists well after τ_{trap} with no confinement frequencies visible in the Fourier spectrum. Furthermore, we find that the dynamics in the BdG formalism after such a quench shows a clear signature of chaos. Having analyzed phase III in detail here and previously phase II in Ref. [\[46\]](#page-8-0) and phase I in Ref. [\[47\]](#page-8-0), we will in the following complete the picture by discussing the whole quench phase diagram for an inhomogeneous system. The following analysis is similar to what has been done for a homogeneous system in the thermodynamic limit [\[49\]](#page-8-0).

IV. QUENCH PHASE DIAGRAM

In this section, we will consider all types of interaction quenches possible on the BCS side of the BCS-BEC crossover which yields a dynamical quench phase diagram for an inhomogeneous ultracold Fermi gas. Further, we will discuss the effect of the aspect ratio *r* on the phase diagram. However, before we analyze this feature of the phase diagram we will locate the different phases in the phase diagram and we will briefly recall the characteristics of the two phases which have been analyzed in detail in previous publications, i.e., phase I $[47]$ and phase II $[46]$.

Figure 5 shows the interaction quench phase diagram for four different aspect ratios $r = 20, 30, 40,$ and 50. Here, we depict $\Delta_{\infty}/\overline{\Delta}_f$, which shows a distinct characteristic for each phase. We choose a longitudinal trap frequency of f_{\parallel} = 120 Hz and keep the system parameter $s = 5.5$ fixed in all

systems. Together with a given *r*, $1/(k_F a_i)$, and $1/(k_F a_f)$, this determines all remaining parameters.

Around the diagonal in each frame of Fig. 5, i.e., for weak quenches in both directions, we find that $\Delta_{\infty}/\overline{\Delta} \approx 1$ which corresponds to the linear dynamics of phase II. Here, the Higgs mode of the order parameter shows a damped oscillation which breaks down at τ_{trap} due to the dephasing of the linearly coupled occupations and coherences of the quasiparticle density matrix [\[46\]](#page-8-0).

In the lower right corner of the phase diagram (marked as I), we depict quenches from the BCS-BEC-crossover regime to the deep BCS regime. These interaction quenches lead to an initial exponential decay and a consecutive dynamical vanishing of the modulus of the order parameter, i.e., the evolution of a flat plateau with an almost vanishing average value. This vanishing is characterized by a small value of Δ_{∞}/Δ_f . The onset of the dynamical vanishing was found to depend crucially on the smallest quasiparticle energy of the final system $E_{\text{min}} = \text{Min}_k(E_k)$ which determines both the initial decay constant and the visibility of a plateau in the dynamics of $\overline{\Delta}(t)$ [\[47\]](#page-8-0). One aspect that has not been discussed previously is the increase of Δ_{∞}/Δ_f for very large quenches, visible by the slightly darker area in the lowest right corner. In this case, the strong interaction quench excites an oscillation with the transverse confinement frequency *f*[⊥] on top of the plateau. This oscillation then prevents the modulus of the order parameter to vanish further and, thus, leads to the observed increase of Δ_{∞}/Δ_f in the phase diagram.

Finally, in the upper left corner of the interaction quench phase diagrams in Figs. $5(a)$ – $5(d)$, we find phase III which has been discussed in Sec. [III](#page-2-0) and is identified by a smooth reduction of $\Delta_{\infty}/\overline{\Delta}_f$, as we have discussed above. We have found that the reduction of $\Delta_{\infty}/\overline{\Delta}_f$ is induced by the breaking of Cooper pairs at the time of the quench, which is independent of the aspect ratio *r*. With this characterization, we will now discuss the dependency of the quench dynamics on the aspect ratio by means of the obtained phase diagrams.

Comparing the four phase diagrams in Fig. 5, we observe that phase II around the diagonal and phase III in the upper left corner of the dynamical phase diagram remain essentially unchanged when changing the aspect ratio. This is expected, since we found that the breaking of Cooper pairs by quasiparticle excitations at the time of the quench leads to the observed reduction of $\Delta_{\infty}/\overline{\Delta}_{f}$. However, the amount of excitations induced only depends on the quench strength and not on the aspect ratio *r* in the case of a constant system parameter *s*, as discussed above.

In contrast, investigating the lower right corner of the dynamical phase diagram, i.e., phase I, there are changes in the transition visible. In the phase diagram for $r = 20$ in Fig. $5(a)$, a darker blue-green area is visible at the transition between phase I and phase II for $1/(k_F a_f) \le -1.5$. In comparison to the phase diagram for larger aspect ratios, we observe that the darker blue-green stripe, which starts at the quench from $1/(k_F a_i) = -1.0$ to $1/(k_F a_f) = -1.6$ for $r = 20$ and extends parallel to the diagonal, moves toward smaller effective interaction strength in the final system until it is not visible any more in the dynamical phase diagram for $r = 50$. The observed shift results from an increase of E_{min} with on the one hand the aspect ratio *r* and on the other hand the interaction strength in the final system $1/(k_F a_f)$: The feature we observe in the phase diagram, i.e., the darker blue-green area, occurs for an identical *E*min and quench strength for all aspect ratios *r*. Therefore, it shifts toward smaller effective interaction strength with an increasing aspect ratio *r* in order to account for the increase of *E*min with *r*. This shift takes place in accordance with the dependence of the onset of the dynamical vanishing order parameter we have previously found for phase I [\[47\]](#page-8-0). In addition, an analogous effect leads to the darkening blue-green feature for the quench from $1/(k_F a_i) = -0.3$ to $1/(k_F a_f) = -1.0$ with an increasing aspect ratio.

Furthermore, we observe that the slightly darker area in the far lower right corner of the phase diagram fades with an increasing aspect ratio. We understand this in terms of the oscillation with *f*[⊥] on top of the plateau: Since *f*[⊥] is increased with the aspect ratio, a stronger quench is necessary in order to excite the additional oscillation with the trap frequency. Hence, these oscillations become less pronounced with an increasing aspect ratio.

In order to highlight the dependence of the dynamical phase diagram on the aspect ratio *r*, we depict $\Delta_{\infty}/\overline{\Delta}_f$ versus the aspect ratio *r* for three exemplary quenches in Fig. 6. The first quench from $1/(k_F a_i) = -1.5$ to $1/(k_F a_f) = -0.7$ (red diamonds), which is located in the transition regime between phase II and phase III, clearly demonstrates that Δ_{∞}/Δ_f is independent of the aspect ratio r in the transition between phases II and III as discussed in Sec. [III.](#page-2-0)

The two other quenches in Fig. 6 are taken from the transition region between phase I and phase II. For the second quench from $1/(k_F a_i) = -1.1$ to $1/(k_F a_f) = -1.7$ (blue dots), we find a jump in $\Delta/\overline{\Delta}_f$ at $r = 30$, which corresponds to a shift of the onset of the dynamical vanishing to larger quench strengths with increasing aspect ratio. The same holds true for the third quench from $1/(k_F a_i) = -0.3$ to $1/(k_F a_f) = -1.0$ (black squares). However, here the jump of $\Delta_{\infty}/\overline{\Delta}_f$ at $r = 42$ is smaller and the shift as a function of the aspect ratio is less pronounced due to the larger effective interaction strength $1/(k_F a_f) = -1.0$, which leads to an exponentially larger *E*min. The observed behavior for both quenches is in full agreement with our previously published

FIG. 6. $\Delta_{\infty}/\overline{\Delta}_f$ in dependence on the aspect ratio *r* for three exemplary quenches from the phase diagrams in Fig. [5.](#page-5-0) All parameters are identical to those before and the dashed lines are a guide to the eye.

result of a shift in the transition quench strength to phase I with $1/E_{\text{min}}$ where we found that $E_{\text{min}} \sim r$ [\[47\]](#page-8-0).

In the last step, we will further investigate the chaotic signature of the dynamics in the obtained dynamical phase diagram. To this end, we will discuss the phase diagram of the first Lyapunov exponent $x_{Ly}^{(1)}$ which reflects the most unstable mode in the entire system. The analysis is carried out for a system with an aspect ratio of $r = 20$, which is an example for all other aspect ratios.

Figure 7 shows the phase diagram of the first Lyapunov exponent calculated by the numerical procedure presented in Sec. [III.](#page-2-0) We find $x_{Ly}^{(1)} = 0$ around the diagonal and in the lower right and lower left corners of the phase diagram. Furthermore, we observe two regions where the Lyapunov exponent takes a finite value: a stripe in the lower right part of the diagram and an extended region in the upper left corner. In the latter region, the Lyapunov exponent increases with an increasing coupling strength in the final system $1/(k_F a_f)$ while the dependence on the quench strength is nonmonotonic.

Comparing the results for $x_{Ly}^{(1)}$ to the phase diagram of $\Delta_{\infty}/\overline{\Delta}$ for *r* = 20 in Fig. [5\(a\)](#page-5-0) yields a good agreement between the area of phase III and a finite and positive

FIG. 7. Phase diagram of the Lyapunov exponent $x_{Ly}^{(1)}$ for $r = 20$ in units of $1/\tau_{trap}$. Because of our numerical implementation, we cannot expect $x_{Ly}^{(1)}$ to vanish identically. Instead, we see a very slow increase of $\ln(\Vert z' - z \Vert / \Vert z \Vert)$ even for small quenches which is not linear and saturates at values $\ln(\|z' - z\|/\|z\|) < -15$. In these cases, we set $x_{Ly}^{(1)} = 0$ since the characteristic of a chaotic system is not fulfilled.

Lyapunov exponent. Hence, we confirm that the emergence of the dynamical phase III is indeed connected to a chaotic signature of the dynamics, which occurs if both the quench strength and the final coupling strength are sufficiently large.

Furthermore, from comparing Fig. [7](#page-6-0) to Fig. $5(a)$, we obtain that the stripe-shaped region with a finite Lyapunov exponent corresponding to the transition regime between phase I and phase II. Here, we find a comparable situation as before: The quench strength, i.e., the distance to the diagonal (black line) is similar as for the onset of the chaos in phase III and the final coupling is still fairly large. As discussed above, this leads to a chaotic behavior of the system, whereas going deeper into phase I the coupling strength in the final system decreases and the dynamics is dominated by a dynamically vanishing order parameter, which is still nonlinear but does not show a chaotic signature due to the small coupling strength in the final system.

Overall, we have obtained the dynamical phase diagram for an inhomogeneous Fermi gas after an interaction quench. We find three distinct phases, in agreement with the phases obtained in a homogeneous system in the thermodynamic limit [\[49\]](#page-8-0). We have analyzed the occurrence of each phase in dependence of the aspect ratio *r*. We demonstrated that phase III and phase II are unaffected by the aspect ratio for a constant system parameter *s*. Further, we have discussed the changes in the onset of phase I in dependence on the aspect ratio, which agrees with our previously published results [\[47\]](#page-8-0). Overall, we have found that the three-dimensional harmonic confinement alters the onset of the dynamical vanishing in phase I, leads to a breakdown of the damped oscillation in phase II, and introduces an amplitude modulation in phase III. However, in phase III we have found no direct evidence of the confinement frequencies in the dynamics, making the persistent oscillations very robust with respect to the details of the confinement potential. Additionally, we have observed that the dynamics of phase III as well as in the transition region between phase I and phase II is connected to a chaotic behavior of the utilized BdG formalism.

V. CONCLUSION

In the current paper, we have analyzed the interaction quench dynamics of an ultracold Fermi gas quenched from the BCS regime to the BCS-BEC-crossover regime. In the

Higgs mode of the superfluid order parameter, we observe a nonlinear persistent oscillation with a small modulation of the amplitude. We have demonstrated that the frequency and the mean value of the oscillation are closely interconnected: Both are reduced simultaneously by the excitation of quasiparticles at the time of the quench which breaks Cooper pairs of the superfluid phase. These excitations are initially introduced at the time of the quench and hence they increase with increasing quench strength while they are independent of the aspect ratio for the case of a constant system parameter *s*. Moreover, we find that these persistent oscillations of phase III are robust toward the influence of the confinement potential and no signature of the confinement frequencies is imprinted on the dynamics in contrast to the dynamical phases I and II [\[46,47\]](#page-8-0). In a further step, we have numerically demonstrated that the occurrence of the persistent oscillation is connected with a finite Lyapunov exponent of the dynamics which clearly reveals the chaotic signature of the dynamics in phase III in the BdG model.

In Sec. [IV,](#page-5-0) we have presented an interaction quench phase diagram of the Higgs mode for an ultracold Fermi gas confined in a harmonic trap. We observe three phases in accordance with the quench phase diagram in a homogeneous system [\[49\]](#page-8-0). For weak quenches of either direction, we find a damped oscillation dominated by linearly coupled oscillators which shows a confinement-induced breakdown at τ_{tran} . However, we observe that the location of phase II in the phase diagram around the diagonal is independent of the aspect ratio of the confinement potential. For strong quenches ending in the deep BCS regime, we find a dynamical vanishing of the order parameter with a revival of the order parameter at τ_{trap} . The onset of phase I is controlled by the ground-state properties of the system, i.e., by *E*min, which are controlled by the confinement potential. This is reflected in the dependence of the dynamical phase diagram on the aspect ratio. Finally, for large quenches towards the BCS-BEC crossover, we find persistent nonlinear oscillations which are connected to a reduction of $\Delta_{\infty}/\overline{\Delta}_f$. The oscillations have been found to be robust toward any imprinting of the confinement frequencies and Δ_{∞}/Δ_f has been found to be independent of the aspect ratio. Therefore, the dynamical phase III as well as the transition between phase II and phase III is unaffected by a change of the aspect ratio, as we have demonstrated in the dynamical phase diagram.

- [76] We estimate the local error of the Runge-Kutta 4(5) method to 1×10^{-13} by comparing the results of fourth- and fifthorder method while the initial perturbations are on the order of $\eta_k \sim 1 \times 10^{-11}$. Furthermore, we estimate the overall noise

of our numerical approach by applying it to the set of linearized equations of motion, which cannot show chaotic behavior. This y ields $\ln(||z' - z||/||z||) < -14$ for a quench from $1/(k_F a_i) =$ -1.1 to $1/(k_F a_f) = -1.0$ with all other parameters identical to those in Fig. [4.](#page-4-0) From this we extract that the global noise level of the calculation of the Lyapunov exponent is well controlled, which is representative for all our calculations. Additionally, we have double checked the quantitative accuracy of our approach to calculate the Lyapunov exponent to the approach presented in Ref. [77], which yields good agreement. An advantage of our approach is the observed saturation of $\ln(||z' - z||/||z||)$ which allows us to directly rule out unbound trajectories.
