In their study of superluminal propagation, rotary drag, and surface polaritons [Khan *et al.*, [Phys. Rev. A](https://doi.org/10.1103/PhysRevA.96.013848) **[96](https://doi.org/10.1103/PhysRevA.96.013848)**, [013848](https://doi.org/10.1103/PhysRevA.96.013848) [\(2017\)](https://doi.org/10.1103/PhysRevA.96.013848); **[96](https://doi.org/10.1103/PhysRevA.96.049906)**, [049906\(E\)](https://doi.org/10.1103/PhysRevA.96.049906) [\(2017\)](https://doi.org/10.1103/PhysRevA.96.049906)], the authors consider a four-level atomic arrangement with transitions in the optical domain. In fact, the values they give to the parameters lead to a probe wavelength lying in the decimeter band and we point out that, in such conditions, all their results are irrelevant.

DOI: [10.1103/PhysRevA.99.057801](https://doi.org/10.1103/PhysRevA.99.057801)

In their study of superluminal propagation, rotary drag, and surface polaritons [\[1,2\]](#page-1-0), Khan *et al.* consider a four-level atomic arrangement with transitions in the optical domain. See Fig. 1(a) in Ref. [\[1\]](#page-1-0). On the other hand, they specify in Ref. [\[2\]](#page-1-0) that all the (angular) frequencies are given in units of  $\gamma = (2\pi) \times 1$  MHz and that the probe frequency  $v_p =$ 1000 $\gamma$ . The corresponding wavelength is thus  $\lambda_p = 30 \text{ cm}$ (in the decimeter band). As shown in the following this invalidates all the results given in Refs. [\[1,2\]](#page-1-0).

As correctly given in Ref. [\[1\]](#page-1-0), the electric susceptibility for the probe reads, in SI units,

$$
\chi = \frac{2N|\wp_{ac}|^2 \rho_{ac}}{\varepsilon_0 \hbar \Omega_p},\tag{1}
$$

where *N* is the atomic number density, *a* (*c*) is the upper (lower) level of the probe transition,  $\mathcal{G}_{ac}$  ( $\rho_{ac}$ ) is the corresponding matrix element of the dipole moment (of the density operator), and  $\Omega_p$  is the Rabi (angular) frequency of the probe. Expressing the susceptibility as a function of the probe wavelength as made to obtain Eq. (5) in Refs. [\[1,2\]](#page-1-0) can be achieved by introducing the Einstein's coefficient *Aac* associated with the transition  $a \to c$ . From its expression given in Ref. [\[3\]](#page-1-0), we get

$$
|\wp_{ac}|^2 = \left(\frac{3\lambda_p^3}{8\pi^2}\right) \hbar \varepsilon_0 A_{ac},\tag{2}
$$

and finally

$$
\chi = \left(\frac{3N\lambda_p^3}{32\pi^3}\right) \left(\frac{8\pi A_{ac}}{\Omega_p}\right) \rho_{ac}.
$$
 (3)

The expression  $\chi = (\frac{3N\lambda_p^3}{32\pi^3\Omega_p})\rho_{ac}$  given by Eq. (5) in Ref. [\[2\]](#page-1-0) thus holds only if  $\Omega_p$  is expressed in units of  $8\pi A_{ac}$ . According to the above choice of  $\gamma$  as unit of (angular) frequency, this implies that  $8\pi A_{ac} = \gamma$ .

It is specified in Ref. [\[2\]](#page-1-0) that "the susceptibility and group index plotted versus probe detuning have units of  $2N|\mathcal{G}_{ac}|^2/\mathcal{E}_0\hbar$ ." As shown in Eq. (1), this quantity has the dimension of an angular frequency and, for consistency, it should also be expressed in units of  $\gamma$ . It then reads  $u_{\gamma} =$  $2N|\mathcal{G}_{ac}|^2/\mathcal{E}_0\hbar\gamma$  and, taking into account the above relations,

$$
u_{\chi} = \left(\frac{3N\lambda_p^3}{32\pi^3}\right). \tag{4}
$$

For wavelengths  $\lambda_p$  in the visible domain and typical values of the atomic number density *N*, the susceptibility unit *u*<sup>χ</sup> given by Eq. (4) is in the order of  $3 \times 10^{-3}$ . On the other hand, for  $\lambda_p = 30$  cm with  $N = 5 \times 10^{12}$  cm<sup>-3</sup> as considered in Ref. [\[2\]](#page-1-0), this unit rises to  $u_x \approx 4 \times 10^{14}$ . Figure 2 in Ref. [2] shows that the peak value of the *relative* susceptibility  $\chi/u_{\chi}$  can exceed 5 <sup>×</sup> <sup>10</sup>−3. The corresponding *absolute* susceptibility  $\chi$  is then in the order of  $10^{12}$ . *Such values are meaningless.* 

Although this point is less important, we note that, in SI units, the refractive index reads  $n = \sqrt{1 + \chi}$  and not  $n =$  $\sqrt{1+4\pi\chi}$  as used in Ref. [\[1\]](#page-1-0) to determine the group index. Anyway, the approximation  $n \approx 1 + 2\pi \chi$  also made to obtain Eq. (6) in Ref. [\[1\]](#page-1-0) fails when  $|\chi| \gg 1$ .

Without examining in detail the parts of  $[1,2]$  devoted to rotary drag and surface polaritons, we remark that these phenomena occur when the sample thickness *L* is large compared to the probe wavelength  $\lambda_p$ . According to [\[2\]](#page-1-0),  $L = 10$  cm and this condition is far from being fulfilled since this thickness is only one-third of the probe wavelength. By the way, we also note the incompatibility of Figs. 3(b) and 4 in Ref. [\[2\]](#page-1-0) which show rotary drags, respectively, in the order of 10−<sup>2</sup> and  $10^{-7}$  rad.

Khan *et al.* support their choice of the ratio  $v_p/\gamma = 1000$ by referring to a paper on the phase control of light velocity [\[4\]](#page-1-0). The same ratio  $v_p/\gamma$  was actually considered in this paper but without specifying the absolute value of the frequencies. We, however, point out that, for a probe frequency in the visible domain, this ratio leads to lifetimes of the excited atomic levels which are fully unrealistic (in the subpicosecond domain).

<span id="page-1-0"></span>Independently of the above criticisms, we remark that, quite generally, large negative group delays are not a sufficient condition to observe significant effects of superluminal propagation. A convincing demonstration of such effects would have required a comparison of the transmitted and incident pulses, which is not made in  $[1,2]$ .
