The studies of multimagnon excitations will extend our understandings of quantum magnetism and strongly correlated matters. Here, by using the time-evolving block decimation algorithm, we investigate the Bloch oscillations of two-magnon excitations under a gradient magnetic field. Through analyzing the symmetry of our Hamiltonian, we derive a rigorous and general relation between ferromagnetic and antiferromagnetic systems. Under strong interactions, in addition to free-magnon Bloch oscillations, fractional bounded-magnon Bloch oscillations appear which can be understood by an effective single-particle model. To extract the frequencies of Bloch oscillations and determine the gradient of the magnetic field, we analyze the fidelity and the substandard deviation in both time and frequency domains. Our study not only explores the interaction-induced Bloch oscillations of multimagnon excitations, but also provides an alternative approach to determine the gradient of the magnetic field via ultracold atoms in optical lattices.

I. INTRODUCTION

The Heisenberg spin chain, a paradigmatic model in many-body physics, is a benefit to studying collective excitations and low-energy properties of quantum magnets. In particular, the elementary aspects of quantum magnetism can be well described by spin excitations. The spin-wave theory provides the fundamental insight that magnons are quasiparticle excitations over ferromagnetic ground states [1,2]. The Bethe ansatz has predicted the existence of magnon bound states (BSs) in Heisenberg chains [3]. It renders an attractive research subject to identify the signatures of magnons [4–7]. The quench dynamics is considered an effective way to probe magnon BSs [8,9]. It has demonstrated that ultracold atomic ensembles offer an ideal platform to simulate spin excitations [10,11]. In particular, single-magnon excitations and multimagnon BSs have been observed in cold-atom experiments [12,13].

In contrast, if a constant force is applied, a quantum particle in a periodic potential will undergo Bloch oscillations (BOs) [14,15]. The BOs have been directly observed with ultracold atoms [16–18]. In multiparticle systems, interparticle interaction will have a huge influence on the BOs. For a strongly interacting few-body system, fractional BOs can arise at a Bloch frequency double (or integer multiple) that of single-particle BOs [19]. Fractional BOs have been studied in various systems, such as photonic systems [20,21], cold-atom systems [22–24], and electronic systems [25]. In addition, BOs of magnetic solitons have been studied theoretically in spin chain systems [26,27]. Similar to the BOs of an electron in a static electric field, the single-magnon dynamics in spin chains subjected to a gradient magnetic field has been examined

[28–30]. However, the BOs of multimagnon excitations are still unclear, in particular how to characterize and extract the effects induced by the intermagnon interactions.

This paper aims to explore the two-magnon dynamics in the Heisenberg spin chain under a gradient magnetic field. We provide a dynamical symmetry analysis to explore the relation between ferromagnetic and antiferromagnetic systems. By analyzing the spin distributions and longitudinal spin-spin correlations, we track the dynamical difference for different interactions via the time-evolving block decimation (TEBD) algorithm [31,32]. From the time evolution of spin distributions and longitudinal spin-spin correlations, we find the dynamical signature from free-magnon BOs to bounded-magnon BOs. We also calculate the fidelity and substandard deviation to extract the multifrequency BOs and determine the gradient of the magnetic field.

This paper is organized as follows. In Sec. II we describe the Heisenberg XXZ chain within a gradient magnetic field and analyze its symmetry. In Sec. III we simulate the BOs of two-magnon excitations via the TEBD algorithm. In Sec. IV we calculate the fidelity and the substandard deviation. In Sec. V we give a brief summary and discussion.

II. MAGNON EXCITATIONS AND THEIR DYNAMICAL SYMMETRY

We consider a spin-1/2 Heisenberg XXZ chain in the presence of a gradient magnetic field

$$\hat{H} = \sum_{l=-L}^L \left(\frac{J}{2} \hat{S}_l^+ \hat{S}_{l+1}^- + \text{H.c.} + \Delta \hat{S}_l^z \hat{S}_{l+1}^z + lB \hat{S}_l^z \right). \quad (1)$$

Here \hat{S}_l^i ($i = x, y, z$) are spin-1/2 operators for the l th site ($l = -L, \dots, 0, \dots, L$), $\hat{S}_l^\pm = \hat{S}_l^x \pm i\hat{S}_l^y$ are spin raising and lowering

*lichao2@mail.sysu.edu.cn

operators for the l th site, J is the spin exchange energy which is set as unity (i.e., $J = \hbar = 1$), Δ is the interaction between nearest-neighbor spins, and B is the magnetic-field gradient.

When $B = 0$, there are three types of ground states: the critical phase in $-1 < \Delta < 1$, the ferromagnetic phase in $\Delta < -1$, and the antiferromagnetic phase in $\Delta > 1$. In the ferromagnetic phase regime $\Delta < -1$, the excitation of a magnon is equal to the flipping of one spin. For a sufficiently large ferromagnetic interaction $\Delta \ll 0$, the ground state is a completely ferromagnetic state $|\mathbf{0}\rangle$ with all spins downward $|\downarrow\downarrow\downarrow\cdots\downarrow\rangle$ or upward $|\uparrow\uparrow\uparrow\cdots\uparrow\rangle$. The multimagnon excitations can be prepared by flipping spins in the completely ferromagnetic state.

The Hamiltonian (1) exhibits a U(1) symmetry under global spin rotations around the z axis and the number of its total spin $\hat{S}^z = \sum_l \hat{S}_l^z$ is conserved (i.e., $[\hat{H}, \hat{S}^z] = 0$). This means that the subspaces with different numbers of magnon excitations are decoupled. Using the mapping $\{|\downarrow\rangle \leftrightarrow |0\rangle, |\uparrow\rangle \leftrightarrow |1\rangle, \hat{S}_l^+ \leftrightarrow \hat{a}_l^\dagger, \hat{S}_l^- \leftrightarrow \hat{a}_l, \hat{S}_l^z \leftrightarrow \hat{n}_l - \frac{1}{2}\}$, the Hamiltonian (1) can be mapped onto $\hat{H} = \sum_l (\frac{J}{2} \hat{a}_l^\dagger \hat{a}_{l+1} + \text{H.c.} + \Delta \hat{n}_l \hat{n}_{l+1} + B l \hat{n}_l)$, with $\hat{n}_l = \hat{a}_l^\dagger \hat{a}_l$. Here \hat{a}_l^\dagger (\hat{a}_l) is particle creation (annihilation) operator at the l th site and they satisfy the commutation relations of hard-core bosons. Thus one can understand the magnon excitations in the picture of a hard-core bosonic system.

Intermagnon interaction is a key ingredient in the formation of BSs and also has an influence on the dynamics. Intuitively, ferromagnetic interactions ($\Delta < 0$) and antiferromagnetic ones ($\Delta > 0$) may affect the dynamics in different ways. Nevertheless, a symmetry protected dynamical symmetry (SPDS) theorem [33] reveals a symmetric relation of the time evolution observable between the repulsive and attractive systems, i.e., dynamical symmetry. Combining with the time-reversal operator \hat{R} and a unitary operator \hat{W} , an antiunitary operator \hat{Q} is defined as $\hat{Q} = \hat{R}\hat{W}$. The SPDS theorem indicates that if the system follows three conditions, i.e., $\{\hat{Q}, \hat{H}'\} = 0$, $[\hat{Q}, \hat{H}''] = 0$ for the two parts of the Hamiltonian $\hat{H} = \hat{H}' + \hat{H}''$, $\hat{Q}^{-1}|\psi(0)\rangle = e^{i\theta}|\psi(0)\rangle$ for the initial state $|\psi(0)\rangle$ with θ a global phase factor, and $\hat{Q}^{-1}\hat{O}\hat{Q} = \pm\hat{O}$ for a certain observable \hat{O} , the system is able to manifest an interaction-induced dynamical symmetry for the time evolution of a certain observable.

According to the SPDS theorem, we divide the Hamiltonian (1) into two parts $\hat{H} = \hat{H}' + \hat{H}''$ with

$$\hat{H}' = \frac{1}{2} \sum_l (\hat{S}_l^+ \hat{S}_{l+1}^- + \hat{S}_l^- \hat{S}_{l+1}^+) \quad (2)$$

and

$$\hat{H}'' = \Delta \sum_l \hat{S}_l^z \hat{S}_{l+1}^z + \sum_l l B \hat{S}_l^z. \quad (3)$$

For the system with only nearest-neighbor spin exchange, one can decompose it as an odd lattice \mathcal{A} and even lattice \mathcal{B} , and thus we can define an operator \hat{W} related to the bipartite lattice symmetry

$$\hat{W}^{-1} \hat{S}_l^- \hat{W} = \begin{cases} \hat{S}_l^- & \text{if } l \in \mathcal{A} \\ -\hat{S}_l^- & \text{if } l \in \mathcal{B}. \end{cases} \quad (4)$$

For the time-reversal operator \hat{R} , $\hat{R}^{-1}i\hat{R} = -i$, it is easy to conclude that

$$\begin{aligned} \hat{R}^{-1} \hat{S}_l^+ \hat{S}_{l+1}^- \hat{R} &= \hat{R}^{-1} (\hat{S}_l^x + i\hat{S}_l^y) (\hat{S}_{l+1}^x - i\hat{S}_{l+1}^y) \hat{R} \\ &= \hat{S}_l^+ \hat{S}_{l+1}^- \end{aligned} \quad (5)$$

and

$$\hat{R}^{-1} \hat{S}_l^z \hat{S}_{l+1}^z \hat{R} = \hat{S}_l^z \hat{S}_{l+1}^z. \quad (6)$$

Thus \hat{H}' and \hat{H}'' satisfy, respectively, the relations

$$\begin{aligned} \hat{Q}^{-1} \hat{H}' \hat{Q} &= \frac{1}{2} \sum_l \hat{W}^{-1} \hat{R}^{-1} (\hat{S}_l^+ \hat{S}_{l+1}^- + \hat{S}_l^- \hat{S}_{l+1}^+) \hat{R} \hat{W} \\ &= \frac{1}{2} \sum_l (\hat{W}^{-1} \hat{S}_l^+ \hat{W} \hat{W}^{-1} \hat{S}_{l+1}^- \hat{W} \\ &\quad + \hat{W}^{-1} \hat{S}_l^- \hat{W} \hat{W}^{-1} \hat{S}_{l+1}^+ \hat{W}) \\ &= -\hat{H}' \end{aligned} \quad (7)$$

and

$$\begin{aligned} \hat{Q}^{-1} \hat{H}'' \hat{Q} &= \sum_l \hat{W}^{-1} (\Delta \hat{S}_l^z \hat{S}_{l+1}^z + l B \hat{S}_l^z) \hat{W} \\ &= \sum_l \hat{W}^{-1} (4\Delta [\hat{S}_l^+, \hat{S}_l^-] \cdot [\hat{S}_{l+1}^+, \hat{S}_{l+1}^-] \\ &\quad + 2l B [\hat{S}_l^+, \hat{S}_l^-]) \hat{W} \\ &= \hat{H}'' \end{aligned} \quad (8)$$

with $\hat{S}_l^z = 2[\hat{S}_l^+, \hat{S}_l^-]$. This antiunitary operator \hat{Q} ensures that \hat{Q} anticommutes with \hat{H}' and commutes with \hat{H}'' ,

$$\{\hat{Q}, \hat{H}'\} = 0, \quad [\hat{Q}, \hat{H}''] = 0. \quad (9)$$

Below we concentrate on discussing the time evolution from the initial state of two-magnon excitations over the fully ferromagnetic state $|\psi(0)\rangle = \hat{S}_{l_1}^+ \hat{S}_{l_2}^+ |\mathbf{0}\rangle$, where $|\mathbf{0}\rangle = |\downarrow\downarrow\downarrow\cdots\downarrow\rangle$ and $l_1 \neq l_2$. Obviously, the initial state is invariant under the transformation \hat{Q} ,

$$\hat{Q}^{-1} |\psi(0)\rangle = -|\psi(0)\rangle, \quad (10)$$

but a global phase factor appears. The spin correlations $\hat{S}_{l'}^z \hat{S}_{l''}^z$ between sites l' and l'' satisfy

$$\hat{Q}^{-1} \hat{S}_{l'}^z \hat{S}_{l''}^z \hat{Q} = \hat{S}_{l'}^z \hat{S}_{l''}^z. \quad (11)$$

Defining

$$C_{l', l''}(t) = \langle \psi(t) | \hat{S}_{l'}^z \hat{S}_{l''}^z | \psi(t) \rangle \quad (12)$$

from Eqs. (9)–(11) and $\hat{Q}^{-1} e^{-iHt} \hat{Q} = e^{\hat{Q}^{-1}(-iHt)\hat{Q}}$, we obtain

$$\begin{aligned} C_{l', l''}(t)_{(\Delta, B)} &= \langle \psi(0) | e^{i(\hat{H}' + \hat{H}'')t} \hat{S}_{l'}^z \hat{S}_{l''}^z e^{-i(\hat{H}' + \hat{H}'')t} | \psi(0) \rangle \\ &= \langle \psi(0) | \hat{Q} e^{i(\hat{H}' + \hat{H}'')t} \hat{Q}^{-1} \hat{S}_{l'}^z \hat{S}_{l''}^z \hat{Q} e^{-i(\hat{H}' + \hat{H}'')t} \hat{Q}^{-1} | \psi(0) \rangle \\ &= \langle \psi(0) | e^{i(\hat{H}' - \hat{H}'')t} \hat{S}_{l'}^z \hat{S}_{l''}^z e^{-i(\hat{H}' - \hat{H}'')t} | \psi(0) \rangle \\ &= C_{l', l''}(t)_{(-\Delta, -B)}. \end{aligned} \quad (13)$$

This means that the time-dependent spin correlation is the same when we simultaneously change the signs of the interaction Δ and magnetic-field gradient B . We can find a direct

FIG. 1. Dynamical symmetry of spin correlations under the parameters (Δ, B) and $(-\Delta, B)$. The time evolution of two-spin correlations at the 9th and 10th sites with ferromagnetic interaction (left half) and the ones at the -10 th and -11 th sites with antiferromagnetic interaction (right half).

connection between the spin correlations with Δ and B and with $-\Delta$ and $-B$. Different from the single-point operators in [33], we extend its conclusions to a two-point operator.

When the sign of the gradient magnetic field is flipped, the system (1) is equivalent if we reverse the lattice around the centroid position of the initial state $l_c^i = \frac{l_1^i + l_2^i}{2}$, that is, the lattice index is changed from l to $2l_c^i - l$. Then we have

$$C_{l',l''}(t)_{(-\Delta,-B)} = C_{2l_c^i-l',2l_c^i-l''}(t)_{(-\Delta,B)}. \quad (14)$$

Combining (13) and (14), we can conclude that

$$C_{l',l''}(t)_{(\Delta,B)} = C_{2l_c^i-l',2l_c^i-l''}(t)_{(-\Delta,B)}. \quad (15)$$

The relation (15) indicates that when the sign of the interaction Δ is changed, the time evolution of the spin correlation is symmetric about the centroid position l_c^i of the initial state. This is to say, once we know the spin correlation under ferromagnetic interactions, we can deduce the results under antiferromagnetic interactions. Therefore, below we consider only the system with ferromagnetic interactions $\Delta < 0$.

In Fig. 1, starting from the initial state $|\psi(0)\rangle = \hat{S}_{-1}^+ \hat{S}_0^+ |\mathbf{0}\rangle$, we compare the spin correlation $C_{-10,-11}(t)$ with antiferromagnetic interaction $(-\Delta)$ and the spin correlation $C_{9,10}(t)$ with ferromagnetic interaction (Δ) . The parameters are chosen as $\Delta = -1.5$, $B = 0.05$, and the total chain length $L_t = 101$. The numerical results completely follow the relation (15).

III. SIGNATURE OF BLOCH OSCILLATIONS IN SPIN CORRELATIONS

In this section we consider how the interactions affect the dynamics of spin excitations under a gradient magnetic field. Here the initial state is chosen as $|\downarrow \cdots \downarrow \uparrow \uparrow \downarrow \cdots \downarrow\rangle$, which means two-magnon excitations at adjacent sites. In the time evolution, the spin excitations will undergo BOs. To show the interaction effects on BOs, we calculate the spin distributions

$$S_l^z(t) = \langle \psi(t) | \hat{S}_l^z | \psi(t) \rangle \quad (16)$$

as a function of time, and the instantaneous longitudinal spin-spin correlations $C_{l',l''}(t)$ between sites l' and l'' among the spin chain. In the absence of interaction, we recover the results of traditional individual-particle BOs with frequency $\omega_B = B$.

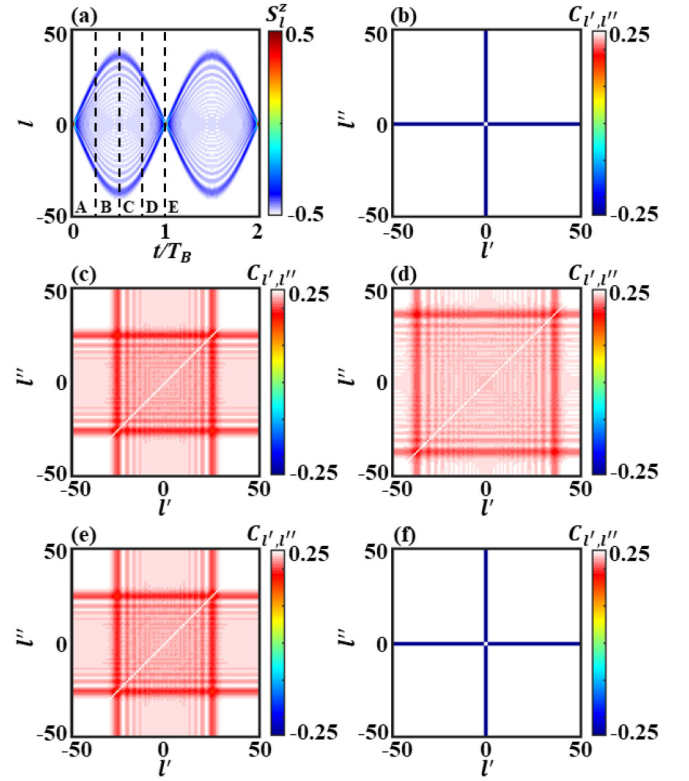

FIG. 2. Bloch dynamics of free magnons. (a) Spin distributions S_l^z versus the rescaled time t/T_B . (b)–(f) Longitudinal spin-spin correlations $C_{l',l''}$ at different times marked as A–E in (a). The parameters are chosen as $\Delta = 0$, $B = 0.05$, and the total chain length $L_t = 101$.

Under strong interaction, we find a doubled Bloch frequency $\omega_B^{\text{eff}} = 2B$, which indicates the appearance of interaction-induced fractional BOs of magnon BSs. In the moderate-interaction case, we find the coexistence of individual-particle and bound-state BOs.

A. Dynamics of free magnons

We first consider the BOs of magnons in a noninteracting system. The eigenvalues form a Wannier-Zeeman ladder with equidistant level spacing $\Delta E = B$ [34], which directly gives the Bloch frequency. We numerically compute the time evolution of the longitudinal spin-spin correlations via the TEBD algorithm. The parameters are $\Delta = 0$, $B = 0.05$, and the total chain length $L_t = 101$. The noninteracting magnons independently undergo BOs with period $T_B = \frac{2\pi}{B}$ [see Fig. 2(a)]. The free magnons periodically widen and shrink in an interval [35]

$$|l| < \frac{2}{B} \left| \sin \frac{Bt}{2} \right| = l_b. \quad (17)$$

Since there is no interaction, each magnon behaves as a free particle and the time evolution recovers the breathing mode in the single-particle BOs.

Now we discuss the connection between the longitudinal spin-spin correlations $C_{l',l''}$ and the two-magnon correlations $\Gamma_{l',l''}(t) = \langle \psi(t) | \hat{S}_{l'}^+ \hat{S}_{l''}^+ \hat{S}_{l''}^- \hat{S}_{l'}^- | \psi(t) \rangle$. The two-magnon correlations $\Gamma_{l',l''}$ describe the probability of detecting one magnon at

site l' and the other one at site l'' . From their definitions, one can find

$$C_{l',l''} = \Gamma_{l',l''} - \frac{1}{2}S_{l'}^z - \frac{1}{2}S_{l''}^z - \frac{1}{4}, \quad (18)$$

with $l' \neq l''$ (see Appendix C for more details). Due to $(\hat{S}_l^z)^2 = 0.25$, the longitudinal spin-spin correlations $C_{l',l''}$ are always equal to 0.25 for $l' = l''$. Therefore, we set $C_{l',l''} = 0.25$ as the background value of the longitudinal spin-spin correlations. As every site in the region of $|l| > l_b$ is spin down and $\Gamma_{l',l''} = 0$ in the region of $|l| > l_b$ or $|l''| > l_b$, the relation (18) is further given as

$$C_{l',l''} = \begin{cases} -\frac{1}{2}S_{l'}^z & \text{if } |l''| > l_b, l' \neq l'' \\ -\frac{1}{2}S_{l''}^z & \text{if } |l'| > l_b, l'' \neq l'. \end{cases} \quad (19)$$

Thus, (i) in the region of $|l'| < l_b$ and $|l''| > l_b$, $C_{l',l''}$ show fringes and may not equal the background value 0.25, and (ii) in the region of $|l'| > l_b$ and $|l''| > l_b$, $C_{l',l''} = \langle \psi(t) | \hat{S}_{l'}^z \hat{S}_{l''}^z | \psi(t) \rangle = (-0.5) \times (-0.5) = 0.25$.

Different from $C_{l',l''}$, only in the region of $(-l_b, l_b)$ are $\Gamma_{l',l''}$ nonzero. Obviously, the cross-overlapping region in $C_{l',l''}$ is consistent with the region of nonzero $\Gamma_{l',l''}$. The significant $\Gamma_{l',l'+1}$ correspond to the BOs of bounded magnons. If there is no significant $\Gamma_{l',l'+1}$, the BOs of free magnons dominate.

As an example, in Fig. 2(d), when the spin excitations propagate to $l_b = 40$ at $t_b = T_B/2$, in the region of $|l| < 40$ we have $-0.5 \leq S_l^z(t) \leq 0.5$, while in the region of $|l| > 40$ we have $S_l^z(t) = -0.5$. From the relation (19), in the four corners of $|l'| > 40$ and $|l''| > 40$, $C_{l',l''} = \langle \hat{S}_{l'}^z \hat{S}_{l''}^z \rangle = (-0.5) \times (-0.5) = 0.25$. Moreover, the longitudinal spin-spin correlations satisfy $-0.25 \leq C_{|l'| < 40, |l''| > 40} \leq 0.25$ and $-0.25 \leq C_{|l'| > 40, |l''| < 40} \leq 0.25$ and show fringes. The basic pattern of the longitudinal spin-spin correlations behaves like a cross in the (l', l'') plane. The cross-overlapping region in $C_{l',l''}$ is consistent with the region of nonzero $\Gamma_{l',l''}$ [see Fig. 2(d) and the top panel in the third column of Fig. 8]. The cross-overlapping region in $C_{l',l''}$ is determined by the amplitude of BOs [see point C in Fig. 2(a)]. These numerical results are consistent with the analytical ones (18) and (19).

In Figs. 2(b)–2(f) we show the $C_{l',l''}$ at different times: $t = 0$ (A), $t = T_B/4$ (B), $t = T_B/2$ (C), $t = 3T_B/4$ (D), and $t = T_B$ (E). As the spin excitations expand and shrink, the cross-overlapping region becomes larger at B ($t = T_B/4$), reaches the maximum at C ($t = T_B/2$), gradually decreases at D ($t = 3T_B/4$), and finally recovers the initial state at E ($t = T_B$). The cross-overlapping regions in Figs. 2(b)–2(f) are in excellent agreement with the regions of spin excitations in A–E in Fig. 2(a), respectively.

B. Dynamics of strongly interacting magnons

Under strong interactions, through implementing the many-body degenerate perturbation analysis, we derive an effective single-particle Hamiltonian and explore the interaction-induced fractional BOs [36–39]. Under the condition of $|\Delta| \gg (1/2, |B|)$, one can treat the hopping term and the gradient-magnetic-field term

$$\hat{H}_1 = \frac{1}{2} \sum_l (\hat{S}_l^+ \hat{S}_{l+1}^- + \hat{S}_l^- \hat{S}_{l+1}^+) + \sum_l l B \hat{S}_l^z \quad (20)$$

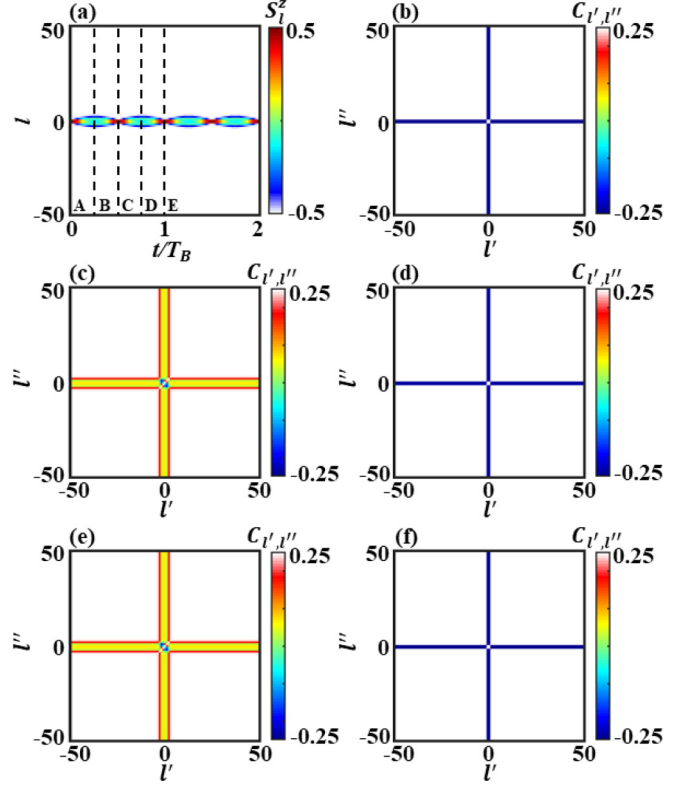

FIG. 3. Bloch dynamics of two strongly interacting magnons. (a) Spin distributions S_l^z versus the rescaled time t/T_B . (b)–(f) Longitudinal spin-spin correlations $C_{l',l''}$ at different times marked as A–E in (a). The parameters are the same as in Fig. 2, except for $\Delta = -5$.

as a perturbation to the interaction term

$$\hat{H}_0 = \Delta \sum_l \hat{S}_l^z \hat{S}_{l+1}^z. \quad (21)$$

The effective single-particle Hamiltonian can be written as

$$\hat{H}_{\text{eff}} = \frac{1}{4\Delta} \sum_m (\hat{C}_m^\dagger \hat{C}_{m+1} + \hat{C}_{m+1}^\dagger \hat{C}_m) + \sum_m 2Bm \hat{C}_m^\dagger \hat{C}_m, \quad (22)$$

with $m = -L, \dots, 0, \dots, L$, whose detailed derivation can be found in Appendix A. Here the operator $\hat{C}_m^\dagger = \hat{S}_m^+ \hat{S}_{m+1}^+$ means simultaneously flipping two adjacent spins at the m th and $(m+1)$ th sites. The two-magnon excitations behave like a single particle in the tilted lattices with doubled frequency $\omega_B^{\text{eff}} = 2B$. The two magnons tend to travel together and undergo fractional BOs [see Fig. 3(a)]. The initial state and parameters are the same as those in Fig. 2, except for $\Delta = -5$. The region of spin excitations is given as

$$|l| < \frac{1}{2\Delta B} |\sin(Bt)|. \quad (23)$$

Compared with Fig. 2(a), the width is reduced by a factor $1/4\Delta$, while the oscillation frequency becomes double. The numerical results are consistent with the analytical ones (23).

The $C_{l',l''}$ reveal the effective single-particle dynamics. Similarly, in one period, $C_{l',l''}$ behave like a cross for each instantaneous state [see Figs. 3(b)–3(f)]. As the spin excitations expand and shrink, the cross-overlapping region reaches a maximum at B ($t = T_B/4$), recovers the initial state at C

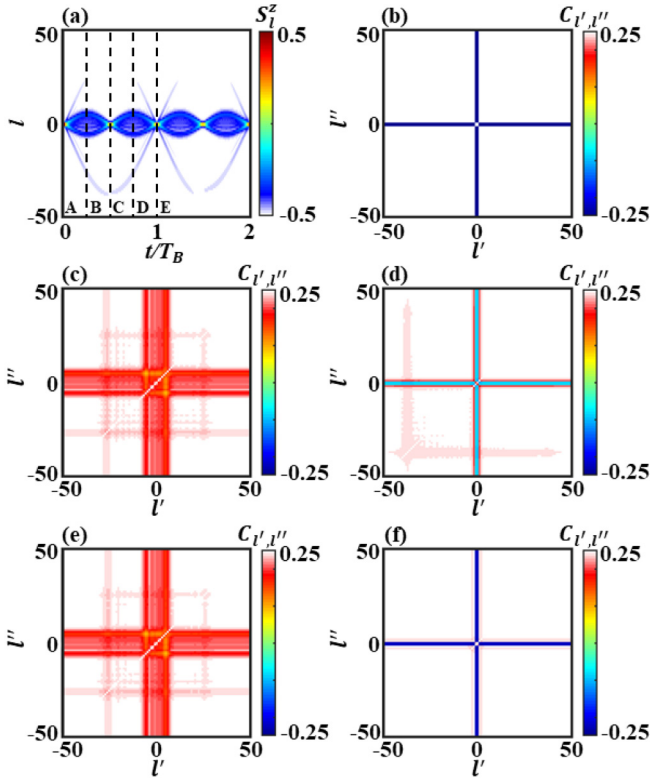

FIG. 4. Bloch dynamics of two moderately interacting magnons. (a) Spin distributions S_l^z versus the rescaled time t/T_B . (b)–(f) Longitudinal spin-spin correlations $C_{l',l''}$ at different times marked as A–E in (a). The parameters are the same as in Fig. 2, except for $\Delta = -1.5$.

($t = T_B/2$), increases to the maximum again at D ($t = 3T_B/4$), and finally recovers the initial state again at E ($t = T_B$). It clearly manifests that the two strongly interacting magnons undergo a breathing motion with the half-period of the free-magnon breathing motion. The cross-overlapping regions in Figs. 3(b)–3(f) are in excellent agreement with the regions of spin excitations in A–E in Fig. 3(a), respectively.

C. Dynamics of moderately interacting magnons

Finally, we study the dynamics of two-magnon excitations in the moderate-interaction case. The initial state and the parameters are the same as those in Fig. 2, except for $\Delta = -1.5$. The spin distributions S_l^z exhibit the coexistence of two breathing modes [see Fig. 4(a)]. The outer and inner breathing modes correspond to the oscillations of free magnons and bounded magnons, respectively. This is because the initial state is prepared as the superposition of scattering and bound states (see Appendix B for more details). Nevertheless, the outer breathing mode is slightly asymmetric about the initial position l_c^i , different from the breathing mode of free magnons. The asymmetry may come from the interaction-induced scattering of the free-magnon component.

Similar to the spin distributions S_l^z , $C_{l',l''}$ also show the coexistence of inner and outer patterns [see Figs. 4(c)–4(f)] for different times: $t = T_B/4$ (B), $t = T_B/2$ (C), $t = 3T_B/4$ (D), and $t = T_B$ (E). The correlations partially recover the initial correlations at C ($t = T_B/2$). This is because the

bound-state component returns to the initial ones while the scattering-state component has not yet. At E ($t = T_B$), both components nearly return to the initial state [see Fig. 4(f)].

So far, we have examined the role of spin-spin interaction on the dynamics of magnon excitations among the spin chain. By increasing the interaction strength, one may observe clear enhancement of the correlated tunneling of two magnons. Moreover, the longitudinal spin-spin correlations can be utilized to characterize the multimagnon BOs.

IV. EXTRACTING MAGNETIC-FIELD GRADIENT FROM MULTIMAGNON BLOCH OSCILLATIONS

In this section we discuss how to determine the magnetic-field gradient from the multimagnon BOs. For convenience, we flip two neighboring spins in the completely ferromagnetic state $|\downarrow\downarrow\downarrow\cdots\downarrow\rangle$. When two-magnon excitations are launched on the adjacent sites of the spin chain under a gradient magnetic field, it may exhibit a dynamical localization in a period. The time-dependent spin distributions and longitudinal spin-spin correlations both show the coexistence of two components when the interaction strength is moderate. However, we cannot accurately determine the magnetic-field gradient (which determines the Bloch frequency) via the spin distributions or longitudinal spin-spin correlations. Below we analyze the fidelity and the substandard deviation in both time and frequency domains to extract the gradient of the magnetic field and the Bloch frequency.

A. Fidelity

By simulating the time evolution with the TEBD algorithm, we calculate the time-dependent fidelity

$$F(t) = |\langle\Psi(0)|\Psi(t)\rangle|^2, \quad (24)$$

which characterizes the probability of the time-evolved state returning to the initial state. A slight change of the interaction may have a huge influence on the dynamics. We discuss the fidelity versus the rescaled time t/T_B for different interaction strengths $\Delta = 0$ [Fig. 5(a)], $\Delta = -1$ [Fig. 5(b)], $\Delta = -1.5$ [Fig. 5(c)], and $\Delta = -5$ [Fig. 5(d)]. The gradient of the magnetic field is chosen as $B = 0.05$ and the total length of the spin chain is $L_t = 101$. For clear visibility, the evolved time is set to be $t = 4T_B$. Without interaction, the sharp peaks perfectly emerge at the integer multiples of period T_B [see Fig. 5(a)]. When the interaction increases, in addition to the peaks at the integer multiples of period T_B , peaks also appear at the integer multiples of half-period $T_B/2$ [see Figs. 5(b)–5(d)]. For the moderate-interaction strength $\Delta = -1.5$, we find the coexistence of peaks at both the integer multiples of periods $T_B/2$ and T_B [see Fig. 5(c)]. The period T_B and half-period $T_B/2$ correspond, respectively, to the free-magnon Bloch frequency B and the bounded-magnon Bloch frequency $2B$. For stronger-interaction strength $\Delta = -5$, the dynamics transfers from the independent BOs to the effective single-magnon BOs and the half-period oscillation of fidelity is dominant [see Fig. 5(d)]. To explain how the interaction affects the fidelity, we project the initial state onto the scattering and the bound states. We find that the occupation on BSs becomes larger as the interaction increases (see Appendix B for more

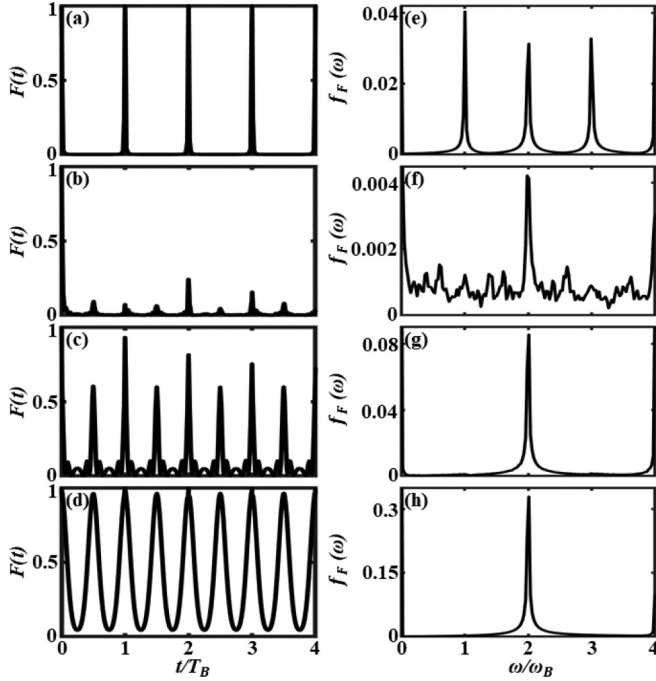

FIG. 5. (a)–(d) Fidelity F versus the rescaled time t/T_B for different values of Δ : (a) 0, (b) -1 , (c) -1.5 , and (d) -5 . (e)–(h) Frequency distribution $f_F(\omega)$ of the fidelity for different values of Δ : (e) 0, (f) -1 , (g) -1.5 , and (h) -5 . The other parameters are $B = 0.05$ and the total chain length $L_t = 101$.

details). Thus the peaks of fidelity at the half-period $T_B/2$ become higher as the interaction increases.

However, when the free-magnon component dominates in the weak-interaction case, it is difficult to distinguish the bound-state component from the scattering-magnon component by directly observing the time evolution of the fidelity. Under such a moderate interaction, the periodicity of fidelity is destroyed due to the appearance of irregular behaviors (such as quantum chaos) [see Fig. 5(b)].

In Figs. 5(e)–5(h) we show the frequency distribution $f_F(\omega)$ of the fidelity $F(t)$ for different interaction strengths $\Delta = 0$ [Fig. 5(e)], $\Delta = -1$ [Fig. 5(f)], $\Delta = -1.5$ [Fig. 5(g)], and $\Delta = -5$ [Fig. 5(h)]. In the absence of interaction, the peaks $n\omega_B$ (with positive integers n) gradually decay [see Fig. 5(e)]. Once the interaction is introduced, significant peaks appear at $2\omega_B$ and the peaks at ω_B vanish [see Figs. 5(f)–5(h)]. This means that, for moderate-interaction strengths, $f_F(\omega)$ cannot successfully identify the free-magnon BOs and it is difficult to show the coexistence of free-magnon BOs and bounded-magnon fractional BOs.

B. Substandard deviation

In this section we present how to use the substandard deviation to extract the multifrequencies of BOs, especially when the free-magnon BOs and bounded-magnon fractional BOs coexist. Here we will analyze the frequency distribution of the time-dependent generalized standard deviation

$$D^x(t) = \sqrt{\sum_l \left(\langle \hat{S}_l^z \rangle + 1/2 \right) |l - l_c(t)|^x}, \quad (25)$$

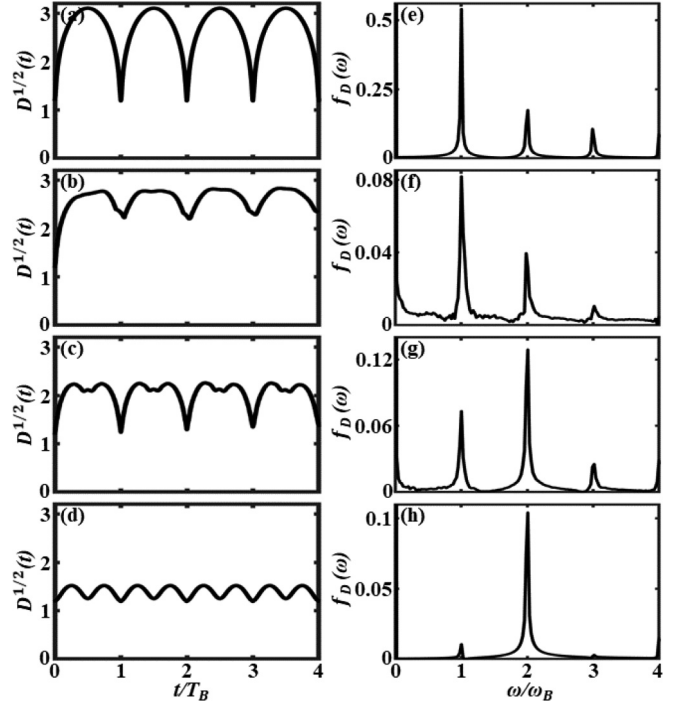

FIG. 6. (a)–(d) Substandard deviation $D^{1/2}$ versus the rescaled time t/T_B for different values of Δ : (a) 0, (b) -1 , (c) -1.5 , and (d) -5 . (e)–(h) Frequency distribution $f_D(\omega)$ of the substandard deviation for different values of Δ : (e) 0, (f) -1 , (g) -1.5 , and (h) -5 . The other parameters are $B = 0.05$ and the total chain length $L_t = 101$.

which can characterize the fluctuation of spin excitations in a spatial distribution. Here $\langle \hat{S}_l^z \rangle$ represents the spin magnetization at site l and

$$l_c(t) = \frac{\sum_l l \left(\langle \hat{S}_l^z \rangle + 1/2 \right)}{\sum_l \left(\langle \hat{S}_l^z \rangle + 1/2 \right)} \quad (26)$$

is the centroid position of the time-evolved state. When $x = 2$, the generalized standard deviation becomes traditional standard deviation. Instead of traditional standard deviation, we define the superstandard deviation for $x > 2$ and substandard deviation for $x < 2$ to highlight the bounded- and free-magnon components, respectively. After a series of trials, we find that one may choose substandard deviation with $x = 1/2$ to extract the multiple Bloch frequencies.

The time-dependent substandard deviations show that the spatial region of spin excitations decreases as the interaction strength increases [see Figs. 6(a)–6(d)]. Making a fast Fourier transform of the substandard deviations to obtain the frequency distribution $f_D(\omega)$, one can observe sharp peaks centered at the integer multiples of ω_B in the frequency domain. The maximum peak centers at ω_B for noninteracting systems [see Fig. 6(e)]. As the interaction increases, the peak at ω_B becomes lower while the peak at $2\omega_B$ becomes higher, and the peak at $2\omega_B$ becomes dominant under strong interactions [see Figs. 6(f)–6(h)]. Since the peaks at ω_B and $2\omega_B$ are mainly induced by BOs of scattering and bounded magnons, respectively, the dominance of the peak at $2\omega_B$ is a clear signature of two-magnon BSs.

Unlike $f_F(\omega)$, the frequency distribution $f_D(\omega)$ of substandard deviation may clearly show the coexistence of the free-magnon BOs and bounded-magnon fractional BOs. This means that $f_D(\omega)$ is a better quantity to witness the coexistence and competition between free-magnon BOs and bounded-magnon fractional BOs. However, for $f_F(\omega)$, although significant peaks appear at $2\omega_B$, the peak at ω_B nearly vanishes and thus cannot show the coexistence of free-magnon BOs and bounded-magnon fractional BOs.

There are two typical schemes to measure the force based on the delocalization-enhanced BOs and driving resonance tunneling effects [40]. Here we find that once we determine the position of the peak ω_B or $2\omega_B$, the magnetic-field gradient can be accurately given. Moreover, bounded magnons undergo fractional BOs with frequency doubling $2\omega_B$. The fractional BOs are an excellent indicator for judging the appearance of two-magnon BSs.

V. SUMMARY AND DISCUSSION

In this work, through considering a Heisenberg XXZ chain under a gradient magnetic field, we studied how the interaction affects the BOs of two-magnon excitations and gave a quantitative method to extract the magnetic-field gradient from the multifrequency BOs. We extended the theory of dynamical symmetry of single-point operators to the one of two-point operators and found that the dynamics in antiferromagnetic systems can be directly derived from the corresponding ferromagnetic ones. As the interaction increases, we found that the spin distribution or longitudinal spin-spin correlation dynamics gradually transfers from BOs of free magnons to the fractional BOs of bounded magnons. The interaction-induced fractional BOs provide a different perspective to observe the magnon BSs. Moreover, we used the fidelity and the substandard deviation in both time and frequency domains to probe the multifrequency BOs and determine the magnetic-field gradient. The substandard deviation is an excellent candidate to witness the coexistence and competition between free-magnon BOs (at frequency ω_B) and bounded-magnon fractional BOs (at frequency $2\omega_B$).

Based on the current techniques in engineering ultracold atoms, it is possible to simulate our Heisenberg spin chain. By loading two-state ^{87}Rb atoms into a one-dimensional optical lattice in the Mott regime with one particle per lattice site, the two hyperfine states with different magnetic dipole moments can be labeled as spin up and spin down, respectively. Applying a gradient magnetic field along the lattice, our spin-dependent lattices can be realized. The dynamics of spin distribution and longitudinal spin-spin correlation can be tracked via the techniques of an atomic microscope [12,13]. The interaction between magnons can be tuned via Feshbach resonance techniques [41,42]. With the observed spin distributions and longitudinal spin-spin correlations, the fidelity and the substandard deviation can be given.

APPENDIX A: EFFECTIVE SINGLE-PARTICLE HAMILTONIAN FOR STRONGLY INTERACTING MAGNONS

Under strong ferromagnetic interactions, the magnons tend to travel together instead of by individual propagation. In order to explain this phenomenon, we analytically construct an effective single-particle Hamiltonian by using the many-body degenerate perturbation theory.

When $|\Delta| \gg (1/2, |B|)$, we can divide the Hamiltonian into \hat{H}_0 as a dominant term and \hat{H}_1 as a perturbation term. In the two-magnon basis $\{|l'_1 l'_2\rangle = \hat{S}_{l'_1}^+ \hat{S}_{l'_2}^+ |\mathbf{0}\rangle : -L \leq l'_1 < l'_2 \leq L\}$, \hat{H}_0 consists of two subspaces \mathcal{U} and \mathcal{V} . The total chain length $L_t = 2L + 1$. The degenerate eigenstates $\{|G_m\rangle = |m, m+1\rangle : -L \leq m \leq L\}$ form the subspace \mathcal{U} with eigenvalues $E_0 = \Delta$. Correspondingly, the degenerate eigenstates $\{|E_{l_1 l_2}\rangle = |l_1 l_2\rangle : l_1 \neq l_2 \pm 1, -L \leq l_1 < l_2 \leq L\}$ form the subspace \mathcal{V} with eigenvalues $E_1 = 0$. The projection operators are defined as $\hat{P}_{\mathcal{U}} = \sum_m |G_m\rangle \langle G_m|$ onto \mathcal{U} and $\hat{P}_{\mathcal{V}} = \sum_{l_2 \neq l_1 \pm 1} \frac{1}{E_0 - E_1} |E_{l_1 l_2}\rangle \langle E_{l_1 l_2}|$ onto \mathcal{V} . The second-order effective Hamiltonian is written as

$$\begin{aligned} \hat{H}_{\text{eff}} &= \hat{h}_0 + \hat{h}_1 + \hat{h}_2 \\ &= E_0 \hat{P}_{\mathcal{U}} + \hat{P}_{\mathcal{U}} \hat{H}_1 \hat{P}_{\mathcal{U}} + \hat{P}_{\mathcal{U}} \hat{H}_1 \hat{P}_{\mathcal{V}} \hat{H}_1 \hat{P}_{\mathcal{U}}. \end{aligned} \quad (\text{A1})$$

The first-order perturbation reads

$$\begin{aligned} \hat{h}_1 &= \hat{P}_{\mathcal{U}} \hat{H}_1 \hat{P}_{\mathcal{U}} \\ &= \sum_{l, mm'} |G_m\rangle \langle G_m| (lB\hat{S}_l^z) |G_{m'}\rangle \langle G_{m'}|. \end{aligned} \quad (\text{A2})$$

Since

$$\begin{aligned} &\sum_l \langle G_m| (lB\hat{S}_l^z) |G_{m'}\rangle \\ &= B\delta_{mm'} \sum_l l (\delta_{lm} + \delta_{l, m+1} - \frac{1}{2}) \\ &= B\delta_{mm'} (2m + 1), \end{aligned} \quad (\text{A3})$$

we have

$$\hat{h}_1 = B \sum_m (2m + 1) |G_m\rangle \langle G_m|. \quad (\text{A4})$$

The second-order perturbation reads

$$\begin{aligned} \hat{h}_2 &= \hat{P}_{\mathcal{U}} \hat{H}_1 \hat{P}_{\mathcal{V}} \hat{H}_1 \hat{P}_{\mathcal{U}} \\ &= \frac{1}{4\Delta} \sum_{mm', l', l_1 l_2} [|G_m\rangle \langle G_m| (\hat{S}_l^+ \hat{S}_{l+1}^- + \hat{S}_l^- \hat{S}_{l+1}^+) |E_{l_1 l_2}\rangle \\ &\quad \times \langle E_{l_1 l_2}| (\hat{S}_{l'}^+ \hat{S}_{l'+1}^- + \hat{S}_{l'}^- \hat{S}_{l'+1}^+) |G_{m'}\rangle \langle G_{m'}|]. \end{aligned} \quad (\text{A5})$$

After careful calculation, we have

$$\begin{aligned}\hat{h}_2 &= \hat{P}_U \hat{H}_1 \hat{P}_V \hat{H}_1 \hat{P}_U \\ &= \frac{1}{4\Delta} \sum_m (|G_m\rangle + |G_{m+1}\rangle)(\langle G_m| + \langle G_{m+1}|). \quad (\text{A6})\end{aligned}$$

Combing Eqs. (A4) and (A6), we derive the effective single-particle Hamiltonian up to the second order

$$\begin{aligned}\hat{H}_{\text{eff}} &= \frac{1}{4\Delta} \sum_m (|G_m\rangle + |G_{m+1}\rangle)(\langle G_m| + \langle G_{m+1}|) \\ &+ B \sum_m (2m+1) |G_m\rangle \langle G_m| \\ &+ \Delta \sum_m |G_m\rangle \langle G_m|, \quad (\text{A7})\end{aligned}$$

with $m = -L, \dots, 0, \dots, L$. We introduce the operator $\hat{C}_m^\dagger = \hat{S}_m^+ \hat{S}_{m+1}^+$, which means simultaneously flipping two adjacent spins at the m th and $(m+1)$ th sites from the vacuum state $|\mathbf{0}\rangle = |\downarrow\downarrow \dots \downarrow\rangle$. Therefore, the bound pairs behave as a composite particle following the Hamiltonian

$$\begin{aligned}\hat{H}_{\text{eff}} &= \frac{1}{4\Delta} \sum_m (\hat{C}_m^\dagger \hat{C}_{m+1} + \hat{C}_{m+1}^\dagger \hat{C}_m) \\ &+ \sum_m 2Bm \hat{C}_m^\dagger \hat{C}_m, \quad (\text{A8})\end{aligned}$$

where the energy constant is omitted. Compared with free magnons, the formation of bound pairs performs BOs with double the frequency.

APPENDIX B: TWO-MAGNON ENERGY SPECTRUM

To explain the interaction effects on magnon dynamics, we calculate the overlaps of the initial state with the scattering and bound states in the absence of a gradient magnetic field. Since $[\hat{H}, \hat{S}^z] = 0$ with $\hat{S}^z = \sum_l \hat{S}_l^z$, the total number of spin excitations is conserved and all states keep evolving in the two-magnon Hilbert space. The two-magnon Hilbert space is spanned by the basis $\mathcal{B}^{(2)} = |l'_1 l'_2\rangle = \hat{S}_{l'_1}^+ \hat{S}_{l'_2}^+ |\mathbf{0}\rangle$ with $-L \leq l'_1 < l'_2 \leq L$ and the total chain length $L_t = 101$. The eigenstates can be expressed as $|\Psi\rangle = \sum_{l'_1 < l'_2} \Psi_{l'_1 l'_2} |l'_1 l'_2\rangle$ with $\Psi_{l'_1 l'_2} = \langle \mathbf{0} | \hat{S}_{l'_2}^- \hat{S}_{l'_1}^- | \Psi \rangle$. Thus the system satisfies the eigenequation

$$\begin{aligned}E \Psi_{l_1 l_2} &= \frac{1}{2} (\Psi_{l_1, l_2+1} + \Psi_{l_1, l_2-1} + \Psi_{l_1+1, l_2} + \Psi_{l_1-1, l_2}) \\ &+ \Delta (\delta_{l_1, l_2-1} + \delta_{-L, L}) \Psi_{l_1 l_2}. \quad (\text{B1})\end{aligned}$$

In the absence of a gradient magnetic field, the Heisenberg XXZ chain has a cotranslational symmetry and the center-of-mass quasimomentum is a good quantum number under the periodic boundary condition. The motion of the two-magnon excitations consists of the motion of the center of mass $R = \frac{1}{2}(l_1 + l_2)$ and the relative position $r = l_1 - l_2$. Defining $\Psi_{l_1 l_2} = e^{iKR} \phi(r)$, the eigenequation (B1) reads

$$E \phi(r) = \cos \frac{K}{2} [\phi(r-1) + \phi(r+1)] + \Delta \delta_{r, \pm 1} \phi(r). \quad (\text{B2})$$

Under periodic boundary conditions, we find $e^{iKL_t} = 1$ and $\phi(r+L_t) = e^{iKL_t/2} \phi(r)$ with the quasimomentum $K =$

FIG. 7. Two-magnon energy spectrum for $B = 0$, $L_t = 101$, and (a) $\Delta = 0$, (b) $\Delta = -1$, (c) $\Delta = -1.5$, and (d) $\Delta = -5$, with the overlaps $P_{K,r}$ between the initial state and each eigenstate shown by the color bar.

$2\pi\alpha/L_t$ (with $\alpha = -L, -L+1, \dots, L$). Moreover, we have $\phi(0) = 0$ and $\phi(r) = \phi(-r)$ with the commutation relations.

We give the two-magnon energy spectrum by numerically diagonalizing the Hamiltonian without a gradient magnetic field. With the nearest-neighbor ferromagnetic interaction, the two magnons are able to form BSs. When the interaction $|\Delta| > 1$, the energy spectrum shows that BSs (corresponding to the lower band) completely separate from the scattering states (SSs). After calculating the overlaps

$$P_{K,r} = |\langle \psi_{K,r} | \psi(0) \rangle|^2, \quad (\text{B3})$$

we reveal exactly the proportion of initial state in each eigenstate $\psi_{K,r}$ (see the color of the energy spectrum in Fig. 7). The interaction values are set as $\Delta = 0$ [Fig. 7(a)], $\Delta = -1$ [Fig. 7(b)], $\Delta = -1.5$ [Fig. 7(c)], and $\Delta = -5$ [Fig. 7(d)]. The proportion in SSs makes the spins undergo independent BOs, while the proportion in BSs induces the correlated and fractional BOs. Once the initial state strongly overlaps with BSs, one can clearly observe the signature in the time evolution of spin distributions. As the interaction increases, the overlaps with BSs become larger and the BOs of bounded magnons become dominant.

APPENDIX C: TWO-MAGNON CORRELATIONS

In addition to the longitudinal spin-spin correlations, we also calculate the time-dependent two-magnon correlation

$$\Gamma_{l',l''}(t) = \langle \psi(t) | \hat{S}_{l'}^+ \hat{S}_{l''}^+ \hat{S}_{l''}^- \hat{S}_{l'}^- | \psi(t) \rangle, \quad (\text{C1})$$

which gives the correlations between magnons at sites l' and l'' . If the two magnons propagate within the region $l \leq l_b$, different from the longitudinal spin-spin correlation, there will be zero complete two-magnon correlations for $|l'| > l_b$ or $|l''| > l_b$. For comparison, we calculate the two-magnon

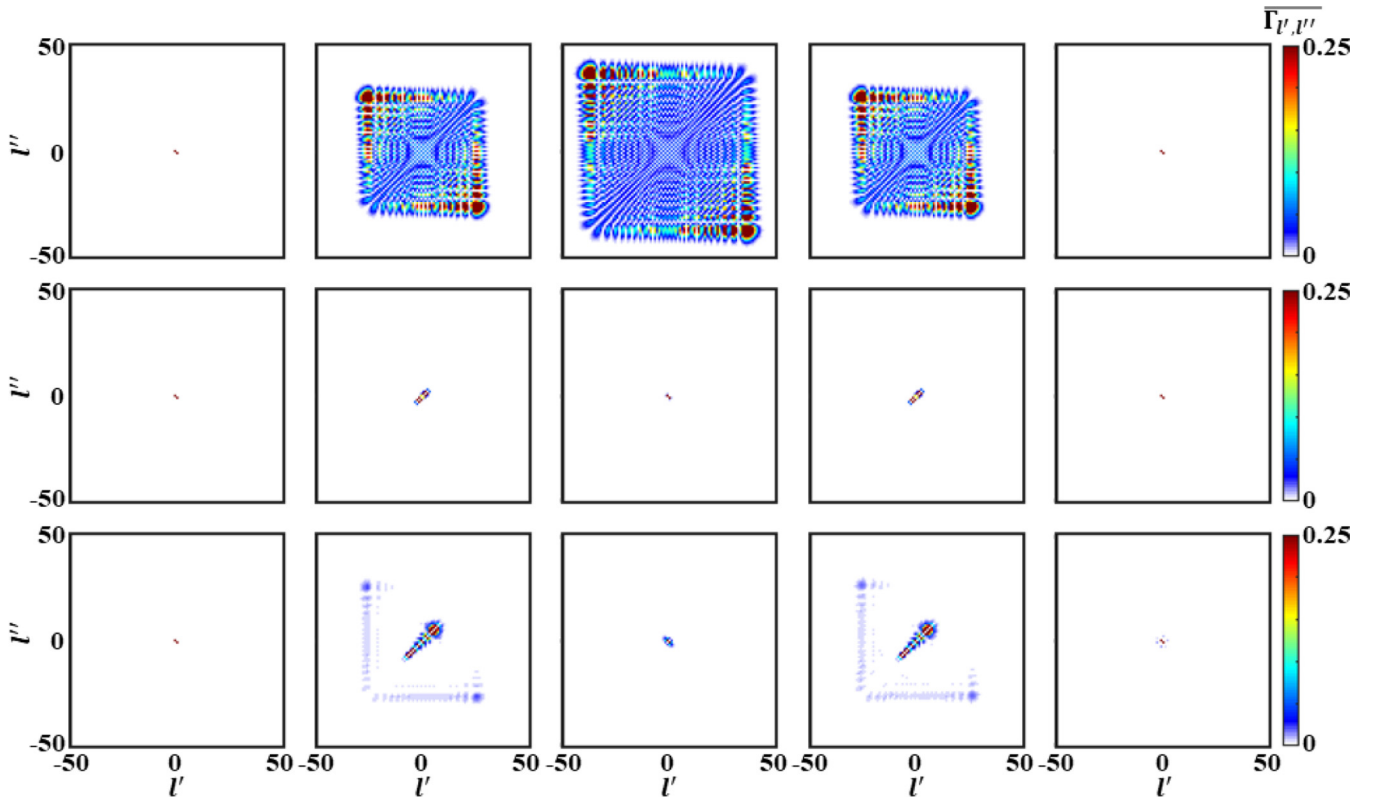

FIG. 8. Rescaled two-magnon correlations $\overline{\Gamma_{l',l''}} = \Gamma_{l',l''} / \Gamma_{l',l''}^{\max}$. The top, middle, and bottom rows correspond to noninteracting $\Delta = 0$, strong-interacting $\Delta = -5$, and moderate-interacting $\Delta = -1.5$ systems, respectively. For all three rows, the evolved time is set as $t = 0$, $T_B/4$, $T_B/2$, $3T_B/4$, and T_B from left to right, respectively. The parameters are $B = 0.05$ and $L_r = 101$. The red regions of $0.25 < \Gamma_{l',l''} \leq 1$ represent regions out of range of the color bar.

correlations in the BOs of noninteracting magnons, strong-interacting magnons, and moderate-interacting magnons (see the top, middle, and bottom rows of Fig. 8, respectively). For all three cases, the evolved time for two-magnon correlations is set as $t = 0$ (A), $t = T_B/4$ (B), $t = T_B/2$ (C), $t = 3T_B/4$ (D), and $t = T_B$ (E) from left to right, respectively. The parameters in the three cases are the same as those in Sec. III A, III B, and III C, respectively.

For noninteracting magnons, the region with nonzero two-magnon correlations expands and shrinks in a Bloch period and is consistent with the region in $|l| < \frac{2}{B} |\sin \frac{Bt}{2}|$ of magnon

excitations (see the top row of Fig. 8). For strong-interacting magnons, $\Gamma_{l',l''}(t)$ is mainly distributed along two minor off-diagonal lines ($l', l' \pm 1$), which significantly manifests the formation of magnon BSs. The two magnons are bound together and undergo a fractional BO with a reduced amplitude $\frac{1}{2\Delta B}$ (see the middle row of Fig. 8). For moderate-interacting magnons, apart from the clear signal in the off-diagonal $\Gamma_{l',l' \pm 1}(t)$, fractional distributions also exist in $\Gamma_{l',l'' \neq l' \pm 1}(t)$, which means that the BOs of free-magnon and bounded-magnon components coexist, as shown in the bottom row of Fig. 8.
