 (Received 14 February 2022; revised 25 May 2022; accepted 17 June 2022; published 5 July 2022)

Ferrimagnetic NiCo<sub>2</sub>O<sub>4</sub> (NCO) films with perpendicular magnetic anisotropy, 12.5 nm in thickness, are epitaxially deposited on (001) MgAl<sub>2</sub>O<sub>4</sub> single-crystalline substrates by pulsed laser deposition. It is observed that the coercive field of the NCO films can be tuned systematically by about 20 times, while keeping the large perpendicular magnetic anisotropy, through simply increasing the deposition temperature from 250 to 350 °C. The increase of resistivity and the increase of low-temperature metal-to-insulator transition temperature suggests increased concentration of defects in NCO films deposited at elevated temperatures. The magnetic and transport characteristics are discussed based on a systematic change in cation valence and coordination in NCO films, as revealed by x-ray photoelectron emission and x-ray absorption spectroscopy measurements. The perpendicular magnetic anisotropy with tunable coercivity makes NCO films promising for multifunctional applications.

## I. INTRODUCTION

High-performance magnetic materials are essential fundamental materials that support modern technologies. The ability to control magnetic properties such as saturation magnetization ( $M_s$ ), remanent magnetization, and coercivity ( $H_c$ ) is critical not only for applications but also for the fundamental understanding of magnetism. Different applications require different  $H_c$  [1–4]. In fact, magnetic materials have been divided into two categories, soft magnets with  $H_c$  in the range of a few to a few hundreds of oersteds used in switching, sensing, and microwave absorbing applications [3–6], and hard magnets with  $H_c$  of a few thousands of oersteds and even larger, useful for electrical-to-mechanical energy conversion, motors, generators, and magnetic resonance imaging devices [3–7]. Specifically in memory applications, different desired amplitudes of  $H_c$  are required for different devices. For example, the write and read heads require low coercivity to enable operations at reasonably high frequencies [8,9], while the recording medium must have coercivity low enough to write on but high enough to resist a demagnetizing field and to store the information for as long as possible [8,9].

Transition metal oxides display a rich variety of fascinating electronic, optical, and magnetic properties owing

to the complex interaction among charge, spin, orbit, and lattice, holding great promise from both applied and fundamental research points of view [10–14]. Among them, ferrimagnetic NiCo<sub>2</sub>O<sub>4</sub> (NCO) with inverse spinel structure has attracted increasing attention in recent years for promising functionalities [15–22]. NCO possesses a high Curie temperature (about 400 K), high saturated magnetization, perpendicular magnetic anisotropy (PMA), and high conductivity [15–22]. However, systematic studies of magnetic and transport characteristics of NCO epitaxial thin films are rarely reported.

In this work, we show that the coercivity of NCO epitaxial films can be tuned by about 20 times from 350 to 7300 Oe by simply increasing the deposition temperature ( $T_g$ ), while maintaining a large PMA. The effective magnetic anisotropy constant ( $K_{\text{eff}}$ ) fluctuates between 1.9 and 5.1 Merg cm<sup>-3</sup>. The analysis of the temperature dependence of longitudinal resistivity manifests the increased disorder in NCO films, indicating the essential pinning effect of disorder during domain switching. The variation of Curie temperature ( $T_C$ ), saturated magnetization, and transport characteristics are discussed based on a systematic change in valence and coordination of cations in the NCO films as functions of  $T_g$ . Our work provides a simple method to tune the coercivity of NCO films with strong PMA for multifunctional applications.

## II. EXPERIMENT

NCO films are deposited by pulsed laser deposition on (001)-oriented  $\text{MgAl}_2\text{O}_4$  (MAO) single-crystalline substrates, ultrasonically cleaned in ethanol for 10 min, then in deionized water for 10 min. During deposition, a NCO ceramic target made by conventional solid-state reaction and sintering is ablated with a 248-nm KrF excimer laser (Compex Pro 205, Coherent) at 4 Hz. The power density on the target is  $2.5 \text{ J cm}^{-2}$ . The oxygen pressure in the chamber is kept at 0.1 mbar, while the substrate temperature is maintained at  $T_g$ , which increases from 250 to 350 °C in 25 °C steps. The surface morphology of these films is checked with an atomic force microscope (Cypher ES, Asylum Research). The crystallinity, thickness and lattice constants of the films are measured on a Bruker D8 Discover x-ray diffractometer with  $\text{Cu K}\alpha 1$  radiation ( $\lambda = 1.5406 \text{ \AA}$ ). Magnetic measurements are carried out on a superconducting quantum interference device magnetometer (MPMS XL-7, Quantum Design). A physical property measurement system (PPMS-9, Quantum Design) is used to measure the transport properties using indium contact electrodes and gold wires in a van der Pauw configuration. X-ray photoelectron spectroscopy (XPS) (K-Alpha, Thermo Scientific) is employed to evaluate the composition and valence states of Ni and Co in the NCO films. X-ray absorption spectra (XAS) are

collected in total electron yield mode at room temperature at the MCD-A and MCD-B (Soochow Beamline for Energy Materials) beamlines at the National Synchrotron Radiation Laboratory (Hefei, China).

## III. RESULTS AND DISCUSSION

### A. Structural characterization

Figure 1(a) shows the  $\theta$ - $2\theta$  x-ray diffraction (XRD) patterns of the NCO films deposited at various  $T_g$ , around the (004) reflection of the MAO substrate. Regardless of the  $T_g$ , NCO films all exhibit (004) diffraction accompanied with distinct Laue thickness fringes and there are no observable secondary phases from any impurities, indicating the high crystallinity of films with smooth surface and sharp interface. It is clear that the (004) diffraction peak of NCO shifts to lower angles as  $T_g$  increases, indicative of an increase in the out-of-plane lattice parameter. As shown in Fig. 1(d), the calculated out-of-plane lattice parameter increases from 8.18 to 8.23 Å as  $T_g$  increases from 250 to 350 °C. Lattice parameter variation may be a result of cation nonstoichiometry [23], different coordination, or oxygen deficiency [24,25], which is discussed in the following. Figure 1(b) shows two-dimensional XRD intensity mapping of a NCO film deposited at 350 °C around the (115) reciprocal spot of the MAO substrate as

FIG. 1. (a)  $\theta$ - $2\theta$  XRD patterns of NCO films deposited at various  $T_g$ . The triangles serve to indicate the peak positions. (b) Two-dimensional diffraction intensity mapping of the NCO film deposited at 350 °C around the (115) reflection of the MAO substrate.  $h$  [110] and  $l$  [001] are coordinates in reciprocal space and represent the in-plane and out-of-plane directions, respectively; rlu represents reciprocal lattice unit. (c) X-ray reflectivity (black open circles) and the corresponding fitting results (color solid lines) of NCO films deposited at various  $T_g$ . (d) Lattice parameter  $c$  calculated from (a) and film thickness extracted from fittings in (c) as a function of  $T_g$ , the error bars denote the standard deviation of film thickness.

an example. The (115) reflection of the NCO film shares the same in-plane reciprocal vector with the substrate, indicating that the epitaxial NCO film is coherently grown and fully strained to the substrate. Shown in Fig. 1(c) is the x-ray reflectivity of NCO films deposited at various  $T_g$ , with fittings to each line, using film thickness as the fitting parameter. The extracted film thickness is around  $12.5 \pm 0.2$  nm and is almost independent of  $T_g$ , as also shown in Fig. 1(d). All the films exhibit a smooth surface with the largest root-mean-square roughness value being only 0.15 nm (see Fig. S1 in Supplemental Material for the surface morphology of films with different  $T_g$  [26]).

## B. Magnetic characteristics

Figures 2(a) and 2(b) show out-of-plane and in-plane  $M$ - $H$  hysteresis loops, respectively, of NCO films deposited at various  $T_g$ , measured at 10 K. Diamagnetic contributions from the MAO substrates, acquired by linear fitting to the saturated high field data, are subtracted. In the out-of-plane direction, NCO films show square hysteresis loops with saturated magnetization decreasing from 2.30 to 1.62  $\mu_B$  per formula unit ( $\mu_B$  f.u.<sup>-1</sup>) as  $T_g$  increases from 250 to 350 °C. In contrast, the in-plane  $M$ - $H$  loops are canted with a much larger saturated magnetic field, confirming the previously reported PMA in epitaxial NCO films [15–22]. The largest out-of-plane saturated magnetization, 2.30  $\mu_B$  f.u.<sup>-1</sup>, is observed in NCO films deposited at 250 °C. This is larger than most magnetization values reported for NCO films, and even

larger than the value in bulk, approximately 2  $\mu_B$  f.u.<sup>-1</sup> [15–22]. Lüders *et al.* reported an enhanced magnetization in epitaxial NiFe<sub>2</sub>O<sub>4</sub> films and explained by cation disorder [27]. A similar mechanism may also work in NCO films, where the general formula can be written as Co<sub>*x*</sub><sup>2+</sup>Co<sub>*1-x*</sub><sup>3+</sup>[Ni<sub>*1-x*</sub><sup>2+</sup>Ni<sub>*x*</sub><sup>3+</sup>Co<sup>3+</sup>]<sub>4</sub>O<sub>4</sub><sup>2-</sup> ( $0 < x < 1$ ) [17,28]. The tetrahedral ( $T_d$ ) sites are occupied by high-spin Co<sup>2+</sup> and Co<sup>3+</sup> cations, carrying  $3\mu_B$  and  $4\mu_B$ , respectively. The octahedral ( $O_h$ ) sites are occupied by high-spin Ni<sup>2+</sup> with  $2\mu_B$ , low-spin Ni<sup>3+</sup> with  $1\mu_B$ , and diamagnetic low-spin Co<sup>3+</sup> [17,28]. The spins at each site are aligned in parallel, but the spins at the  $O_h$  sites are aligned antiparallel with those at the  $T_d$  sites. As a result, a saturation moment of 2  $\mu_B$  f.u.<sup>-1</sup> can be expected irrespective of  $x$  [17,28]. An increase of magnetization at the  $T_d$  sites, a decrease of magnetization at the  $O_h$  sites, or both, may increase the net magnetization.

PMA describes the magnetic anisotropy, in which the direction of easy axes is perpendicular to the film surface. This magnetic anisotropy can be regarded as a field that tends to hold the magnetization in certain equivalent crystallographic directions. To evaluate the PMA properties quantitatively, we estimate the effective PMA constant  $K_{\text{eff}}$ , which can be deduced from the area enclosed between the magnetization curves with the applied field parallel and perpendicular to the film plane in the first quadrant [3,4]. Figure 3(e) shows that  $K_{\text{eff}}$  increases generally with the increase of  $T_g$ , suggesting the enhanced PMA in samples deposited at higher  $T_g$ . The maximum  $K_{\text{eff}}$  of 5.1 Merg cm<sup>-3</sup> is comparable to the values reported

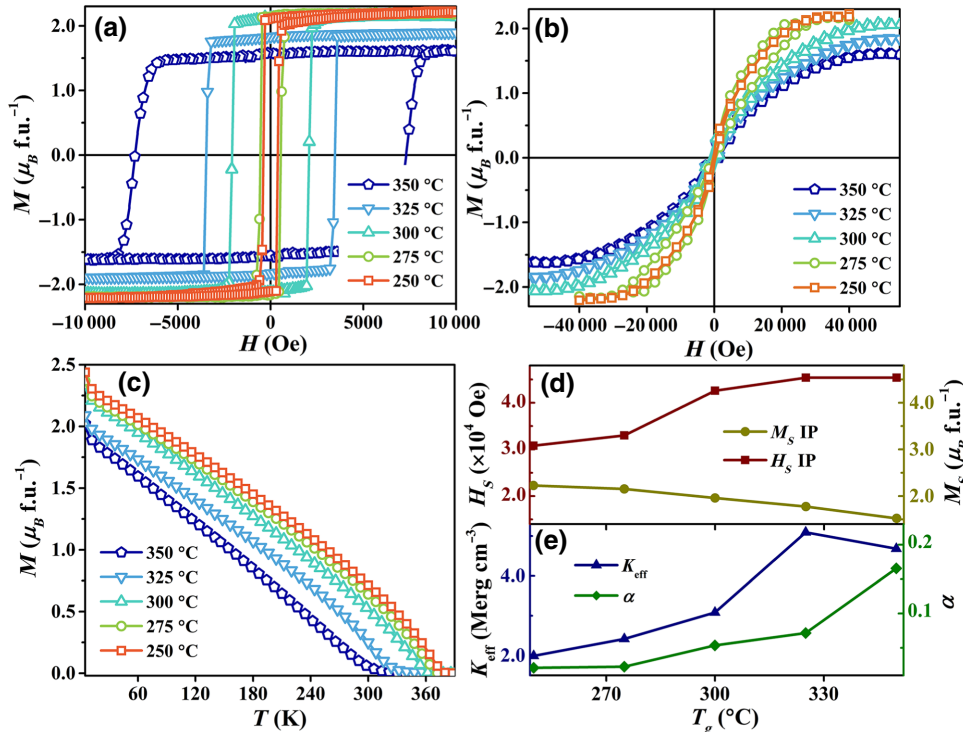

FIG. 2. (a) Out-of-plane and (b) in-plane  $M$ - $H$  hysteresis loops measured at 10 K. (c)  $M$ - $T$  curves of NCO films deposited at various  $T_g$ . (d) In-plane saturation fields ( $H_s$  IP) and saturated magnetizations ( $M_s$  IP) as functions of  $T_g$ . (e) The effective PMA constant  $K_{\text{eff}}$  and the inhomogeneity factor  $\alpha$  as functions of  $T_g$ .

FIG. 3. (a) Temperature dependence of longitudinal resistivity of NCO films deposited at various  $T_g$ . (b) Low-temperature resistivity of NCO films deposited at  $T_g = 250, 275, 300,$  and  $325$  °C fitted to Eq. (1). (c) Resistivity of NCO film deposited at  $T_g = 350$  °C fitted to Eq. (2). (d) Resistivity in the metallic state of NCO films deposited at  $T_g = 250, 275, 300,$  and  $325$  °C fitted to Eq. (3). Data for  $T_g = 300$  °C are scaled by 1.3 for clarity.

previously in NCO films [29]. PMA is a crucial feature in the design of spintronic devices such as spin transfer torque magnetoresistive random access memories, but it is relatively rare in oxide thin films due to the strong shape anisotropy [3,4,29–31]. For example,  $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$  thin films usually exhibit an in-plane easy axis. When compressively strained,  $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$  thin films may show PMA with  $K_{\text{eff}}$  being only  $0.2 \text{ Merg cm}^{-3}$  [32,33]. The large  $K_{\text{eff}}$  observed in the NCO films are beneficial to PMA-based perpendicular magnetic recording.

Another obvious feature in Fig. 2(a) is that the out-of-plane coercive field increases significantly from 350 to 7300 Oe as  $T_g$  increases from 250 to 350 °C. The increase of coercivity has often been ascribed to the change of electronic structure and/or pinning by defects. For example, Park *et al.* reported a large reduction in  $H_c$  from 4000 to 300 Oe in  $\text{Fe}_3\text{GeTe}_2$  thin flakes due to Fe deficiency [34]. A wide-range continuous modulation of  $H_c$  from 48 to 16 KOe in  $\text{SrTiO}_3$ -capped  $\text{SrRuO}_3$  films has been attributed to domain pinning and depinning by controlled migration of oxygen vacancies [35]. According to the simplified phenomenological model proposed by Kronmüller [36],  $H_c = 2\alpha K_1/M_s - N_{\text{eff}}M_s$ , where  $\alpha$  is the inhomogeneity factor, representing the influences from the defects acting as pinning centers during domain switching [4,35].  $K_1$  is the first magnetocrystalline anisotropy constant and can be calculated as  $K_1 = 1/2H_sM_s$ , where  $H_s$  and  $M_s$  are the saturation field and saturated magnetization,

respectively, measured with the applied field in the film plane [3,4], as shown in Fig. 2(d).  $N_{\text{eff}}$  is the demagnetization factor related to the shape and the magnetization direction of sample. For NCO films with PMA,  $N_{\text{eff}}$  can be taken as 1, then  $\alpha$  can be calculated [4,35,36]. As shown in Fig. 2(e),  $\alpha$  increases monotonically by 7.86 times with  $T_g$  increasing from 250 to 350 °C. By comparison, the monotonically increased  $H_c$  in NCO films with increasing  $T_g$  can be mainly ascribed to the increase of  $\alpha$ , which indicates the increased pinning effect of disorder with increasing  $T_g$ . The increased disorder at higher  $T_g$  is also confirmed by the following transport analysis. Lattice defects, such as cation and oxygen vacancies or antiphase boundaries, may pin domain switching [34–36].

Figure 2(c) shows the out-of-plane  $M$ - $T$  curves of the NCO films deposited at various  $T_g$ . Diamagnetic contributions from bare MAO substrates are measured and subtracted. Unlike ferromagnetic materials that usually show a sharp increase in magnetization below  $T_C$ , the magnetization of NCO films increases at nearly the same rate with decreasing temperature for all the NCO films studied, indicating the ferrimagnetic nature of NCO films [3,4].  $T_C$ , determined by extrapolating the linear dependence to zero magnetization, decreases from 380 to 302 K as  $T_g$  increases from 250 to 350 °C. The reduction of  $T_C$  may be attributed to the appearance of residual strain, oxygen vacancies, and local disorder in cation distribution, as has often been reported in transition metal oxide thin films [37,38].

### C. Transport characteristics

Temperature-dependent longitudinal resistivity of NCO films deposited at various  $T_g$  is measured from 2 to 390 K with the current along the [110] direction. In general, the resistivity increases with increasing  $T_g$ , as shown in Fig. 3(a). The NCO film deposited at the highest  $T_g = 350^\circ\text{C}$  is insulating in the entire temperature range measured. When deposited at 325 and  $300^\circ\text{C}$ , NCO films show an insulating behavior at high temperature, a metallic behavior in the intermediate temperature, and a reentry into the insulating state at low temperature. The high-temperature transition from the insulating to the metallic state upon cooling occurs at around the ferrimagnetic  $T_C$  of the NCO films, obviously associated with the appearance of the long-range magnetic order that facilitates electron hopping, as previously reported [17,19,20,39]. When further decreasing  $T_g$  to 275 and  $250^\circ\text{C}$ , the resistivity of NCO films decreases with decreasing temperature until the metal-to-insulator transition occurs at low temperature.

This low-temperature metal-to-insulator transition is observed in all the NCO films deposited at  $T_g$  below  $350^\circ\text{C}$ . The transition temperature  $T_{\min}$ , at which the minimum resistivity occurs, increases from 46 to 78 K as  $T_g$  increases from 250 to  $325^\circ\text{C}$ . This kind of low-temperature resistivity upturn has been frequently observed in correlated oxide thin films. For example, the low-temperature metal-to-insulator transition in ultrathin SrRuO<sub>3</sub> and LaNiO<sub>3</sub> films was explained by weak localization due to quantum interference via electron-electron or electron-phonon interactions [40,41]. The increase of resistivity below 47 K in Mn<sub>3+x</sub>Sn<sub>1-x</sub> thin films was ascribed to the Kondo effect due to the scattering of conduction carriers by the localized spins of magnetic impurities [42]. The mechanism can be extracted by examining the temperature dependence of resistivity. As shown in Fig. 3(b), we fit the resistivity below  $T_{\min}$  with [40,41,43]

$$\rho(T) = \rho_0 + aT^{3/4} + bT^n, \quad (1)$$

where  $\rho_0$ ,  $a$ ,  $b$ , and  $n$  are fitting parameters. Equation (1) describes the weak localization due to the disorder-enhanced electron-electron scattering in the dirty limit [43].  $\rho_0$  is the temperature-independent residual resistivity correlated with defects and impurities. The second term describes the elastic electron-electron scattering and all the inelastic scattering processes due to electron-phonon, electron-magnon, and electron-electron interactions are assumed to be adequately described by a single power law  $bT^n$  [40,41,43]. The continuous increase of  $\rho_0$ ,  $b$ , and the absolute value of  $a$  indicate the increased disorder and localizations in films deposited at higher  $T_g$  (see Fig. S2 in the Supplemental Material for the  $T_g$  dependence of fitting parameters in Eq. (1) [26]). Correspondingly,  $T_{\min}$  can be interpreted as a representation of the competition between localization induced by the electron-electron scattering and

the thermal delocalization. In films deposited at higher  $T_g$ , the enhanced localization shifts  $T_{\min}$  to higher temperature.

The NCO film deposited at  $T_g = 350^\circ\text{C}$  shows an insulating behavior in the whole temperature range measured. The low-temperature resistivity in this sample can be well fitted to the three-dimensional Mott variable range hopping (VRH) model [19,44,45],

$$\rho(T) = A \exp(T_0/T)^{1/4}, \quad (2)$$

as shown in Fig. 3(c), where  $A$  is a constant and  $T_0$  is the VRH characteristic temperature associated with the density of localized states, indicating the increased disorder in the sample with  $T_g = 350^\circ\text{C}$  [19,44,45]. According to Mott [45], carriers hop among localized states, assisted by atomic displacements in the lattice. As the temperature decreases, phonons do not have enough energy to assist hopping, resulting in the increase of resistivity [44,45].

Bulk NCO exhibits a ferrimagnetic metallic behavior with  $d\rho/dT > 0$  below  $T_C$  [15–22]. NCO films deposited at  $T_g \leq 325^\circ\text{C}$  are metallic in the intermediate temperature region, with a linear resistivity-temperature dependence [46],

$$\rho(T) = \rho_1 + BT, \quad (3)$$

as demonstrated in Fig. 3(d). The linear dependence of  $\rho(T)$  is well known as a result of electron-phonon scattering [46]. The residual resistivity  $\rho_1$  and the temperature-independent coefficient  $B$  obtained from fitting to Eq. (3) for different  $T_g$  are summarized in the Supplemental Material Fig. S3 [26]. The decrease of  $B$  for  $T_g$  above  $275^\circ\text{C}$  implies the weakened electron-phonon scattering, and the increased  $\rho_1$  suggests the increased amount of disorder in films deposited at higher  $T_g$ .

### D. Cation coordination and valance analyses

To further understand the transport and magnetic characteristics described above, XPS and XAS measurements are performed to study the electronic structure of Ni and Co cations in NCO films. Figure 4(a) shows the XPS  $2p_{3/2}$  core level spectra of Ni cations as functions of  $T_g$ . It is observed that the Ni  $2p_{3/2}$  peak shifts by 0.5 eV towards lower binding energy as  $T_g$  increases from 250 to  $350^\circ\text{C}$ . In NCO, Ni cations predominantly occupy the  $O_h$  sites [16–22], and the binding energy shift mainly comes from the variation of Ni valence states [47]. Ni cations with higher valence usually show a higher binding energy [47–49]. Therefore, the downshift in Fig. 4(a) indicates that the average valence of Ni cations decreases, with more Ni<sup>2+</sup> cations in samples deposited at elevated  $T_g$ . By fitting the XPS results in Fig. 4(a) using the peak at 853.78 eV for Ni<sup>2+</sup>, and the peak at 855.51 eV for Ni<sup>3+</sup> [47–55], the Ni<sup>3+</sup> : Ni<sup>2+</sup> atomic ratio can be obtained as a function of  $T_g$ , as shown in Fig. 4(c) (see Supplemental Material for

FIG. 4. (a) XPS spectra of Ni  $2p_{3/2}$  core level and corresponding fitting results for NCO films deposited at various  $T_g$ . The fitting is performed with components at 853.78 eV for  $\text{Ni}^{2+}$  cations, 855.51 eV for  $\text{Ni}^{3+}$  cations, and 861.22 eV for the satellite peak (Sat.). (b) XAS spectra of Ni  $L_3$  absorption edge and corresponding fitting results for NCO films deposited at various  $T_g$ . The olive curves represent XAS spectra for  $\text{Ni}^{3+}(O_h)$  from  $\text{LaNiO}_3$ , the wine curves represent XAS spectra for  $\text{Ni}^{2+}(O_h)$  from  $\text{NiO}$ . (c) The  $\text{Ni}^{3+} : \text{Ni}^{2+}$  atomic ratio as a function of  $T_g$ , acquired from fitting the XPS (orange solid squares) and XAS results (wine solid triangles).

fitting details [26]). The  $\text{Ni}^{3+} : \text{Ni}^{2+}$  atomic ratio is 1.33 when  $T_g$  is 250 °C, then decreases to about 0.83 when  $T_g$  is 350 °C.

Figure 4(b) shows the Ni  $L_3$  XAS edges for NCO films deposited at various  $T_g$ . It is observed that the absorption edge also shifts towards lower energy with increasing  $T_g$ . The absorption peak is at 853.8 eV for the  $T_g = 250$  °C sample and 853.4 eV for the  $T_g = 350$  °C sample, with the full width at half maximum of about 2.8 eV. For  $\text{Ni}^{3+}$  cations occupying the  $O_h$  sites in  $\text{LaNiO}_3$ , for example, the  $L_3$  edge shows a plateau with a full width at half maximum of about 3.5 eV, and the maximum appears at around 854.0 eV [56]. However,  $\text{Ni}^{2+}$  cations in  $\text{NiO}$  exhibit a much sharper peak with a full width at half maximum of only about 1.5 eV, and the maximum appears at around 853.0 eV [57]. Therefore, the XAS results also indicate the coexistence of  $\text{Ni}^{2+}$  and  $\text{Ni}^{3+}$  cations at  $O_h$  sites, the reduced Ni valence states, and the increased amount of  $\text{Ni}^{2+}$  at  $O_h$  sites in NCO films deposited at elevated  $T_g$  [56,57]. The  $\text{Ni}^{3+} : \text{Ni}^{2+}$  atomic ratio can also be estimated by fitting the measured Ni  $L_3$  edges with a linear combination of those from  $\text{LaNiO}_3$  and  $\text{NiO}$ , as shown in Fig. 4(b) (see Supplemental Material for the fitting details [26]) [58]. According to the relative spectral weight, the  $\text{Ni}^{3+} : \text{Ni}^{2+}$  atomic ratio can be estimated, decreasing with the increase in  $T_g$  in good agreement with the XPS results, as also

shown in Fig. 4(c). The average valence state of Ni can be estimated, from the  $\text{Ni}^{3+} : \text{Ni}^{2+}$  atomic ratio, as  $\text{Ni}^{2.59+}$  for the  $T_g = 250$  °C sample, and  $\text{Ni}^{2.45+}$  for the  $T_g = 350$  °C sample.

Figure 5(a) shows the Co  $2p_{3/2}$  XPS core level spectra of NCO films deposited at various  $T_g$ . The peak shifts by 0.4 eV towards lower binding energy as  $T_g$  increases from 250 to 350 °C. However, the analysis of the Co XPS chemical shift is much more complex, as not only the valence states but also the coordination correlate with the chemical shift [59,60]. The XPS spectra should be deconvoluted into three peaks representing  $\text{Co}^{2+}$  on  $T_d$  sites,  $\text{Co}^{3+}$  on  $T_d$  sites, and  $\text{Co}^{3+}$  on  $O_h$  sites. However, we try in vain to find a reliable binding energy for  $\text{Co}^{3+}$  on  $T_d$  sites, and therefore, give up on decomposing the Co XPS spectra. We then try to analyze Co valence and coordination by XAS.

Figure 5(b) shows the Co  $L_3$  XAS edges for NCO films deposited at various  $T_g$ . The main feature is a broad peak around 780.0 eV. As reported previously, the  $L_3$  absorption peaks of both  $\text{Co}^{3+}$  at  $T_d$  sites and  $\text{Co}^{3+}$  at  $O_h$  sites appear at about 780.2 eV [61–64]. As  $T_g$  increases, a shoulder at around 778.0 eV, indicated in Fig. 5(b) by arrows, appears gradually. As proposed by Kan *et al.* [21], this shoulder originates mainly from  $\text{Co}^{2+}$  at  $T_d$  sites in NCO films [22]. Therefore, the concentration of  $\text{Co}^{2+}$  cations occupying the  $T_d$  sites increases with increasing  $T_g$ . As shown

FIG. 5. (a) XPS spectra of Co  $2p_{3/2}$  core level for NCO films deposited at various  $T_g$ . (b) XAS spectra of Co  $L_3$  absorption edge and corresponding fitting results for NCO films deposited at various  $T_g$ . The olive curves represent XAS spectra for Co<sup>2+</sup> at  $T_d$  sites, the grey curves represent XAS spectra for Co<sup>3+</sup> at  $T_d$  sites, and the wine curves represent XAS spectra for Co<sup>3+</sup> at  $O_h$  sites. (c) The Co<sup>2+</sup> : Co<sup>3+</sup> atomic ratio as a function of  $T_g$ , acquired from fitting the XAS results.

in Fig. 5(b), the Co  $L_3$  edges of the NCO films can be well fitted with a linear combination of the  $L_3$  edges of Co<sup>2+</sup> at  $T_d$  sites, Co<sup>3+</sup> at  $T_d$  sites, and Co<sup>3+</sup> at  $O_h$  sites (see Supplemental Material for fitting details [26]) [17,58,61–64]. Based on the relative spectral weights, the relative fraction of Co<sup>2+</sup> at  $T_d$  sites, Co<sup>3+</sup> at  $T_d$  sites, and Co<sup>3+</sup> at  $O_h$  sites can be estimated. It is, for example, 0.35:0.45:1.2 for the  $T_g = 250$  °C sample. With increasing  $T_g$ , the number of Co cations at the  $T_d$  sites increases while that at  $O_h$  decreases. It becomes 0.66:0.32:1.02 for the  $T_g = 350$  °C sample. As a result, the Co<sup>2+</sup> : Co<sup>3+</sup> atomic ratio increases from 0.21 to 0.49, as shown in Fig. 5(c), and the average valence state decreases from Co<sup>2.83+</sup> to Co<sup>2.67+</sup> with  $T_g$  increasing from 250 to 350 °C. Although Co<sup>3+</sup> at  $O_h$  sites were frequently assumed in the low-spin state [15–22,28], the XAS component of Co<sup>3+</sup> at  $O_h$  sites can be well represented by XAS from Co<sup>3+</sup> in LaCoO<sub>3</sub>. As well known in LaCoO<sub>3</sub>, Co<sup>3+</sup> cations are only in the low-spin state at very low temperatures [63,64], thus it is reasonable that Co<sup>3+</sup> cations at the  $O_h$  sites are in a mixture of low- and high-spin states at room temperature.

### E. Discussions

The variation in cation valence and coordination in NCO films with increasing  $T_g$  has profound influences on the structure, magnetic, and transport properties of NCO films.

At  $O_h$  sites, the atomic radius of a Ni<sup>2+</sup> cation is 0.69 Å, much larger than that of Ni<sup>3+</sup> cation (0.53 Å) [19,20]. The continuous increase of Ni<sup>2+</sup> concentration with increasing  $T_g$  may lead to a systematic increase in lattice parameters. At the same time, the increased Co<sup>2+</sup> and the decreased Co<sup>3+</sup> concentration at the  $T_d$  sites also contributes to the lattice expansion, with the atomic radius being 0.72 Å for the former and 0.61 Å for the latter [65,66]. Lattice expansion shown in Fig. 1(a) results in larger compressive strain in NCO films with higher  $T_g$ . The strain modifies the local environment of magnetic ions through the magnetoelastic effect, changing their preferred spin orientations due to spin-orbit coupling [21,22,29]. Recent works pointed out that among the magnetic ions in NCO films, Co cations at  $T_d$  sites play a key role in determining the PMA, while the contribution of Ni ions is less dominant. This is because of the large orbital moment of the in-plane Co  $3d_{x^2-y^2}$  state and the magnetoelastic effect due to the compressive strain. According to the analysis above, Co concentration at the  $T_d$  sites increases in NCO films deposited at higher  $T_g$ . The increased Co concentration, together with the increased compressive strain, results in the enhanced PMA observed in Fig. 2(e), which inevitably leads to a larger  $H_c$ . As for the transport property, recent experimental results and first-principles calculations have shown that the Fermi surface in NCO is composed of spin-down electrons of Ni cations at the  $O_h$  sites, making NCO

half-metallic [17,67,68]. The appearance of  $\text{Ni}^{3+}$  at the  $O_h$  sites provides a partially occupied  $e_g$  orbital and facilitates carrier transport through  $\text{Ni}^{2+}\text{-O-Ni}^{3+}$  and  $\text{Co}^{2+}\text{-O-Ni}^{3+}$  [17,67,68]. At the same time, Co at either  $T_d$  or  $O_h$  sites provides almost no density of states at the Fermi level and has less influence on electrical conduction in NCO films [17,68]. Hence, having fewer  $\text{Ni}^{3+}$  cations in NCO is detrimental to carrier transport. The resistivity of NCO films increases with increasing  $T_g$ , which leads to a higher concentration of  $\text{Ni}^{2+}$  cations in the films. For magnetization, assuming  $\text{Co}^{3+}$  cations at the  $O_h$  sites are completely in the low-spin state, providing no magnetization, the obtained cation concentration, as shown in Figs. 4(c) and 5(c), generates a total magnetization increasing with the increase of  $T_g$ , contrary to the observation in Fig. 2. However, deposition at higher  $T_g$  induces more defects, as concluded from the analysis of resistivity. These defects inevitably have effects on not only the transport, but also the structure and magnetic properties. The concentration of oxygen vacancies can be estimated based on charge neutrality, being 1.25%, 2.25%, and 2.75% for samples with  $T_g = 275, 325,$  and  $350^\circ\text{C}$ , respectively, suggesting the increased oxygen vacancy concentration at higher  $T_g$ . It has been well documented that oxygen vacancies may lead to the reduction of magnetization by disturbing the double exchange interaction, which may occur in NCO films and lead to the decreased magnetization [69,70].

#### IV. CONCLUSION

In summary, epitaxial NCO films, with large PMA, are deposited on single-crystalline MAO (001) substrates by pulsed laser deposition at various  $T_g$ . The out-of-plane  $H_c$  can be tuned systematically by about 20 times from 350 to 7300 Oe with  $T_g$  increasing from 250 to  $350^\circ\text{C}$ . Such a significant  $H_c$  tunability can be explained by the increased concentration of defects and the enhanced PMA in NCO films as  $T_g$  increases. Based on XPS and XAS analyses, the variations of magnetic and transport characteristics are attributed to the variation of the valence and coordination of Ni and Co cations as functions of deposition temperature. These results are helpful to the optimization and application of NCO films for multifunctional magnetic devices.
