(Received 9 June 2023; revised 21 September 2023; accepted 2 November 2023; published 27 November 2023)

We study the frequency nonreciprocity of the spin waves in symmetric $\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}/\text{Ru}/\text{Co}_{40}\text{Fe}_{40}\text{B}_{20}$ synthetic antiferromagnet stacks set in the scissors state by in-plane applied fields. Using a combination of Brillouin light scattering and propagating spin-wave spectroscopy experiments, we show that the acoustical spin waves in synthetic antiferromagnets possess a unique feature if their wave vector is parallel to the applied field: the frequency nonreciprocity due to layer-to-layer dipolar interactions can be so large that the acoustical spin waves transfer energy in a unidirectional manner for a wide and bipolar interval of wave vectors. Analytical modeling and full micromagnetic calculations are conducted to account for the dispersion relations of the optical and acoustical spin waves for arbitrary field orientations. Our formalism provides a simple and direct method to understand and design devices harnessing unidirectional propagation of spin waves in synthetic antiferromagnets.

DOI: 10.1103/PhysRevApplied.20.054051

Spin waves (SW), introduced by Bloch [1], are the elementary excitations of the magnetic order parameter. They have interesting properties, such as nonlinear effects, anisotropic propagation, and frequency nonreciprocity (NR) [2–4]. NR is the situation where the frequency ω of a SW of wave vector \vec{k} changes upon reversing the direction of phase propagation [5]. The asymmetry of the dispersion relation $\omega(\vec{k}) \neq \omega(-\vec{k})$ can be harnessed to design devices with very peculiar behaviors, such as magnonic diodes [6,7], directional spin-wave emitters [8,9], curved spin-wave antennas [10], chiral magnonic logic devices [11], and passive nonreciprocal filters [12].

Layer-to-layer dipolar interactions in a multilayer can lead to large NR [13]. This requires some contrast of magnetization—orientation or magnitude—with the thickness of the multilayer [14]. The contrast is maximal for synthetic antiferromagnets (SAFs), i.e., two ferromagnetic layers separated by a spacer layer that mediates an effective interlayer interaction of coupling parameter $J < 0$ favoring an antiparallel state. In SAFs, SWs have two precession modes [13] namely acoustical (in phase) and optical (out of phase). Owing to the strong interest on nonreciprocal SW modes, the analysis of the dispersion relations in SAFs has already been undertaken by several authors [4,14–19]. Analytical expressions were proposed for a symmetric SAF in Refs. [14], [15] at zero applied field. Expressions of $\omega(\vec{k})$ valid at finite fields were then

provided by Ishibashi *et al.* [16]. They were successfully used for a qualitative discussion of experimental results. One special character of nonreciprocity is unidirectionality, achieved when reversing the sign of the wave vector does *not* reverse the direction of the group velocity $\vec{\nabla}_{\vec{k}}(\omega)$, such that the energy carried by a wavepacket is truly “unidirectional”: SW can carry energy in one direction but not its opposite. The concept of unidirectional SWs and its potential applications has been reviewed in Ref. [20], which mentions examples of successful implementations on various configurations.

In this paper, we show that when a SAF is set in a scissors state, its acoustical spin-wave mode can have a very unique dispersion relation: there exists field conditions and wave-vector orientations for which unidirectionality is achieved, and in addition is reconfigurable. We demonstrate switchable unidirectionality of acoustical spin waves, in line with previous observations of reconfigurable frequency nonreciprocity in SAF (Refs. [15], [16]). Furthermore, we develop an easy-to-use formalism validated by simulations and measurements. Our results and the associated understanding could then be used to design optimally nonreciprocal devices. The paper is organized as follows. In Sec. I, we evidence this unique NR feature by Brillouin light scattering (BLS); we then design a device that benefits from this feature. In this device, inductive propagating spin-wave spectroscopy (PSWS) experiments demonstrate that the energy flow associated with SWs can be fully unidirectional. In Sec. II we derive an approximate description of the group velocities, enabling

* florian.millo@universite-paris-saclay.fr

a physical understanding of the peculiarities of the SW propagation within SAFs. These expressions are compared with Ref. [16] and with our full micromagnetic calculations in Sec. III. Finally, their accuracy is discussed.

I. EVIDENCE OF UNIDIRECTIONALITY OF SPIN WAVES IN SYMMETRIC SAF

A. Materials: synthetic antiferromagnets

We use symmetric SAFs of composition: substrate/Ta(6 nm)/Co₄₀Fe₄₀B₂₀(t_{mag})/Ru(0.7 nm)/Co₄₀Fe₄₀B₂₀(t_{mag})/Ru(0.4 nm)/Ta(3 nm), where $t_{\text{mag}} = 17$ nm. The properties of the SAFs were characterized in Refs. [21], [22], notably to derive the interlayer exchange field $H_J = -2J/\mu_0 M_s t_{\text{mag}}$, where M_s is the saturation magnetization.

Two different substrates were needed: Y-cut LiNbO₃ substrates, which are optimal for microfabrication [23], are used for electrical measurements, while naturally oxidized silicon substrates are optimal for Brillouin light scattering experiments. The corresponding samples have slightly different properties. Both samples have in-plane uniaxial anisotropies much smaller than their respective spin-flop fields. They share the same saturation magnetization $\mu_0 M_s = 1.71$ T and the same damping $\alpha \approx 0.0045$, although different interlayer exchange fields: $\mu_0 H_J = 148$ mT for Y-cut LiNbO₃ and $\mu_0 H_J = 78$ mT for oxidized silicon substrates (more details are given in the Appendix). Since we will focus on SWs of long wavelengths where the shapes of the dispersion relations are mainly determined by layer-to-layer dipolar effects [4,5,15,16,24], we will consider that the two samples are essentially comparable.

B. Spin-wave dispersion relations

We measured the dispersion relations of the SWs within the SAF by performing wave-vector-resolved BLS spectroscopy. The experimental configuration is sketched in Fig. 1(b). The applied field $\mu_0 |\vec{H}_0| = 25$ mT, higher than the spin-flop field ($\mu_0 |\vec{H}_{\text{SF}}| = 8$ mT), was chosen to set the SAF in one of the two degenerate scissors states [16] sketched in Fig. 2(c). The BLS laser beam impinges the sample surface with an incidence $\theta \in [5^\circ - 30^\circ]$ with respect to the normal and we analyze the back-scattered photons. The scattering conserves the total momentum, so the wave number of the magnons annihilated (anti-Stokes process) or created (Stokes process) in the scattering process obeys $k_x = \pm 4\pi/(\lambda) \sin \theta \in [\pm 2, \pm 12]$ rad/ μm with a frequency shift allowing to construct $\omega(k)$. Figure 1(c) reports the measured dispersion relations $\omega(\vec{k})/2\pi$ for $\vec{k}_x \parallel \vec{H}_0$. Two points are worth emphasizing:

(a) The optical spin-wave mode has a tilted (i.e., non-symmetric) V-shaped dispersion relation [see Fig. 1(c)]: it is nonreciprocal. The NR is classical in the sense that the group velocity has always the same sign as the wave

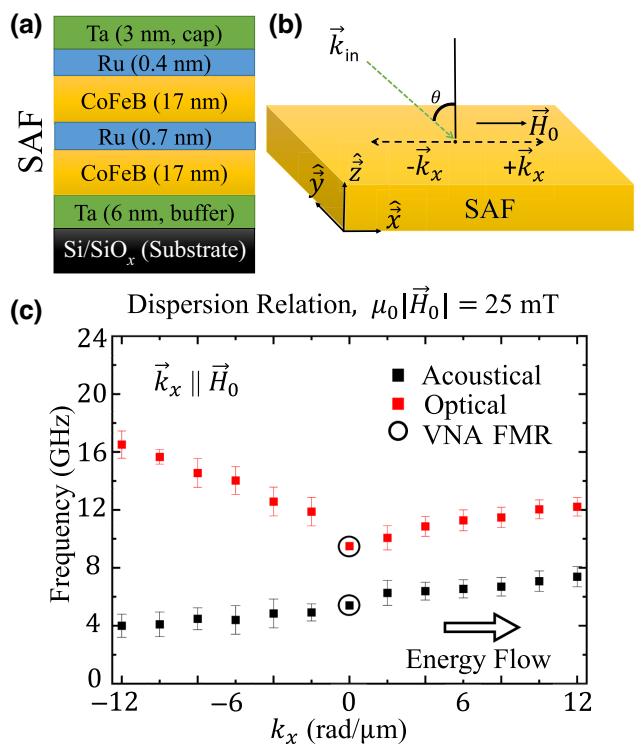

FIG. 1. (a) Multilayer stack of the synthetic antiferromagnet used for the BLS experiments. (b) BLS geometry: applied field \vec{H}_0 parallel to the \hat{x} axis, plane of incidence (xz), wavelength of laser beam $\lambda = 532$ nm. (c) Dispersion relations are measured by BLS for $\vec{k}_x \parallel \vec{H}_0$. The uniform resonances (circles at $k=0$) were measured by vector network analyzer ferromagnetic resonance (VNA FMR). The error bars are the linewidths (full width at half maximum). The black arrow emphasizes that the group velocity of the acoustical SWs always points toward the positive side, irrespective of the sign of the wave vector.

vector, i.e., it is a “forward” wave, in agreement with the forthcoming modeling (Table I and Sec. III).

(b) In contrast, the dispersion relation of the acoustical spin-wave branch is quasilinear in the range explored here $[-12, 12]$ rad/ μm , a fact that is very unusual for a wave. The group velocity of these SWs is always positive, whatever the sign of the wave vector. This is a unique feature of the acoustical SWs of a SAF set in the scissors state. As a result, the energy carried by a wavepacket of acoustical SWs is expected to propagate in a one-way manner.

It is also interesting to note that the frequency NR $\delta f = 1/2\pi(\omega(|\vec{k}|) - \omega(-|\vec{k}|))$ of the two modes are of comparable magnitudes although with opposite signs. For $k = 2$ rad/ μm , the NRs amount already to $\delta f_{\text{ac}} = 1.35$ GHz and $\delta f_{\text{op}} = -1.81$ GHz. For $k = 12$ rad/ μm , the NRs are as large as $\delta f_{\text{ac}} = 3.39$ GHz and $\delta f_{\text{op}} = -4.29$ GHz. These very large values demonstrate that the SAF has an exceptional NR.

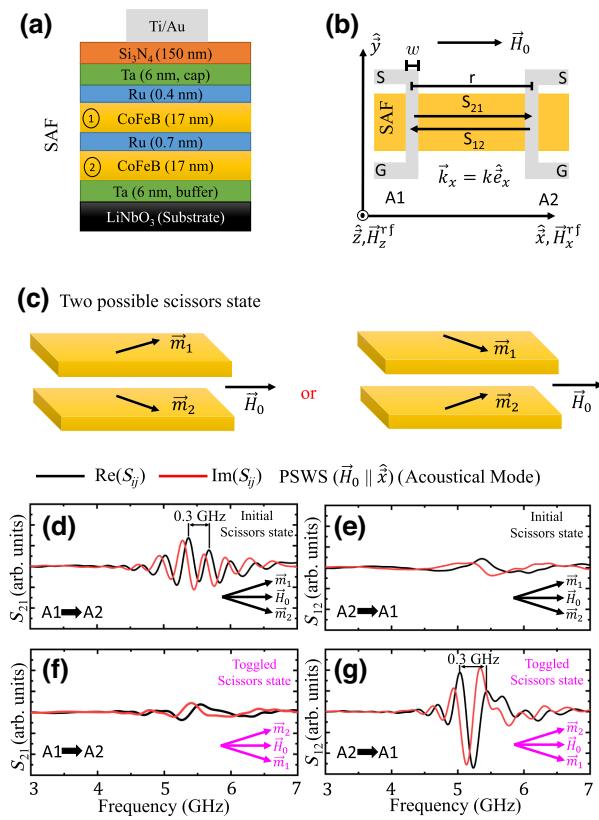

FIG. 2. (a) Stack of synthetic antiferromagnetic film patterned into devices for propagating spin-wave spectroscopy experiments. (b) Geometry of the device. Gray: single-wire antennas with $r = 6 \mu\text{m}$ and $w = 1.8 \mu\text{m}$. Antenna 1 (A1) and antenna 2 (A2) are connected to a VNA to collect transmission [S_{12}, S_{21}] parameters. (c) Two possible scissors state of the system. (d),(e) Forward and backward transmission parameter measured for wave propagating from A1-to-A2, A2-to-A1, respectively, and at one of two possible degenerate scissors state. (f),(g) Forward and backward transmission parameter measured for propagating SWs after toggling the scissors state.

Gallardo *et al.* [15] predicted, by theoretical and micromagnetic simulations and measured by BLS, a high NR in frequency in a bilayer system due to the layer-to-layer dipolar interactions. They found that this high NR of acoustical SWs can be controlled by equilibrium configuration and by the geometry of the system. Our results fully agree with their study. For the acoustical mode, the NR even achieves unidirectionality of the energy flow [see Fig. 1(c)]. Let us illustrate this point using electrical measurements.

C. Energy flow carried by propagating spin waves

In this section, we perform propagating spin-wave spectroscopy measurements to identify in which direction the spin waves effectively transfer energy. The measurement relies on the device sketched in Figs. 2(a) and 2(b). The device is a SW conduit made of a 20-μm-wide SAF stripe

covered by a thick insulating layer and two inductive antennas. These rf antennas have a width of $w = 1.8 \mu\text{m}$ and a center-to-center distance of $6 \mu\text{m}$ in the \hat{x} direction. The antennas can be considered as infinite in the \hat{y} direction and therefore they couple only to SWs with wave vectors directed in the \hat{x} direction, as seen in Fig. 2(b). When connected to a vector network analyzer, the antennas emit a circulating rf field $\vec{H}^{\text{rf}}(x, z)$ with components along both \hat{x} and \hat{z} axes. Thanks to these two components the rf field can couple with the acoustical spin waves even when $\vec{H}_0 \parallel \hat{x}$. The applied field $\mu_0 |\vec{H}_0| = 41 \text{ mT}$ was chosen to lead to the same uniform resonance acoustical frequency $f_{\text{ac}}^{k=0} = 5.4 \text{ GHz}$ as in Fig. 1(c).

The four measurements of Figs. 2(d), 2(e), 2(f), 2(g) are done for exactly the same applied field $\vec{H}_0 \parallel \hat{x}$. This field sets the SAF in one of two degenerate scissors state [see Fig. 2(c)] where the equilibrium magnetizations of each layer [see Fig. 2(c)], \vec{m}_1 and \vec{m}_2 , scissors toward the direction of the applied field \vec{H}_0 . The scissors state that is effectively obtained is unknown: $(\vec{m}_1 \times \vec{m}_2) \cdot \hat{z}$ can be either positive or negative. However, a toggle-switching experiment [25] can switch the scissors from one state to the other.

The experiment is done in four steps. First we apply \vec{H}_0 in the $+\hat{x}$ direction and characterize the sample [see Figs. 2(d) and 2(e)]. The SAF is in one of the two possible scissors states [see Fig. 2(c)]. Then, we rotate \vec{H}_0 by 180°. The scissors state follows the rotating field. We then take back \vec{H}_0 to 0 mT, then apply again \vec{H}_0 in the $+\hat{x}$ direction: the obtained “toggled” scissors state [see Figs. 2(f) and 2(g)] is the inverse of the initial one. Finally, we perform the characterization exactly as for the initial state.

Figure 2(d) shows that in the first scissors state, the forward transmission parameter is oscillatory and strong, while in the toggled scissors state [Fig. 2(f)] it is weak and nonoscillatory, with a quasi-Lorentzian shape. The oscillatory character is indicative [26] that the forward transmission arises from propagating waves. The quasi-Lorentzian shape is indicative [27] that it arises from quasiumiform SWs excited under the receiving antenna by the rf field of the exciting antenna, cf. Figs. 2(e) and 2(f), without a significant propagation of the involved SWs.

This interpretation—propagating SWs in the sole forward direction—is corroborated by the frequency contents of the transmission signals. Indeed the backward signal is finite only near the uniform resonance $f_{\text{ac}}^{k=0} = 5.4 \text{ GHz}$ within its linewidth. In contrast, the forward transmission parameter spans over frequencies both much below and much above $f_{\text{ac}}^{k=0}$. This stems from the linear character of the acoustical dispersion relation: the SWs with $k < 0$ have frequencies below $f_{\text{ac}}^{k=0}$ and the SWs with $k > 0$ are above $f_{\text{ac}}^{k=0}$. They have both a group velocity pointing towards the receiving antenna, such that this leads to a

TABLE I. Group velocities of SWs in a SAF for a two-macrospin ground state in the long wavelength limit. The SAF is isotropic and fully symmetrical. The field \vec{H}_0 is applied along the \hat{x} direction. The group velocities are meant as $\frac{d\omega}{dk}$, irrespective of the sign of k . They are given in units of $\frac{1}{2}\gamma_0 M_s t_{\text{mag}}$. The colored cells highlight the situations when the SWs show frequency nonreciprocity. The † symbol recalls that the Taylor expansion to first order in $k t_{\text{mag}}$ is not legitimate when the acoustical eigenfrequency vanishes. Note that the sign of nonreciprocal terms within the group velocities are reversed when toggling the magnetizations of the two layers of the SAF.

one-way transfer of energy between the antennas, in the same direction for frequencies above and below $f_{\text{ac}}^{k=0}$.

Interestingly also, when toggling the SAF from one of degenerate scissors state to the other, we observe that the direction in which the acoustical spin waves can transfer energy is reversed [compare the panels of Figs. 2(d), 2(f) and Fig. 2(e), 2(g)]. As we shall see later, this arises from the fact that the dispersion relation of acoustical spin waves undergoes the transformation $\vec{k}_x \rightarrow -\vec{k}_x$ when the two magnetizations of the SAF are toggled while keeping \vec{H}_0 applied along $+\hat{x}$ direction. This experiment can be interpreted as switching the unidirectionality of the acoustical SWs, to be compared to the experiment of Ref. [16] that switches the nonreciprocity of optical SWs.

II. APPROXIMATE GROUP VELOCITIES

Let us model the dispersion relations of SW in SAF and their dependence over the field orientation. We shall make approximations to get insightful expressions.

A. Simplifying assumptions and methods

We describe the ground state in the two-macrospin approximation, i.e., we assume that the SAF comprises

two films (labeled 1 and 2 [see Fig. 2(a)]) that are uniformly magnetized across their thickness. For an applied field $|H_0| < H_j$, the SAF is in one of the two degenerate scissors states [13,28]. Note that to consider the other scissors state [obtained by swapping of the magnetizations of the top (*t*) and bottom layers (*b*)], one just needs to rotate the sample by 180° around the \hat{y} axis, which changes $+\hat{x}$ into $-\hat{x}$ and $+\vec{k}_x$ into $-\vec{k}_x$. The measurement geometry does not change in this process, but the top layer become the bottom one and the antennas 1 and 2 get exchanged. The measured dispersion relations have thus to obey the bottom-top swapping property:

$$\omega_{tb}(\vec{k}) = \omega_{bt}(-\vec{k}), \quad (1)$$

as confirmed from the PSWS characterizations [see Figs. 2(d), 2(e), 2(f), 2(g)]. The dynamical matrix of the system can be calculated following the standard methodology [5,29–31] and must be augmented with the contribution of finite wave vectors to the self- and mutual demagnetizing effects of the two magnetic layers [see Eq. (25) and (26) of Ref. [24] for a general description, or Ref. [16] for the specific case of a SAF set in scissors state]. The two eigenvalues of the dynamical matrix are

the frequencies of the SWs: the acoustical [13] SW mode for which the scissoring state undergoes essentially a rigid rocking, and the optical SW mode for which the scissoring angle breathes. At $k = 0$ the eigenfrequencies reduce to

$$\frac{\omega_{\text{ac}}^{k=0}}{\gamma_0} = H_0 \sqrt{\frac{M_s + H_j}{H_j}} \quad \text{and} \quad \frac{\omega_{\text{op}}^{k=0}}{\gamma_0} = \sqrt{\frac{M_s}{H_j}} \sqrt{H_j^2 - H_0^2}, \quad (2)$$

where γ_0 is the gyromagnetic ratio.

Being solutions of a biquadratic equation, the expressions of the frequencies of the optical and acoustical spin waves are heavy [see, for instance, Eq. (1) and (2) Ref. [16]]. To get linear in kt_{mag} (simple to apply) formulas, these frequencies were Taylor expanded to first order in kt_{mag} near $kt_{\text{mag}} = 0$. The noticeable expressions of the group velocities are gathered in Table I, given in $\frac{1}{2}\gamma_0 M_s t_{\text{mag}}$ units. We must again emphasize that we are in a dipolar-dominated system where at low \vec{k} , $\lambda/t_{\text{mag}} \gg 1$. For $\vec{H}_0 \perp \vec{k}_x$ and $\vec{H}_0 \parallel \vec{k}_x$, the group velocities have simple expressions that are consistent with previous reports [16,23]. For wave vectors directed in other directions, getting simple formulas requires a further Taylor expansion assuming $H_0 \ll H_j$ to provide an analytical angular dependence of the v_g 's valid at low fields.

B. Peculiarities of the group velocities of a SAF in the scissors state

Several points are worth noticing in Table I.

(i) At low applied fields, the group velocities of the acoustical SWs follow a natural scale, which is $\frac{1}{2}\gamma_0 M_s t_{\text{mag}}$. It amounts to 2.5 km/s for our material parameters. This velocity scale is independent from the exchange coupling J .

In contrast, the group velocities of the optical SWs comprise an additional dimensionless accelerating factor that depends on J . For $\vec{k} \parallel \vec{H}_0$ this accelerating factor is either $+(\sqrt{M_s/H_j} + 1)$ or $- (\sqrt{M_s/H_j} - 1)$. These are, respectively, 5.6 and -3.6 for our samples. This is in agreement with the BLS study that concluded that optical SWs are faster than acoustical ones when $\vec{k} \parallel \vec{H}_0$ [see Fig. 1].

(ii) In the scissors state, the SWs in a SAF are *almost always* nonreciprocal. The only reciprocal case is when $\vec{H}_0 \perp \vec{k}_x$. The dispersion is then V-shaped for the acoustical mode and flat for the optical mode. In the other cases, despite its nonreciprocity, the dispersion relation of the optical SWs is still conventional in the sense that the sign of group velocity and the sign of k are always correlated. For most [32] wave-vector orientations, the dispersion relation of the optical SWs has the shape of a tilted V: the group velocity and the wave vector are of the same sign and a SW transmits energy in the direction of its wave vector.

(iii) As anticipated from the experimental results, the most counterintuitive situation is that of acoustical SWs of wave vectors $\vec{H}_0 \parallel \vec{k}_x$ in the scissors state. In this case, the dispersion relation is quasilinear across $k = 0$, such that the group velocity points towards the same direction *regardless* of the sign of k . Acoustical spin waves with $\vec{H}_0 \parallel \vec{k}_x$ can transfer energy only in one direction. Since toggling the SAF to the other scissors state is equivalent to changing the sign of k , this also explains why the direction in which SWs can transfer energy is reversed when toggling the SAF.

(iv) The nonreciprocities of the acoustical and optical modes defined as $\delta f_{\text{ac, op}} = f_{\text{ac, op}}(k) - f_{\text{ac, op}}(-k)$ are predicted to be equal in magnitude but opposite. From Taylor-expanded expressions of the SW frequencies versus \vec{k}_x we find

$$\delta f_{\text{op}}, \quad -\delta f_{\text{ac}} = \gamma_0 M_s k t_{\text{mag}} \sqrt{1 - \left(\frac{H_0}{H_j}\right)^2} \cos \varphi. \quad (3)$$

This expression is exact for $\phi = 0$ and $\pi/2$ but defined at $O(H_0^2)$ otherwise.

(v) Finally we emphasize that the group velocity $\vec{V}_{\vec{k}}(\omega)$ is in general not colinear with the wave vector, such that wavepackets with a two-dimensional content of wave vectors will propagate with potentially nontrivial deformations like self-focusing and caustics, as already mentioned in Ref. [4].

The expressions gathered in Table I are convenient for the physical understanding. They must however be considered with care: indeed the linear Taylor expansion over kt_{mag} leads to negative (unphysical) frequencies when used at low fields. Besides, the expressions in Table I suffer from a fundamental limitation: the two-macrospin ground state is inaccurate for SAFs thicker than the exchange lengths [21]. In this case, a gradient of the magnetization orientation can develop within each layer [21], which renders incorrect the eigenfrequencies at $k = 0$. The micromagnetic configuration and its SWs must then be calculated numerically using a full micromagnetic framework.

III. MICROMAGNETIC SIMULATIONS OF THE DISPERSION RELATIONS

In this section we will develop micromagnetic simulations based on the Mumax3 software [33] to provide more reliable dispersion relations of Si/SiO_x/SAF system. After describing the geometry, we detail how to selectively excite the acoustic or optic modes. Then we describe a method that allows to differentiate $+k$ (forward phase velocity) and $-k$ (backward) in any nonreciprocal situation.

A. Simulation geometry

To mimic experiments, we first define a SAF slab of in-plane dimensions $\{l_x \times l_y\}$ where $l_x = l_y = 4\pi \mu\text{m} \approx 12.6 \mu\text{m}$ and total thickness of 34 nm. The slab is replicated 10 times in \hat{x} and \hat{y} directions to approximate an infinite thin film. To optimize the calculation time, each slab is meshed into $512 \times 64 \times 16$ cells. The slices along the thickness are numbered $i = 1, \dots, 16$ upward. An inter-layer exchange coupling is applied between slices $i = 8$ and $i = 9$ to account for the Ru layer whose thickness is neglected. We first apply an in-plane static field H_0 and let the system relax to its ground state. As in the experiments, the angle φ is defined between the SW wave vector (k_x conventionally along x), and the field H_0 [see Fig. 3(c)].

B. Methods

To identify the dispersion relations, we excite the sample with stimuli that bring it out of equilibrium and we analyze the spectral content of the magnetization response.

1. Mode-resolved dispersion relations

A frequently implemented stimulus is a short field pulse that imprints a spatial periodicity and contains a broadband frequency content. We choose to apply a pulsed rf field of the form:

$$\vec{H}^{\text{rf}}(x, t, z) = h_0 f(x) g(t) q(z) \hat{\vec{e}}_z \quad (4)$$

where

- the peak of the excitation field is $\mu_0 h_0 = 1 \text{ mT}$;
- the temporal shape of the pulse is $g(t) = \text{sinc}(\pi f_c t)$, with its duration set by $f_c = 100 \text{ GHz}$ [see Fig. 3(b)];
- the thickness profile of the stimulus is $q(z)$ [Fig. 3(e)];
- its spatial profile is $f(x) = \sin(\vec{k}_x \cdot \hat{\vec{e}}_x x)$ [Fig. 3(a)].

The spatial periodicity of the stimulus along $\hat{\vec{e}}_x$ is chosen so as to fit an integer number of wavelengths within the slab in the x direction, by setting $\vec{k}_x = (2\pi n/l_x) \hat{\vec{e}}_x$ with $n \in \mathbb{N}$. This leads to a wave-vector resolution of $\frac{1}{2} \text{ rad}/\mu\text{m}$.

The selective excitation of the acoustical mode is depicted in Fig. 3(f). To excite the sole acoustical modes, the torque from the stimulus must be made uniform across the thickness of the SAF. This is ensured by setting $q(z) = q_{\text{ac}}(z) = 1$ and an orientation of the rf field along $\hat{\vec{e}}_z$ [see Fig. 3(f)]. Conversely, to excite the sole optical mode one applies torques that are opposite in the two layers. For an rf field along $\hat{\vec{e}}_z$, this condition is ensured by choosing $q(z) = q_{\text{op}}(z) = \text{sgn}(i - 8.5)$ where sgn is the signum function, which is -1 for the bottom layers ($i \leq 8$) and $+1$ for the top layers ($i > 8$). Finally, if one aims to excite both

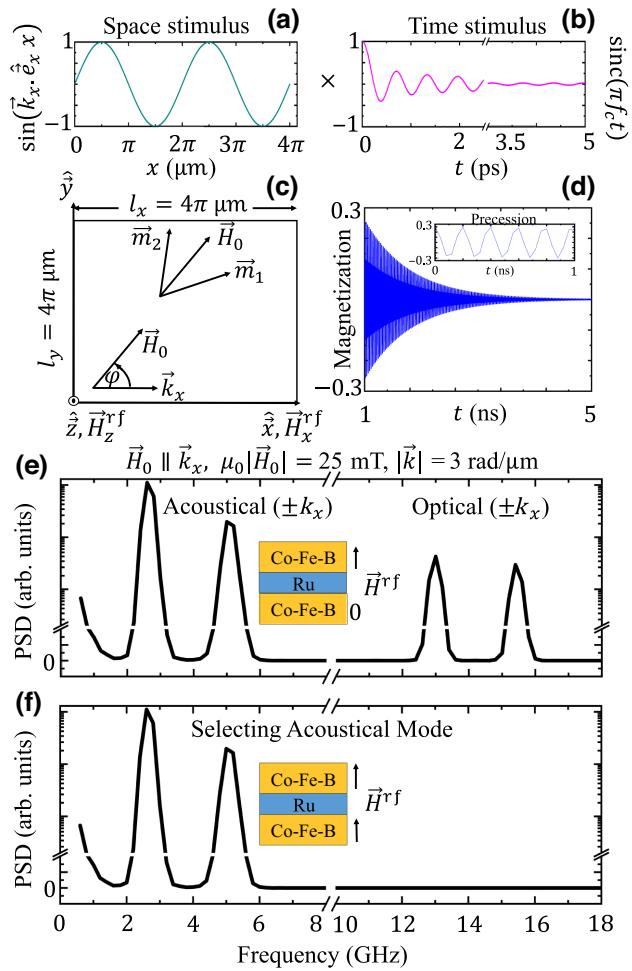

FIG. 3. Method used to construct the mode-resolved dispersion relations as described in Sec. III B 1. (a) Spatial dependence and (b) time dependence of the pulsed rf field [Eq. (4)]. (c) Top view of the simulated system with lateral dimensions of $(4\pi \times 4\pi) \mu\text{m}^2$. The SAF is in the scissors state. The angle between SW wave vector \vec{k} and the dc field \vec{H}_0 is φ . (d) Sketched time-resolved response of the magnetization to the stimulus of (a) for $q(z) = \Theta(i - 8.5)$. (e) Power spectral density (PSD) of this response after apodization [Eq. (6)]. The maxima correspond to the acoustical and optical modes sharing the common spatial periodicity defined in (a). (f) PSDs obtained after the selective excitation of acoustical mode using a uniform $q(z)$. Insets in (e) and (f): sketches of the thickness profiles of the stimuli.

modes, one can just add the two stimuli and use a thickness profile $q(z) = q_{\text{op}}(z) + q_{\text{ac}}(z) = \Theta(i - 8.5)$, where Θ is the Heaviside distribution.

The magnetization response to the stimulus is simulated for $t_s = 5 \text{ ns}$. This duration appears sufficient to reach the ground state [Fig. 3(d)]. We perform a Fourier analysis of the magnetization response averaged over one row of cells $\vec{m}_i(t)$, aligned in the direction perpendicular to the wave vector; in practice [21], we choose the row $\{i = 1, x = l_x/2\}$. To minimize the spectrum leakage we apodize this

averaged moment with a Hann-window function:

$$A_{\text{Hann}}(t) = \begin{cases} \cos^2 \frac{\pi(t-t_s/2)}{t_s} & \text{for } 0 \leq t \leq t_s \\ 0 & \text{otherwise} \end{cases}. \quad (5)$$

We then make a Fourier transform of the apodized form of $\tilde{\vec{m}}_{i=1}(t)$:

$$\tilde{\vec{m}}_{i=1}(f) = \mathcal{F}(A_{\text{Hann}}(t)\tilde{\vec{m}}_{i=1}(t)), \quad (6)$$

where “ \sim ” recalls the complex-valued nature of frequency-domain magnetization. The SW frequencies are finally identified by the maxima of the power spectra of the x component of magnetization $\tilde{\vec{m}}_{i=1}(f)$:

$$\max \left(\left| \tilde{\vec{m}}_{i=1}^x(f) \right|^2 \right). \quad (7)$$

One representative result of this procedure [Eq. (4) to (7)] is illustrated in Fig. 3(e). When the thickness-resolved stimulus $q(z)$ is meant to excite both optical and acoustical SWs, two eigenfrequencies are expected if the situation is reciprocal. However, in a nonreciprocal situation like ours, four eigenfrequencies are generally obtained. This arises because the spatial stimulus $f(x) = \sin(\vec{k}_x \cdot \hat{\vec{e}}_x x)$ is a standing wave composed of the sum of waves of wave vectors \vec{k}_x and $-\vec{k}_x$ [notice that $f(x) \propto e^{i(\vec{k}_x \cdot \hat{\vec{e}}_x x)} - e^{-i(\vec{k}_x \cdot \hat{\vec{e}}_x x)}$]. As a result, even if exciting only the acoustical branch [Fig. 3(f)] or only the optical branch (not shown), one is still left with a pair of eigenfrequencies $\{f_0, f'_0\}$ that must be attributed to either $\{+\vec{k}_x, -\vec{k}_x\}$ or $\{-\vec{k}_x, +\vec{k}_x\}$.

2. Sign-of- k -resolved dispersion relations

Getting sign-of- k -resolved dispersion relations requires application of a stimulus that exclusively excites either the $+\vec{k}_x$ or the $-\vec{k}_x$ spin wave [Fig. 4(a)]. We thus replace the previously used broadband stimuli of Eq. (4) by traveling-wave stimuli at the previously identified f_0 . The alternative stimuli have the form [see Fig. 4(a)]:

$$\tilde{H}^{rf}(x, t, z) = h_0 q(z) \sin(\vec{k}_x \cdot \hat{\vec{e}}_x x - 2\pi f_0 t) \hat{\vec{e}}_z. \quad (8)$$

To ensure that at least one of these stimuli is resonant with f_0 , we investigate now *signed* wave vectors, i.e. spanning over the bipolar interval:

$$\vec{k}_x = (2\pi n/l_x) \hat{\vec{e}}_x \text{ with } n \in \mathbb{Z}. \quad (9)$$

A much smaller value of $\mu_0 h_0 = 1 \text{ }\mu\text{T}$ is chosen for the (continuously applied) stimulating field to remain in the linear domain.

To determine whether a given $\{\vec{k}_x, f_0\}$ combination is resonant, the relevant information is the susceptibility, i.e., the

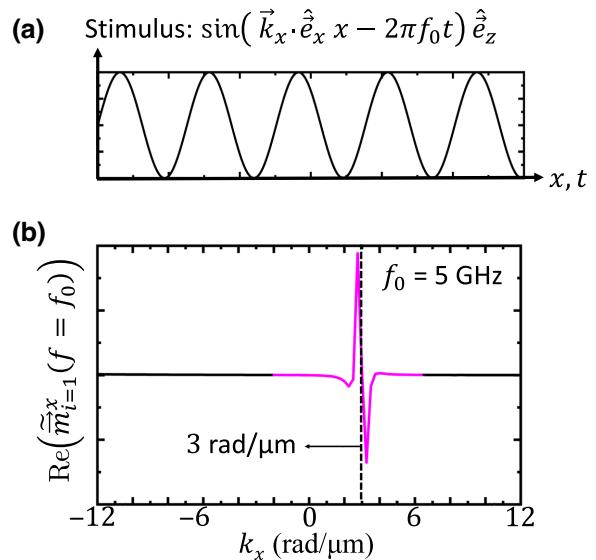

FIG. 4. Method used to construct the sign-of- k -resolved dispersion relation, as described in Sec. III B 2. (a) Traveling-wave-like stimulus used to excite. (b) Real part of the dynamical magnetic response of the system at $f_0 = 5 \text{ GHz}$ versus wave vector according to Eq. (10).

amplitude of the magnetization response once the steady-state regime is reached. As before, we focus on one particular row of cells [e.g., $\{i = 1, x = l_x/2\}$] on which we average the magnetizations. We apodize the time response using Eq. (5) to minimize the spectral leakage and in addition, to cancel the spectral contribution of the transient response of the magnetization. This requires calculation of the magnetization response for a longer duration, e.g., $t_s = 10 \text{ ns}$.

Since the power of the stimulus is fixed, the resonant or nonresonant character of the dynamical magnetic response versus $\{\vec{k}_x, f_0\}$ can be evaluated by simply plotting

$$\text{Re}(\mathcal{F}(A_{\text{Hann}}(t) \cdot \tilde{m}_{i=1}^x(t))) (f = f_0) \quad (10)$$

at a given frequency f_0 versus $\vec{k}_x \cdot \hat{\vec{e}}_x$. The system's response for a frequency $f_0 = 5 \text{ GHz}$ versus the wave vector is shown in Fig. 4(b). From this plot, we can conclude that the specific frequency f_0 corresponds to $k_x = +3 \text{ rad}/\mu\text{m}$ and not to $k_x = -3 \text{ rad}/\mu\text{m}$ [see Fig. 4(b)]. By performing this analysis for each SW frequency that was identified from the broadband stimulus, we can assign each eigenfrequency to a wave vector of the correct sign, and thus we can construct the dispersion relation even in nonreciprocal cases.

C. Dispersion relations

Figure 5 shows the micromagnetic dispersion relations for $\vec{k}_x \parallel \vec{H}_0$ and $\vec{k}_x \perp \vec{H}_0$ at $\mu_0 |\vec{H}_0| = 25 \text{ mT}$.

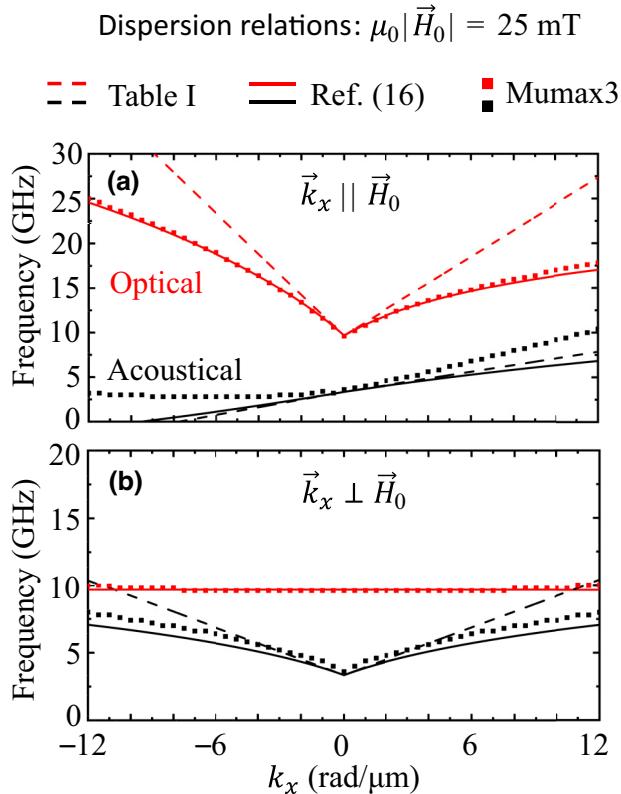

FIG. 5. Comparison between our model (Table I, dashed lines), Ishibashi's analytical model [16] (continuous lines) and Mumax3 simulation (squared dots) adapted with our parameters of Si/SiO_x/SAF system for an applied dc field 25 mT. (a) Spin waves with $\vec{k}_x \parallel \vec{H}_0$ (nonreciprocal situation). (b) Spin waves with $\vec{k}_x \perp \vec{H}_0$ (reciprocal situation). For the optical mode, the dashed and continuous lines are superimposed.

When $\vec{k}_x \parallel \vec{H}_0$, a strongly nonreciprocal behavior due to layer-to-layer dipolar interactions [15] is observed for both modes [see Fig. 5(a)]. The dispersion relation of the optical mode has the shape of a tilted V. The dispersion relation of the acoustical mode still exhibits its quite unique feature: it is *essentially linear* at low wave vectors. Micromagnetic calculations confirm that the amplitude of the nonreciprocity is very strong.

For instance, for $|\vec{k}| = 2$ and 12 rad/μm, it predicts, respectively, $\delta f_{ac} = 1.6$ and 7.2 GHz, and exactly opposite values $\delta f_{op} = -1.6$ and -7.2 GHz. These equalities confirm the analytical prediction of Eq. (3).

Conversely, when $\vec{k}_x \perp \vec{H}_0$, a perfectly reciprocal behavior is observed [Fig. 5(b)]. An additional striking feature that is specific to SAFs is that the optical mode has a very flat dispersion relation (i.e., $V_g^\perp \approx 0$ km/s, $\forall k$).

To discuss these micromagnetic dispersion relations, we have superimposed the predictions of two analytical two-macrospin models based on dynamic matrix theory [5,29–31]: our formalism [Eq. (2) and Table I] and that of

Ishibashi *et al.* [16]. These analytical models do not take into account the limited intralayer exchange stiffness.

IV. DISCUSSION

In this section, we compare the approximate models to the micromagnetic calculations. The results for $\vec{k}_x \parallel \vec{H}_0$ and $\vec{k}_x \perp \vec{H}_0$ shown in Figs. 5(a) and 5(b) are completed by additional field magnitudes given in Fig. S1 within the Supplemental Material [34]. We also provide angle-resolved dispersion relations for $\mu_0|\vec{H}_0| = 25$ mT in Fig. S2 within the Supplemental Material [34]. The fields span from 10 mT, for which the scissors state is close to antiparallel with magnetizations that are quite uniform across the two Co-Fe-B layers, up to 75 mT, i.e., close to $\mu_0 H_J = 78$ mT where the SAF is close to the parallel state but with a very significant gradient of the magnetization orientation within each Co-Fe-B layer [21]. Several points arise from these comparisons:

(i) Uniform resonance ($k = 0$). At low fields Eq. (2) correctly accounts for the precession frequencies. As the applied field increases, the magnetizations of each layer develop an increasing gradient within thickness, and Eq. (2) progressively fails to account for the two precession frequencies (see Fig. S1 within the Supplemental Material [34]). This failure of the 2-macrospin model for nearly saturated thick SAF was already noticed and discussed in Ref. [21]. An unavoidable consequence of this failure of the two-macrospin model at large fields is that the group velocities of Table I and of Ishibashi *et al.* [16], which are both calculated assuming a two-macrospin ground state, are increasingly failing when approaching saturation.

(ii) Concerning the optical mode, a thorough examination of Fig. 5 and Fig. S1 within the Supplemental Material [34] indicates that the three models agree for low and moderate applied fields, i.e., $\mu_0 H_0 \leq 50$ mT (see Fig. S1 within the Supplemental Material [34]). The linear expansions of Table I are usable for wave vectors $k \in [-12, 12]$ rad/μm when $\vec{k}_x \perp \vec{H}_0$: the dispersion relation $f_{op}(k)$ is then very flat and one can hardly perceive some curvature of the largest wave vectors [see Fig. 5(b)]. For $\vec{k}_x \parallel \vec{H}_0$, the linear expansions of Table I are usable only up to $k \in [-3, 3]$ rad/μm. Above 3 rad/μm, Ishibashi's model performs better and almost agrees with the result of micromagnetic calculations [see Fig. 5(a)]. This agreement indicates that the intralayer exchange stiffness—neglected in the approximate models—has little influence on the optical dispersion relation at least up to 12 rad/μm.

(iii) Concerning the acoustical mode, for $\vec{k}_x \perp \vec{H}_0$, the approximate models perform well at low and moderate applied fields. At fields $H_0 \leq 15$ mT [see Fig. S1(b),(f) within the Supplemental Material [34]], the predictions of Table I are closer to full micromagnetic calculations than those of Ref. [16]. At these fields, the branches of

the V-shaped dispersion relation are remarkably close to linear. The branches acquire progressively a curvature for $\mu_0 H_0 \geq 25$ mT [see Fig. 5(a)], and then Ishibashi's model starts performing better than the expressions of Table I.

The case of $\vec{k}_x \parallel \vec{H}_0$ is far less satisfactory [Fig. 5(a)]. The approximate models perform reasonably well but only at very low $k \in [-3, 3]$ rad/ μm , and provided that the applied field is low. For instance, at a field of 25 mT, a linear fit through positive wave vector yields $V_g = 2.95$ km/s for micromagnetic calculations [Fig. 5(a)] to be compared with $V_g = 2.57$ km/s from Table I and $V_g = 2.4$ km/s from Ishibashi's analytical model. Besides, these three velocities are higher than the experimental results, which were $V_g(k_x > 0) = 1.25$ km/s for Si/SiO_x/SAF system studied by BLS [see Fig. 1(c)], and $V_g(k_x > 0) = 1.9$ km/s for LiNbO₃ / SAF system by propagating spin-wave spectroscopy [see Figs. 2(d), 2(e), 2(f), 2(g)].

There is thus a discrepancy for $\vec{k}_x \parallel \vec{H}_0$ both among the models and with the experimental results. We believe that this is an indication that the texture of the ground state—it being different from a two-macrospin scissors—has a major impact on the dispersion relation of the acoustical mode for this field orientation. As mentioned in Sec. II B, the slope of the dispersion relation of the acoustical mode is set by the scaling factor $\frac{1}{2}\gamma_0 M_s t_{\text{mag}}$: it is proportional to the thickness t_{mag} of each layer; if a gradient of the magnetization develops within each layer, the relevant thickness to be considered becomes ill defined. This is also probably the case in experimental samples where the exchange stiffness is potentially nonuniform near the Ru barrier because of composition gradients [22]. This has a substantial impact on the acoustical dispersion relation for $\vec{k}_x \parallel \vec{H}_0$, which remains to be fully expressed analytically.

V. CONCLUSIONS

In summary, we have combined experiments, analytical modeling and numerical simulations to study the spin waves in symmetric synthetic antiferromagnets in the scissors state. The nonreciprocity comes from the layer-to-layer dipolar interactions, which is the only contribution. Whatever the wave-vector orientation, the frequency nonreciprocities of the acoustical and optical spin waves coincide in magnitude but have opposite signs. Our modeling explains why the frequency nonreciprocity can reach unusually large magnitudes, especially when the static field is oriented close to the spin-wave wave vector (Fig. S2 within the Supplemental Material [34]). In this case, the acoustical spin waves exhibit a unique dispersion relation: it is close to linear around $k = 0$. As a result, reversing the sign of the SW wave vector does not reverse the direction of the group velocity, such that the energy flow associated to a wavepacket of acoustical spin waves is truly

unidirectional: these wavepackets can carry energy in one direction but not the opposite. We have developed a simple analytical model to approximate group velocities and evidenced switchable unidirectionality of spin waves in synthetic antiferromagnets, a feature that opens potential applications.

APPENDIX: SAMPLE DETAILS

Piezoelectric Y-cut LiNbO₃ substrates were used for the fabrication of devices meant for electrical measurements. A strong interlayer exchange coupling $J = -1.7$ mJ/m² is obtained when using these substrates [21,22], leading to an interlayer exchange field $\mu_0 H_J = -2J/M_s t_{\text{mag}}$, which amounts to 148 mT. The relatively low exchange stiffness $A_{\text{ex}} = 16$ pJ/m within this SAF allows for gradients of magnetization orientation within the thicknesses of the Co-Fe-B layers [21,23], which increases the saturation field up to $\mu_0 H_{\text{sat}} = 251$ mT. There is a small (unwelcome) uniaxial anisotropy field, with anisotropy field being $\mu_0 H_k = 3$ mT and spin-flop field $\mu_0 H_{\text{SF}} = 19$ mT.

Si/SiO_x substrates were used instead of the piezoelectric LiNbO₃ substrates when preparing samples meant for Brillouin light scattering. Using Si/SiO_x substrates ensures that the BLS signals can be unambiguously attributed to spin waves and not to the surface or bulk acoustical waves potentially present in the LiNbO₃ substrates. On these Si/SiO_x substrates, a thermal treatment can be applied to suppress any anisotropy [22]. It was effectively reduced to only $\mu_0 H_k = 0.8$ mT. The thermal treatment also reduces the interlayer exchange energy down to $J = -0.9$ mJ/m² (i.e., $\mu_0 H_J = 78$ mT) while it increases the exchange stiffness $A_{\text{ex}} = 28.3$ pJ/m. Spin-flop field amounts to $\mu_0 H_{\text{SF}} = 8$ mT. As a result of the strong intralayer exchange, this SAF behaves more like a two-macrospin system and its saturation field $\mu_0 H_{\text{sat}} = 100$ mT is thus close to its $\mu_0 H_J$.
