(Received 7 July 2017; revised manuscript received 7 June 2019; published 11 July 2019)

We report measurements of photon-assisted transport and noise in a tunnel junction in the regime of dynamical Coulomb blockade. We have measured both dc nonlinear transport and low frequency noise in the presence of an ac excitation at frequencies up to 33 GHz. In both experiments we observe replicas at finite voltage of the zero bias features, a phenomenon characteristic of photon emission/absorption. However, the ac voltage necessary to explain our data is notably different for transport and noise, indicating that usual theory of photon-assisted phenomena fails to account for our observations.

Introduction. The physics of dynamical Coulomb blockade (DCB) in a tunnel junction can be understood in simple terms: When an electron tunnels through the barrier, the voltage *V* across the contacts suddenly changes by e/C with *e* the electron charge and *C* the capacitance between the contacts. Thus next electrons have less probability to cross the barrier. With two tunnel junctions in series, thus defining a conducting island between the two insulating barriers, a complete blocking of electron transport may occur at very low temperature $k_B T \ll e^2/C$, referred to as Coulomb blockade [\[1\]](#page-3-0). With one junction only, the charge accumulated in the contacts leaks continuously into the circuit, leading to a progressive recovery of the tunneling [\[2\]](#page-3-0). This occurs on a time scale that depends on the circuit in which the junction is embedded, given for example by the product *RC* if the electromagnetic environment of the junction consists of a resistor *R*. This mechanism gives its dynamical aspect to the DCB, which can be seen as a frequency-dependent feedback of the electromagnetic environment of the junction on electron transport. It is the very same feedback that leads to corrections to high order cumulants of current fluctuations (in both cases current fluctuations generated by the environment also matter) $[3-5]$.

The theory of DCB is well established $[6,7]$ and has been successfully confirmed by many transport experiments [\[8–12\]](#page-3-0). It consists of describing the electromagnetic environment of the junction by a collection of modes characterized by their density $P(E)$ and population. In this picture, the environment authorizes inelastic tunneling of the electrons, which is possible only if the energy gained or lost by the electron can be accommodated by the environment. While very efficient, this description however seems to rely on different ingredients than the description of DCB by feedback. In particular, the

-bertrand.reulet@usherbrooke.ca

dynamical response of the environment does not appear in a clear way.

Here we report an experiment that aims at probing the dynamical aspect of DCB by measuring the dc transport in a tunnel junction embedded in a resistive environment in the presence of an ac voltage. The frequency *f* and amplitude *Vac* of the excitation can be tuned to explore different regimes, from weak $eV_{ac} \ll hf$ to strong $eV_{ac} \gg hf$, and from slow $f < (RC)^{-1}$ to fast $f > (RC)^{-1}$ excitation. Together with the dc nonlinear transport, we measure the zero frequency current noise to determine the ac voltage experienced by the junction, thus leaving no free parameter to fit the experimental transport data. We show that our transport data cannot be explained by a recent theory that includes the periodic voltage drive into the $P(E)$ theory [\[13,14\]](#page-3-0) if we use the values of the ac voltage given by the noise measurements.

Experimental Setup. Measurements are carried out on a 500 nm \times 100 nm Al/Al oxide/Al tunnel junction fabricated by e-beam lithography using the Dolan bridge technique [\[15\]](#page-3-0). The sample is placed in a dilution refrigerator of base temperature 8 mK. A strong permanent magnet underneath the sample keeps the aluminum in its normal, nonsuperconducting state even at the lowest temperatures. The experimental setup is shown in Fig. [1.](#page-1-0) The junction is dc biased through a bias tee and ac biased through a 16 dB directional coupler placed between the bias tee and the junction. The dc biasing is performed through a 1 $M\Omega$ resistor at room temperature and cryogenic low pass filters (not shown). Thus the sample of resistance $R_{\infty} = 620 \Omega$ (measured at high voltage) is effectively current biased at low frequency. We measure both the dc voltage *V* across the junction and the differential resistance d*V*/d*I* with usual, high impedance lock-in technique, with an excitation current of 1 nA at 77 Hz. The sample's current fluctuations in the range 1 MHz-1 GHz are attenuated by a 6 dB cryogenic attenuator placed at the lowest temperature, amplified by a 50 Ω cryogenic amplifier on the 3 K stage of the refrigerator, then further amplified at room temperature and bandpass filtered in the 1–80 MHz range. The power *P* of the resulting signal is measured by a power detector as a function of the dc current *I* as well as its derivative *dP*/*dI*. At low frequency, the impedance of the sample is

FIG. 1. Experimental setup. The (V) symbol represents a high impedance (10 $M\Omega$) voltmeter/lock-in. The (P) symbol represents an RF power detector. Filtering of the DC lines has been omitted for clarity. The green rectangle indicates the region of the tunnel junction which has a capacitance $C \sim 0.2$ pF.

purely resistive, so the low frequency reflection coefficient is $\Gamma = (R - R_0)/(R + R_0)$, with *R* the differential resistance of the junction ($\Gamma \simeq 0.85$ at high voltage). The detected power *P* is related to the noise spectral density *S* of the tunnel junction by:

$$
P = G[\alpha (1 - \Gamma^2)T_N + \alpha^2 \Gamma^2 T_{A1} + T_{A2}], \tag{1}
$$

where $T_N = RS/(2k_B)$ is the noise temperature of the sample, *TA*¹ the equivalent temperature of the noise emitted by the amplifier towards the sample, *TA*² the equivalent temperature of the noise added by the setup, *G* the power gain of the setup, and $\alpha = 10^{-0.6} \approx 0.25$ the attenuation provided by the 6 dB attenuator. The main purpose of the attenuator is precisely to minimize the contribution of the noise emitted by the amplifier T_{A1} to the total detected noise. Indeed, since *R* depends on the bias, so does Γ . Thus the bias dependence of *P* comes from that of the noise generated by the sample as well as from the noise of the amplifier being reflected in a bias-dependent way. Since $T_{A1} \gg T_N$, the presence of the attenuator is essential. The amount of attenuation is chosen so as to keep enough signal while greatly attenuating the reflection of the amplifier's noise. The attenuator also helps keep the electron temperature reasonably low (according to our noise measurements, $T = 50$ mK, see below) and helps define the electromagnetic environment of the junction, which is approximately described at high frequency by its geometric capacitance *C* in parallel with a resistor $R_0 = 50 \Omega$ (the input impedance of the microwave amplifier seen through the attenuator). An ac excitation can be sent to the sample through the 2–40 GHz coupler placed next to it. The relevant frequency scale f_c for the circuit is given by an inverse "RC" time where "R" corresponds to the parallel combination of R and R_0 , i.e., $f_c \simeq (2\pi R_0 C)^{-1}$. In order to know *C* we have measured the frequency dependence of both the reflection coefficient of the bare junction and the noise emitted by the junction with high bias (data not shown). We observe $f_c \simeq 14 \text{ GHz.}$

Results: Differential resistance. We show in Fig. 2 the measurement of $\Delta R/R_{\infty}$, with $\Delta R = dV/dI - R_{\infty}$ the excess

FIG. 2. Rescaled differential resistance vs bias voltage. (a): $f =$ 5 GHz (b): $f = 12$ GHz, (c): $f = 19.9$ GHz, (d): $f = 33$ GHz. In all graphs, symbols are experimental data and black, solid lines fits using theory of Eq. [\(2\)](#page-2-0). The blue symbols correspond to $V_{ac} = 0$. The different colors represent different ac excitation amplitudes $z = eV_{ac}/hf$: (a): $z = 0$, 2.05, 3.67, 6.53, 8.22, 14.62; (b): $z =$ 0, 0.87, 1.24, 1.96, 3.90, 9.40; (c): *z* = 0, 0.8, 1.14, 2.05, 2.88, 4.58; (d): *z* = 0, 0.48, 0.88, 1.53, 2.40, 3.81. The dashed vertical lines correspond to *V* = nhf/e with *n* integer. Inset of (d): $\Delta R/R_{\infty}$ measured at $V = 0$ (blue) and $V = hf/e$ (red) as a function of *z* at $f = 33$ GHz.

resistance, as a function of the voltage *V* across the junction at very low electron temperature $T = 50$ mK. In the absence of ac excitation [dark blue curves in Figs. $2(a)-2(d)$] we observe a peak at zero bias, characteristic of DCB. This peak decreases when the temperature is increased and disappears at $T \sim$ 0.6 K. In the presence of ac bias of frequency f , we observe replicas of the central DCB peak that appear at finite voltage. Figure 2 shows our results for excitations $f = 5$ GHz (a), $f = 12 \text{ GHz (b)}$, $f = 19.9 \text{ GHz (c)}$, and $f = 33 \text{ GHz (d)}$. The positions of the replicas depend on the excitation frequency *f* and is given by $V = nhf/e$ with *n* integer (vertical dashed lines in Fig. 2). At low excitation frequency $f = 5$ GHz, there is a strong overlap between the replicas. As the frequency increases, the peaks are more and more separated and clearly distinguishable at $f = 19$ GHz and $f = 33$ GHz. We observe that the amplitude of the various peaks, including the one at zero voltage, depends in a nontrivial way on the amplitude of the ac excitation, clearly indicating that our observations are not due to simple heating of the electrons by the ac excitation, see inset of Fig. $2(d)$.

Interpretation: Tien-Gordon mechanism. Similar observations have been performed a long time ago with Josephson junctions $[16]$. These observations are well understood if the only effect of the ac excitation is to induce a time-dependent, homogeneous voltage in one of the contacts. This voltage induces a time dependent phase in the electron wave functions in the contact given by $\varphi(t) = \int eV(t')/\hbar dt'$. For a sine-wave excitation $V(t) = V + V_{ac} \cos 2\pi f t$, this phase results in the *I*(*V*) (current-voltage) and *S*(*V*) (noise-voltage) characteristics of the Josephson junction being modified into:

$$
I(V) = \sum_{n=-\infty}^{\infty} J_n^2(z)I_0(V + nhf/e)
$$

$$
S(V) = \sum_{n=-\infty}^{\infty} J_n^2(z)S_0(V + nhf/e)
$$
 (2)

with $I_0(V)$ and $S_0(V)$ the current and noise characteristics of the junction without ac excitation, and $z = eV_{ac}/hf$. Here J_n are the Bessel functions of the first kind. This formula predicts that the $I(V)$ characteristics of the junction is a superposition of many copies of the original characteristic shifted in voltage by nhf/e with weights given by $J_n^2(z)$. Clearly this result is not restricted to the *I*(*V*) characteristic of Josephson junctions but should apply to a broader range of quantities and devices. An important condition is however the absence of dynamical degrees of freedom in the system. Let us consider for example a mesoscopic diffusive wire. Since such a conductor is linear, its $I(V)$ characteristics is not modified by the ac excitation, in agreement with Eq. (2), since $\sum J_n^2(z) = 1$. However, its shot noise does show replicas that are well described by Eq. (2) *provided the excitation frequency is low as compared to the inverse diffusion time of the wire*. Such replicas have been ob-served experimentally in the noise of wires [\[17\]](#page-3-0), tunnel junctions [\[18\]](#page-4-0), and quantum point contacts [\[19\]](#page-4-0). The breakdown of Eq. (2) at high frequencies has been calculated $[20,21]$ but not yet observed. The conditions of validity of Eq. (2) can also be understood in the Landauer-Büttiker framework of quantum transport, where the transport properties of the sample are embedded in transmission coefficients. In this description, Eq. (2) is obtained only if the transmission coefficients are energy independent, as for a tunnel junction. However, DCB induces energy dependence in the transmissions even in a tunnel junction $[22,23]$, thus Eq. (2) might not hold. Furthermore, following [\[23\]](#page-4-0), at low voltage and temperature, the strength of the energy dependence should be influenced by the environmental impedance at the excitation frequency f , thus DCB might be different for $f > f_c$ or $f < f_c$. Our experiment allows us to probe the two regimes, where the charge has time to be evacuated before the ac voltage reverses or not. A recent theoretical paper has explicitly addressed the case of DCB in a tunnel junction in the presence of an ac voltage [\[13\]](#page-3-0). Despite what we just discussed, the prediction is that Eq. (2) should still be valid. The only dynamical effect is that the ac voltage seen by the sample depends on frequency since the electromagnetic environment acts as a low-pass filter for the excitation. It is thus crucial to have a way to know the actual*Vac* experienced by the sample, which is provided by the

FIG. 3. Normalized differential resistance (a) and noise (b) vs bias voltage for an ac excitation at 5 GHz. Symbols are experimental data and black lines are fits. Curves at $z = 2.9$ and $z = 6.48$ are obtained by fitting noise; those at $z = 3.67$ and $z = 8.22$ by fitting transport. Inset of (b): '+' symbols are experimental raw data, circles are data after subtraction of the noise emitted by the amplifier being reflected by the sample. Black lines are fits of the corrected data using $S = el \coth(eV/2k_BT)$ for $z = 0$. Blue: $z = 0$. Purple: finite ac bias, well fitted by $z = 6.48$.

measurement of low frequency noise. Note that the prediction is valid for any electromagnetic environment, so there is no need for our experiment to make it a perfect *RC* circuit.

Results: Noise. In order to probe potential dynamical effects in the photon-assisted DCB, it is necessary to calibrate the voltage experienced by the junction for each excitation frequency. We have done this by measuring the low frequency photon-assisted noise of the junction as in Ref. [\[24\]](#page-4-0). We show in Fig. $3(b)$ results for the normalized differential noise e^{-1} *dS*/*dI*, for an ac excitation at $f = 5$ GHz. DCB corrections to the noise are of the order of a few % and can be neglected [\[25\]](#page-4-0), so we can fit our data with the usual theory [\[26\]](#page-4-0). However corrections due to the bias-dependent reflection of the noise of the amplifier must be taken into account, according to Eq. [\(1\)](#page-1-0). The only unknown parameter is T_{A1} , the noise of the amplifier that is emitted towards the sample, which we determine as follows. The differential noise vs *V* in the absence of ac excitations should look like a smooth step function, the width of which is proportional to the temperature. As shown in the inset of Fig. $3(b)$, the experimental curves show additional steps. These steps are very well taken into account if we fit the data by Eq. [\(1\)](#page-1-0) with $T_{A1} = 3$ K [\[27\]](#page-4-0). This represents about half the total noise temperature of the amplifier, which is typical for such a component. We show in Fig. $3(b)$ the normalized differential noise after correction. Corrected data are very well fitted by usual theory [Eq. (2)] with an electron temperature $T = 50$ mK. From the noise measurements we can infer the renormalized ac voltage *z* across the junction for each excitation frequency. Note that the contribution of the reflected noise is most important when Γ depends strongly on bias, i.e., mainly at low ac excitation: In the inset of Fig. $3(b)$ while the raw data at $z = 0$ (blue crosses) clearly have an extra

FIG. 4. Ratio $r = z_T / z_N$ between the normalized ac voltages $z =$ eV_{ac}/hf used to fit transport data (z_T) and noise (z_N) as a function of the normalized ac voltages obtained from noise. The length of the error bars represents two standard deviations. Inset: ratio *r* as a function of frequency. The values assigned to r for each frequency are obtained by averaging over r for the four highest values of z_N for that particular frequency. The vertical dashed line indicates the characteristic frequency $f_c = 14$ GHz.

step as compared with the corrected data (blue circles), the effect of the correction becomes negligible at $z = 6.48$ (purple crosses/circles).

Interpretation: Effective ac voltage. In order to compare experiment with theory we fit the transport data using Eq. [\(2\)](#page-2-0) leaving the ac voltage as the only fitting parameter (solid lines on Fig. [2\)](#page-1-0). For the $I_0(V)$ characteristics in the absence of ac excitation, we take the experimental data at $z = 0$. The agreement between theory and data is excellent. Then we compare the rescaled values of the ac voltage used to fit the transport data *zT* with those extracted from our noise measurements *z_N*: We show in Fig. 4 the ratio $r = z_T/z_N$ as a function of the ac excitation obtained from noise measurements (both z_T and z_N scale like the square root of the applied microwave power). While for low excitation the uncertainty on *z* does not allow for a definitive conclusion, one clearly observes *r* \neq 1 at 5 and 12 GHz for *V_{ac}* > 50 μ V (deviation by ∼3.5 and ∼2 standard deviations). The value of *r* at 33 GHz also

significantly deviates from unity but to a lesser extent (∼1.2 standard deviation). At 19 GHz, $r \sim 1$. An example of the discrepancy in *z* between transport and noise is reported in Fig. [3](#page-2-0) where differential resistance (a) and differential noise (b) are plotted vs dc voltage for two excitation powers at $f = 5$ GHz. While each of the curves can be very well fitted, it is clearly impossible to fit both transport and noise with the same V_{ac} . The ratio r is plotted as a function of frequency in the inset of Fig. 4. The characteristic frequency $f_c = 14 \text{ GHz}$ is indicated as a vertical dashed line. One should also have $r = 1$ at low enough frequency.

A measurement of photoassisted transport in the DCB regime has been reported in Ref. [\[28\]](#page-4-0). Unfortunately, only one frequency and one value of the ac voltage $(z = 1.15)$ have been measured, and there was no way to calibrate *z* beside estimating the attenuation in the circuit. Thus the phenomenon we report here could not have been observed in Ref. [\[28\]](#page-4-0).

Conclusion. Our experiments show that Tien-Gordon mechanism applied to the usual theory of transport and noise of a tunnel junction embedded in an electromagnetic environment does not explain our observations, showing the existence of dynamical phenomena not well taken into account. This suggests that more ingredients should be taken into account by theory. For example, the ac voltage experienced by the sample should depend on the value of the ac complex impedance of the junction at the excitation frequency, which itself depends on the dc and ac bias of the sample [\[28–30\]](#page-4-0). The ac excitation of the sample may also induce nonthermal distribution functions in the contacts that influence differently the noise and transport [\[31,32\]](#page-4-0). More experiments are called for, for example with a different electromagnetic environment, or using nonclassical light as recently proposed [\[33\]](#page-4-0), in order to probe more in depth the dynamical properties of DCB.

- [27] Similar extra steps have been reported in Ref. [25] and attributed to the noise being measured given by nonsymmetrized current-current correlator. This discussion is irrelevant here since our measurement corresponds to zero frequency

noise, for which commutativity of current operators is not an issue.

- [31] Indeed, we note that our photon-assisted transport data are well fitted by taking replicas of the data at $V_{ac} = 0$ and the lowest temperature, whereas noise data at high excitation show an increased effective temperature.
- [32] Such effects have been discussed in similar samples where the amplitude of quantum oscillations could not be explained by the ac voltage excitation deduced from photon-assisted noise measurements [24].
