The  $\delta$  phase of Bi<sub>2</sub>O<sub>3</sub> has the highest known value of oxide ion conductivity within the solid state and, therefore, remains a benchmark for the development of future generations of electrolyte materials to fuelcell technologies. Conventionally, the high value of conductivity in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> has been explained by a large concentration of inherent vacancies together with a strongly polarizable Bi-O bond. We show from *ab initio* molecular dynamics simulations that short "chains" of collective migrating oxygens also contribute strongly to the high value of conductivity with the single-particle Nernst-Einstein (N.E.) conductivity to collective (dc) conductivity  $\sigma^{N.E.}/\sigma^{dc} \sim 0.57 \pm 0.05$  at 1033 K. The nature of collective events is investigated from a hopping model, the distinct part of the van Hove function and from the extent of dynamical heterogeneities in the superionc regime. Results from this analysis indicate that the main contribution to collective ionic diffusion in δ-Bi2O3 involves short *collinear* chains of two or three oxygens. These chains are either initiated by an oxygen that jumps into an already occupied oxygen cavity (where they coexist for a very short time before the residential oxygen is kicked out of its cavity) or from a jump into a vacant cavity which triggers a next-nearest-neighboring oxygen to migrate. Since  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> is easily stabilized in a range of environments, the nature of these collective chains can give important insight into the design of  $\delta$ -Bi<sub>2</sub>O<sub>3</sub>-based fuel cells for the future.

#### **I. INTRODUCTION**

Atomistic insight into the nature of ionic diffusion in the superionic regime has unveiled strong evidence for collective "multi-ion" migration [\[1–13\]](#page-6-0). Although first suspected in the 1960s when Yokota showed that the popular Einstein relation failed to explain the discrepancy between the mobility and the conductivity in silver halides [\[14\]](#page-6-0), it has not been until quite recently that atomistic simulations have shown that collective chains of migrating ions may possess lower-energy barriers than those calculated from single-particle jump-diffusion models [\[2,3,8,15,16\]](#page-6-0). Recent demonstrations include several density functional theory (DFT) studies of highly mobile "chains" of  $Li<sup>+</sup>$  ions in sulfides and phosporites  $[6,8]$ , "string-like" movements of fluorines in fluorites [\[12\]](#page-6-0) as well as two-dimensional collective transport of oxygens in reduced perovskites [\[2\]](#page-6-0). Collective dynamics in these compounds are often advantageous since the nature of energetically preferred local motifs and their connectivity patterns are kept intact as the chain of ions migrate, minimizing bond breaking and bond formation  $[2,11]$ . In the fast-ion conducting phase of strongly nonideal  $BalnO<sub>2.50</sub>$ , for example, the vacancies are not distributed at random but order on local and intermediate length scales in corner sharing networks of  $InO<sub>4</sub>$ ,  $InO<sub>5</sub>$ , and  $InO<sub>6</sub>$ polyhedra. These motifs can only remain intact if the ions migrate in a highly collective fashion. Single-particle jumps

would, in contrast, involve strongly repulsive O-O interactions and strained configurations, and the calculated activation energy for uncorrelated oxygen hops is, therefore, high [\[2\]](#page-6-0). Collective mechanisms appear, therefore, to be advantageous over isolated jumps in nonideal compounds where the ions are not randomly distributed over positions in a sublattice and, therefore, not "free" to jump to a random neighboring cavity [\[15\]](#page-6-0). Bearing in mind recent effort in the search for new materials to operate solid oxide fuel cells (SOFCs) at lower temperatures, capturing the nature of collective dynamics in fast-ion conductors can give useful input in the design and development of new electrolyte materials.

Superionic bismuth oxide ( $\delta$ -Bi<sub>2</sub>O<sub>3</sub>) has the highest known value of oxide ion conductivity within the solid state  $[17–19]$ and remains a benchmark for understanding ionic transport processes in the superionic regime. It adopts the cubic fluorite crystal structure (space-group  $Fm\overline{3}m$ ) where the oxygens form a simple cubic anion sublattice and the bismuths occupy alternate cube centers [the 4*a* site at (0,0,0)]. The stoichiometry of  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> implies that two of the eight anion cavities centered at the 8*c* site at 1/4, 1/4, 1/4, etc., surrounding each  $Bi^{3+}$  are vacant. This provides, together with a strongly polarizable and transient Bi-O bond, a plausible explanation for the high value of ionic conductivity. Previous *ab initio* molecular dynamics (MD) calculations [\[20,21\]](#page-6-0) of the ionic conductivity used the Einstein relation  $\sigma^{N.E.} = \frac{\rho(eZ^{-})^2}{k_B T} D^{N.E.}$  to calculate the Nernst-Einstein (N.E.) conductivity  $\sigma^{N.E.}$  from the diffusion coefficient  $D^{N.E.}$ . Here,  $\rho^-$  and  $Z^-$  are the density and the formal charge of the diffusing oxygens. The

<sup>\*</sup>chrism@geo.uio.no

<span id="page-1-0"></span>calculated  $\sigma^{N.E.}$  was found to be in good agreement with that obtained experimentally [\[17–19\]](#page-6-0), which could indicate that collective diffusion does not contribute strongly to the overall ionic conductivity. On the other hand, previous studies have shown that  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> is surprisingly *nonideal* since only a fraction of the oxygen-vacancy configurations are thermally available even at high temperatures [\[20\]](#page-6-0). The oxygens, therefore, cannot jump entirely at random to one of their nearestneighboring cavities since this could involve strongly repulsive vacancy interactions. This implies, in turn, that collective conductivity may be non-negligible for a critical comparison with conductivity measurements. Contribution from collinear chains of migrating oxygens may, therefore, enhance the conductivity, and the good agreement between experiment and *ab initio* calculations could be fortuitous.

The extent of collective dynamics is often interpreted from the Haven ratio  $H_R = D<sup>N.E.</sup>/D<sup>dc</sup>$ , where  $D<sup>N.E.</sup>$  is calculated directly from the tracer-diffusion experiment, and  $D<sup>dc</sup>$  is estimated from conductivity experiment using the relation  $\sigma^{dc}$  =  $\frac{(eZ^{-})^2}{k_B T} D^{dc}$ . Although the Haven ratio can be used to determine the nature of collective diffusion in the superionic regime, the dynamics of many superionic conductors with a high defect concentration is complex, and the extent of collective dynamics is difficult to interpret from the Haven ratio alone [\[22\]](#page-6-0). The advantage with *ab initio* MD simulations is that the nature of single-particle (tracer) correlation and collective dynamics can be investigated *directly* from the atomic trajectory which allows one to calculate the Haven ratio and compare with the results from the conductivity measurement.

In this paper, we will investigate atomistically different collective transport mechanisms in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> using *ab initio* MD at the level of the generalized-gradient approximation to DFT. Understanding at the atomic level collective conductivity in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> and other fluorite-structured fast-ion oxide conductors remains unexplored, probably because much longer MD runs are needed to collect sufficient statistics in order to calculate the dc conductivity compared to that needed to calculate the (single-particle) tracer diffusion coefficient.

### **II. THEORY**

The ionic conductivity itself is calculable by integrating the charge-current correlation function,

$$
\sigma = \frac{1}{k_{\rm B} T V} \int_0^\infty J(t) dt, \tag{2.1}
$$

where *V* is the volume and  $J(t) = e^2 \sum_{ij} Z_i Z_j \langle \mathbf{v}_i(0) \cdot \mathbf{v}_j(t) \rangle$ with  $e$ ,  $Z_i$ , and  $v_i$  being the elementary charge, the charge number, and the velocity of ion *i*, respectively. To avoid the slow convergence in the integral over the charge-current correlation function associated with the possibly non-negligible contribution from the tails in  $J(t)$ , we assume that we can ignore the correlation between the velocities and reexpress the conductivity in the form of a mean-square displacement (MSD) [\[1\]](#page-6-0),

$$
\sigma^{\rm dc} = \frac{e^2}{k_{\rm B}TV} \lim_{t \to \infty} \frac{1}{6t} \left\langle \left| \sum_{i} Z_{i}^{+} \delta \mathbf{r}_{i}^{+}(t) + \sum_{i} Z_{i}^{-} \delta \mathbf{r}_{i}^{-}(t) \right|^{2} \right\rangle.
$$
\n(2.2)

Here, the summations within the brackets are the chargeweighted *net* displacements of all cations and anions, respectively. If we also ignore the correlations in the positions of the different ions in Eq.  $(2.2)$ , we can write down the analogous (single-particle) Nernst-Einstein equation,

$$
\sigma^{\text{N.E.}} = \frac{e^2}{k_\text{B}T} \lim_{t \to \infty} \frac{1}{6t} (\langle \rho^+ | Z^+ \delta \mathbf{r}^+(t) |^2 \rangle + \langle \rho^- | Z^- \delta \mathbf{r}^-(t) |^2 \rangle), \tag{2.3}
$$

where  $\rho^+$  and  $\rho^-$  are the densities of the cations and anions, respectively. If we assume that the oxygen charge is a constant (*Z*<sup>−</sup> = −2) and that the cations do not diffuse (at least, on the timescale of the MD simulation), we can calculate the dc conductivity from the MSD of the center of mass (c.m.) of the mobile oxygen ions as

$$
\sigma^{\rm dc} = \frac{(eZ^-)^2}{k_{\rm B}TV} \lim_{t \to \infty} \frac{1}{6t} \text{MSD}^{\text{c.m.}},\tag{2.4}
$$

where  $MSD^{c.m.} = \langle |\sum_i \delta \mathbf{r}_i^-(t)|^2 \rangle$  and, similarly, the N.E. conductivity,

$$
\sigma^{\text{N.E.}} = \frac{(eZ^{-})^2 \rho^{-}}{k_{\text{B}}T} \lim_{t \to \infty} \frac{1}{6t} \text{MSD}^{\text{N.E.}},\tag{2.5}
$$

with MSD<sup>N.E.</sup> =  $\langle |\delta^{-}(t)|^2 \rangle$  [where  $\delta^{-}(t)$  is the average displacement of a single oxygen ion].

### **III. COMPUTATIONAL DETAILS**

All results reported here are calculated using the *ab initio* Born-Oppenheimer MD simulation in the *NV T* ensemble  $[N = 270$  atoms,  $V = (16.95 \text{ Å})^3$ , and  $T = 1033 \text{ K}$ ] with a time step of 4 fs. The volume was the same as those obtained from neutron-diffraction experiment at 1033(3) K [\[23\]](#page-6-0) and MD runs [\[20\]](#page-6-0). We use VASP [\[24–26\]](#page-6-0) with the Perdew-Burke-Ernzerhof functional [\[24\]](#page-6-0), an energy cutoff of 400 eV for the electronic wave function, and 605 eV for the electronic charge density. Consistent with previous MD calculations [\[20\]](#page-6-0), the  $6s<sup>2</sup>6p<sup>3</sup>$  and  $2s<sup>2</sup>2p<sup>4</sup>$  electron configurations for the bismuths and oxygens were used, and the Brillouin zone was samples at the  $\gamma$  point only. In all MD runs, we start by generating random oxygen positions by distributing oxygen/vacancies over the tetrahedral positions in the fluorite structure, and in all runs, statistics were collected for, at least, 150 ps after about 20 ps of equilibration. This ensured sufficient statistics for the sampling of collective dynamics and, thus, the ionic conductivity after the ballistic regime, i.e., from  $t = 1$  to  $t = 5$  ps.

## **IV. RESULTS AND DISCUSSION**

The single-particle and collective mean-square displace-ments are shown in Fig. [1.](#page-2-0) From  $D<sup>N.E.</sup> = \lim_{t \to \infty} \frac{1}{6t} MSD<sup>N.E.</sup>$ and  $D^{dc} = \lim_{t \to \infty} \frac{1}{6t} MSD^{c.m.}$ , we find that  $D^{N.E.} = 8.8 \times$  $10^{-6}$  cm<sup>2</sup> s<sup>-1</sup> and that  $D^{dc} = 1.5 \times 10^{-5}$  cm<sup>2</sup> s<sup>-1</sup>. Our value of *D*<sup>N</sup>.E. is in good agreement with those found in previous MD runs [\[20,21\]](#page-6-0) and with that measured from the tracerdiffusion experiment ( $D^* = 1 \times 10^{-5}$  cm<sup>2</sup> s<sup>-1</sup>) [\[27\]](#page-6-0). We find that the Nernst-Einstein conductivity  $\sigma^{N.E.} = 2.7 \ (\Omega \text{ cm})^{-1}$ at 1033 K is consistent with previous *ab initio* studies on superionic  $Bi<sub>2</sub>O<sub>3</sub>$  at similar temperatures [\[20,21\]](#page-6-0), but  $\sigma$ <sup>dc</sup> = 4.7 ( $\Omega$  cm)<sup>-1</sup> which is about a factor of 3 higher

<span id="page-2-0"></span>

FIG. 1. The collective (center of mass) and the Nernst-Einstein MSD of the oxygens from two *ab initio* MD simulations carried out at 1033 K. The MSD<sup>dc</sup>'s are only plotted to  $t = 3$  ps where we have enough statistics.

than that measured from the dc conductivity experiment [\[17\]](#page-6-0) [which is  $\sim$ 1.5 ( $\Omega$  cm)<sup>-1</sup>]. Bearing in mind the large uncertainties associated with such a conductivity experiment and that the approximation made to DFT as well as constraints imposed by periodic boundary conditions may influence ionic diffusion, the agreement is quite satisfactory.

We find that the Haven ratio  $H_R = 0.57 \pm 0.05$ , calculated using Eq. [\(2.2\)](#page-1-0) and  $H_R^{\text{dir}}$  calculated directly from Eq. [\(2.1\)](#page-1-0) is  $0.33 \pm 0.13$ . The discrepancy between these two values is probably due to the non-negligible contribution in the tails in  $J(t)$  in Eq.  $(2.1)$ .

The low value of the Haven ratio is indicative for collective diffusion of oxygens, and to provide some mechanistic insight into the diffusion of the oxygens in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub>, we first carry out a detailed atomistic analysis by calculating singleparticle and collective diffusion coefficients from a hopping model. We, thus, analyze characteristic times for hopping of isolated oxygens from an inspection of the ionic trajectories and then analyze the nature of collective events. Collective dynamics is then analyzed from dynamical heterogeneities in the simulation box by identifying atoms that move considerable distances—characteristic for interbasin jumps—in a short time interval. If these ions cluster together, the nature and size of these can help capturing the nature of collective excitation in the superionic regime.

#### **A. Single-particle dynamics from a jump diffusion model**

We analyze correlations between successive jumps of an oxygen by dividing the simulation cell into distinct spacefilling primitive oxygen cubes [\[28–30\]](#page-6-0) with the cube center located at the peak density position of the oxygens (i.e., at the tetrahedral 8*c* site of  $Fm3m$  [\[31\]](#page-6-0). To distinguish vibrations with large amplitudes stretching into a neighboring cavity and unsuccessful "back jumps" (jump relaxation), a jump is assumed to take place if the oxygen jumps from cavity "*A*" to cavity "*B*" and stays within the new cavity for some time given by  $\tau^{\text{thresh}}$ . The value of  $\tau^{\text{thresh}}$  should be chosen with

some care because if  $\tau^{\text{thresh}}$  is too large, i.e., on the size of the average residence time  $\sim$ τ<sup>esidence</sup>, two consecutive jumps may be identified as a single jump. If we set  $\tau^{\text{thresh}} = 1 \text{ ps}$ , the calculated jump frequency is the same as that we find from an inspection of the ionic trajectories. Furthermore, the calculated diffusion coefficient using this threshold is in good agreement with  $D<sup>N.E.</sup>$  calculated from the  $MSD<sup>N.E.</sup>$  which we turn to discuss below.

Results from this analysis shows that  $\tau$ <sup>residence</sup> of an oxygen is slightly less than 10 ps with large vibrational amplitudes occurring dominantly in the crystallographic  $\langle 111 \rangle$  direction. Although the peak position in the ionic density of the oxygens is at the center of the cavity (i.e., at the 8*c* site of  $Fm\overline{3}m$ ) [\[20\]](#page-6-0), a typical oxygen position, when viewed locally, is shifted markedly in the direction of the octahedral hole in the  $(111)$  direction. We find that the oxygens migrate rapidly and decisively with  $\tau^{jump} \sim 0.5-1.0$  ps. About 90% of the jumps are between nearest-neighboring tetrahedral cavities aligned in the crystallographic  $(100)$  direction, whereas ∼10% of the jumps are between the next-nearest neighbors aligned in the  $\langle 110 \rangle$  direction. Occasionally a jumping oxygen will carry out a short loop or wiggle near an interstitial octahedral position, but the octahedral site is not a residential site for the oxygen. In fact, it corresponds to an ionic density minimum [\[20\]](#page-6-0), which also rules out an interstitial/interstitialcy diffusion mechanism for oxygen transport in superionic bismuth oxide. Of particular note is that we find that 20% of all jumps take place to an already occupied cavity which can initiate chains of collective migrating oxygens as discussed below.

Correlation between successive jumps *f* can be calculated using  $f = 1 + 2\langle \cos \theta_{l,l+1} \rangle$ , where  $\theta$  is the angle between jump *l* and jump  $l + 1$ . We then calculate  $f$  by decomposing two consecutive oxygen jumps in the three distinct directions. *Back jumps* (jump relaxations) take place when an atom jumps back to where it came from. *Sideway jumps* involve two consecutive jumps in different crystallographic directions whereas a *forward jump* describes an oxygen that jumps in the same direction as it did in the previous step, i.e., a jump in the  $\langle 100 \rangle$  direction is followed by a jump in  $\langle 100 \rangle$ .

We find that *f* is about 0.35 due to the high fraction of back jumps which is also higher than that expected for a random diffusion process at  $t > \tau^{\text{residence}}$ . We can calculate the tracer-diffusion coefficient from a hopping model using:  $\tilde{D}^{N.E.} = \frac{1}{6} f \Gamma a^2$ , where  $\Gamma$  and *a* are the jump frequency and the hopping lengths. Inserting the values of  $f$ ,  $a$ , and  $\Gamma$  gives  $\tilde{D}^{N.E.} = 1.0 \times 10^{-5}$  cm<sup>2</sup> s<sup>-1</sup> which is in good agreement with both *D*<sup>N</sup>.E. 's calculated from the MSDs above (shown in Fig. 1) and with result from the tracer-diffusion experiment reported in Ref.  $[27]$ . The good agreement between  $\tilde{D}^{N.E.}$ calculated from a hopping model and *D*<sup>N</sup>.E. calculated from the MSD, gives some confidence in that a hopping model provide a useful tool to also analyze collective dynamics in the superionic regime.

#### **B. Collective dynamics from a pair hopping model**

We now investigate collective diffusion of oxygens along the MD trajectory from an inspection of correlation between pairs of jumping oxygens. We distinguish between events where the diffusion mechanism involves a common cavity

<span id="page-3-0"></span>

FIG. 2. (a) The left picture shows a cartoon of the collinear kick out mechanism where O1 and O2 share a common cavity for a few vibrational periods before O2 is kicked out. (b) is an example of a crystallographically collinear mechanism where O1 triggers an oxygen O2 to jump in a neighboring cavity during diffusion whereas (c) is a noncollinear mechanism.

[i.e., a "kick out" mechanism as shown in Fig.  $2(a)$ ], or if they do not involve a common cavity as visualized in Fig. 2(b). The kick out mechanism involves two oxygens, O1 and O2, that typically stay together in the same cavity *B* for a very short time (between 0.1 and 0.3 ps) before O2 is kicked out. Diffusion of an oxygen from cavity *A* to an empty cavity *B* can also trigger an oxygen in a neighboring cavity "*C*" to jump to cavity "*D*" [see Fig. 2(b)]. We further distinguish among collinear, noncollinear, and exchange mechanisms: If cavities *A*, *B*, and *C* involved in the diffusion of the two oxygens are all aligned in the same crystallographic direction [as shown in Figs.  $2(a)$  and  $2(b)$ ], the mechanism is termed collinear. If O1 jumps to cavity *B* while O2 jumps to cavity *A*, the oxygens exchange positions which gives no *net* charge transport. A noncollinear mechanism involves cavities that are not aligned in the same crystallographic directions as shown in Fig. 2(c).

About 20% of the oxygens jump into an already occupied cavity and will, therefore, trigger collective chains of migrating oxygens. Of these, about 40% are involved in a collinear mechanism, 60% in a noncollinear path, whereas less than 1% exchange positions. The fraction of knock out collinear chains is, thus, substantially higher compared to that of a random diffusion process where the probability of collinear chains is 1/6. This suggests that a collinear kick out mechanism could explain, in part, the low value of the calculated Haven ratio. We can quantify the contribution from a collinear kick out mechanism to the Haven ratio by comparing the MSD of a "quasiparticle" of two oxygens involved in a collective chain with that when two oxygens hop at random on the oxygen sublattice. Since 40% of the 20% that jump into an already occupied cavity follow a collinear kick out mechanism, we can calculate the MSD from such a pair model from: MSD<sup>kick out</sup> =  $\frac{1}{6} f \Gamma(P_{\text{vac}} \times$ 

 $a_{\text{pair random}} + P_{\text{kick out}} \times a_{\text{kick out}}^2 = \frac{1}{6} f \Gamma(0.8 \times \sqrt{2} a_{nn} + 0.2 \times$  $(0.4 * 2 + 0.6 * \sqrt{2}) a_{nn}$ <sup>2</sup> where *P*<sub>vac</sub>, *P*<sub>kick out, *a*<sub>random</sub>,</sub> and *a*kick out are probabilities and hopping lengths for oxygens pairs that follow a (random) vacancy mechanism or kick out mechanisms, respectively. The calculated Haven ratio from this pair model is, therefore,  $H_{\rm R}^{\text{collinear kick out}} \approx \text{MSD}^{\text{random}}/\text{MSD}^{\text{kick out}} = 0.9$ , which is markedly higher than that calculated from the ratio of the  $MSD<sup>N.E.</sup>$  to  $MSD<sup>dc</sup>$ . It is, however, worth bearing in mind that this model does not include contributions from migrating chains involving three or more oxygens. If we assume that chains of three migrating oxygens follow the same probability distribution as that of pairs, the Haven ratio calculated from a collinear kick out mechanism will decrease to about 0.8. We do not expect a significant contribution to the Haven ratio from collective chains with more than three oxygens since the kick out chains are quickly terminated by a jump into a vacant cavity. This is also confirmed from an inspection of the trajectory which shows that chains involving more than three ions are rare. Collective collinear strings of two and three oxygens, therefore, contribute slightly less than 50% to all collective events.

The discrepancy between the Haven ratio calculated from  $\text{MSD}^{\text{N.E.}}/\text{MSD}^{\text{dc}}$  and that estimated from a hopping model of pairs (and triplets) of migrating oxygens may, in part, be due to collective chains that have been averaged out in our analysis due difficulty in distinguishing vibrations and jumps. We have not yet included correlated events where pairs of oxygens do *not* stay within the same cavity *B* at the same time during diffusion, such as if O2 jumps to cavity *C before* O1 jumps to *B*. Our jump diffusion model of oxygen pairs would identify such a collective oxygen pair as two uncorrelated jumps to vacant cavities. To estimate the contribution from

FIG. 3. Distinct part of the van Hove correlation function of the oxygens  $G_d^{OO}(r,t) = \frac{1}{N(M-1)} \sum_{i \neq j}^{N} \langle \delta(|\mathbf{r}_{ij}(t+t_0) - \mathbf{r}(t_0)|) \rangle$  from *ab initio* MD runs at 1033 K. The indices *i* and *j* run over all *N* oxygens in the simulation box, and the brackets denote averaging over different time origins *t*0.

such events to the Haven ratio, we carried out an inspection of the oxygen trajectories which indicates that these events are rare (i.e., we found that such events contribute less than 5% to the Haven ratio). In addition, our analysis does not, so far, include events where the two cooperatively migrating oxygens are *not* nearest neighbors as shown in Fig. [2\(b\).](#page-3-0) Such a mechanism was found to be more important in superionic CuI than the kick out mechanism [\[31,32\]](#page-6-0) and is not expected to contribute to the a first peak in  $G_d^{OO}(r, t)$ . We will turn to investigate if such events contribute to the Haven ratio from the nature of the dynamical heterogeneities.

## **C. Collective diffusion from the distinct part of the van Hove function**

The collinear kick out mechanism appears not to fully capture all collective events in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> which can be further investigated from the distinct part van Hove function  $G_d^{OO}(r, t) = \frac{1}{N(N-1)} \sum_{i \neq j}^{N} \langle \delta(|\mathbf{r}_{ij}(t + t_0) - \mathbf{r}(t_0)|) \rangle$ . If the kick out mechanism would account for all collective jumps, we might expect a peak to grow at short distances and times in the distinct part of the van Hove function  $G_d^{OO}(r, t)$  as demonstrated for collective kick out chains of Li<sup>+</sup> ions in Li-based superionic conductors [\[6\]](#page-6-0).

That is, since—in the kick out mechanism—cavity *B* is occupied by O1 even before O2 has left the cavity, we expect a peak in  $G_d^{OO}(r, t)$  at times consistent with the characteristic jump time of an oxygen  $(<1$  ps) within intrabasin distances at  $r < 1$  Å. However, as seen in Fig. 3, the peak position in  $G_d^{OO}(r,t)$  at 0.7 Å is first visible at around 4 ps which suggests that kick out events are not captured in  $G_d^{OO}(r, t)$ . The peak in  $G_d^{OO}(r=0.7 \text{ Å}, t)$ , therefore, reveals little information about the collective diffusion of oxygens but rather reflects the presence of large thermal anharmonic vibrations and a highly asymmetric local oxygen arrangement around the bismuth as discussed previously in Refs. [\[20,23,33\]](#page-6-0).

#### **D. Collective diffusion from dynamical heterogeneity**

Challenges in capturing many collective events from a hopping model and the distinct part of the van Hove function—due to difficulties in distinguishing vibrations

with large amplitudes and jumps—has motivated us to investigate the nature of dynamical heterogeneity as a possible route to identify cooperative migrating oxygens. We, therefore, define the "rearrangement indicator"  $R_i$ [\[34,35\]](#page-6-0) of an oxygen *i* in order to measure the spacious region of its trajectory (within a small time window) as:  $R_i = \sqrt{\frac{\left(\frac{r_i - (r_i)}{r_i} - \frac{r_i}{r_i}\right)^2}{r_i + \frac{2r_i}{r_i}}}$   $\frac{\left(\frac{r_i - (r_i)}{r_i} - \frac{r_i}{r_i}\right)^2}{r_i + \frac{2r_i}{r_i}}}$ where  $\langle \rangle_{t+\delta t/2}$  and  $\langle \rangle_{t-\delta t/2}$  denote time averages from *t* to  $t + \delta t/2$  and from  $t - \delta t/2$  to  $t$  with  $\delta t = 1$  ps. Note that this choice of δ*t* is the same as that used above for distinguishing vibrations with large amplitudes and ion hops above  $(\tau^{\text{thresh}})$ , but we stress that our results below are not strongly influenced by the choice of δ*t* as long as 0.1 ps  $\langle \delta t \rangle$  3 ps. We identify oxygens that are likely to migrate or hop as those with  $\sqrt{R_i} > 0.95a_{nn}$ , (where  $a_{nn}$ again is the distance between nearest-neighboring oxide ion positions). The oxygens that are moving a distance of a typical jump with time characteristic of a jump are marked as "red balls" in Fig. [4,](#page-5-0) which shows three typical snapshots along an MD trajectory. It is evident that these oxygens form dynamical clusters and that these clusters can contain more than two oxygens! We can quantify the size of these clusters by counting all oxide ions with  $\sqrt{R_i} > 0.95$ a<sub>nn</sub> that are within a cutoff distance  $d_{\text{max}} = 1.1a_{nn}$  of another "rearranging" oxygen with  $\sqrt{R_i} > 0.95a_{nn}$ . This cutoff distance captures cooperative migrating groups of oxygens involving primarily nearest-neighboring atoms, and results from this analysis shows that 14% and 3% of the clusters contain two and three (or more) oxygens, respectively, compared to 6% and less than 1% for a random distribution of red balls. If we increase  $d_{\text{max}}$  to 1.5 $a_{nn}$ —and thereby include a larger fraction of oxygens involved in the mechanism shown in Fig.  $2(b)$ —we find that 26%, 12%, and 6% of the clusters contain two, three, and more than three oxygens, respectively. If we assume that the oxygens do not correlate, we find that these numbers reduce to 19% and 4% for two- and three-atom clusters. At an even higher cutoff distance  $(d_{\text{max}} = 2.0a_{nn})$ , there is a significant and higher fraction of three-atom clusters (18%) compared to that of a random distribution (12%). This indicates that oxygen clusters of next-nearest and even a few third-nearest neighbors are involved in collective diffusion of oxygens. If these jumps are in the same directions [e.g., as that shown in Fig.  $2(b)$ ], they will contribute to the low value of the Haven ratio.

The results form the cluster analysis are in good agreement with results from the hopping models discussed above. Both models indicate that about 20% of the oxygens jump to an already occupied cavity and are, thus, involved in a kick out mechanism. This suggests, in turn, that the rearranging oxygens are indeed oxygens that jump to new cavities and the shape and size of the clusters visualize chains of migrating oxygens.

Results from the hopping of pairs, the distinct part of the van Hove function, and the nature of dynamical heterogeneities show that diffusion processes in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> are complex and include several distinct mechanisms. Hopping to an already filled cavity can initiate collective collinear chains [see Fig.  $2(a)$ ], and hopping to vacant cavities can trigger hopping of an another oxygen that is not necessarily a nearest neighbor to O1 [see Fig.  $2(b)$ ]. The high

FIG. 4. Three random snapshots of oxide ion positions during an MD run at 1033 K. The red spheres are oxygens with a rearrangement indicator  $\sqrt{R_i} > 0.95a_{nn}$ , representing jumping oxygen ions, whereas the gray ones are those with  $\sqrt{R_i} < 0.95a_{nn}$  (the nonmigrating oxygens). Sticks are drawn between red balls with  $d_{\text{max}} = 1.5a_{nn}$ .

inherent vacancy concentrations in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> indicate that these strings are short, involving up to a maximum of four oxygens.

architectures providing a possible new route to implement  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> as nanopillars/nanotubes to lower the current operation temperature of SOFCs.

### **E. Implication for the design of future solid oxide fuel cells**

The insight into collective diffusion from *ab initio* MD can provide us with essential input in the design and development of the next generation SOFCs. Although the  $\delta$  phase of Bi<sub>2</sub>O<sub>3</sub> itself is not a particular interesting candidate electrolyte material for the use within SOFCs because of its high-temperature window of stability, it can easily be stabilized to lower temperatures by aliovalent doping [\[36,37\]](#page-6-0) or as thin films grown on a suitable substrate [\[38,39\]](#page-6-0). This provides a range of opportunities to implement  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> within intermediateand low-temperature fuel-cell devices. Functionally graded bismuth oxide/ceria bilayers [\[40\]](#page-6-0), for example, and ultrathin multilayers consisting of alternate  $Er_2O_3$ -doped  $Bi_2O_3$  and  $Gd_2O_3$ -doped  $CeO_2$  sheets [\[41\]](#page-6-0) both possess high chemical stability and high power densities at modest to low temperatures. However,  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> films grown directly on suitable substrates, such as  $SrTiO<sub>3</sub>$ , may relax to new phases [\[42\]](#page-6-0) or can easily "crack up" forming dislocation misfits near the interface as shown from *ab initio* DFT calculations [\[43,44\]](#page-6-0). Such a mismatch may increase the contribution from the *p*-type electronic conductivity to the total conductivity, but it is often extremely difficult to distinguish the electronic and ionic contributions to the conductivity in layered heterostructures [\[45–47\]](#page-6-0).

Vertically grown architectures have challenged conventional lateral heterostructures for oxide fuel-cell technology where nanorods and thin layers can be self-assembled *vertically* on a suitable substrates [\[48\]](#page-6-0). This allows for both high strain tunability—which is extremely difficult to achieve using  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> thin films grown layer by layer—and much better control of the contribution from the electronic currents to the conductivity. Indeed, Sm-doped  $CeO<sub>2</sub>$  electrolytes grown vertically as nanopillars on  $SrTiO<sub>3</sub>$  show an order of magnitude higher oxide ion conductivity compared to plain Smdoped films with fast-ion diffusion occurring to a large extent *inside* the nanopillars [\[48\]](#page-6-0). Collinear strings of cooperatively migrating oxygens can easily be accommodated within such

#### **V. CONCLUSIONS**

We have carried out a detailed analysis of the nature of oxygen diffusion in the superionc phase of  $Bi<sub>2</sub>O<sub>3</sub>$  using *ab initio* MD. The calculated Haven ratio  $H_R = D<sup>N.E.</sup>/D<sup>dc</sup>$  is markedly lower than 1 which indicates that collective chains of migrating oxygens contribute strongly to the dc conductivity. We explore the atomistic origin of these collective events from: (1) a hopping model of oxygen pairs, (2) the distinct part of the van Hove function, and (3) the nature of dynamical heterogeneities. We are unable to capture collective chains from the functional form of  $G_d^{OO}(r, t)$  but from a pair hopping model (where the number of oxygen hops in and out of their residential cavities are counted); we identify short collective chains of migrating oxygens that follow a kick out mechanism similar to that shown in Fig.  $2(a)$ . These chains are initiated by an oxygen that jumps into an already occupied cavity and then kicks out the residential oxygen from that cavity. The calculated contribution to the Haven ratio from such collective "two-atom chains" is only about 40%, indicating that collective chains may contain, at least, three oxygens, and/or that correlation length between different oxygen jumps may be longer than only involving nearest neighbors as, for example, cartooned in Fig.  $2(b)$ . To investigate this further, we explore the nature of dynamical heterogeneities, where clusters of oxygens that move distances characteristic of typical a jump are identified. The nature of these clusters confirms that crystallographically collinear chains containing more than two atoms also contribute to the ionic conductivity and that hops into vacant cavities can correlate with oxygen hops when these are aligned further apart than nearest neighbors [as in Fig. [2\(b\)\]](#page-3-0). Results from hopping of pairs, the distinct part of the van Hove function, and the nature of dynamical heterogeneities show that the ion diffusion processes in  $\delta$ -Bi<sub>2</sub>O<sub>3</sub> are complex, blurred, and involve different mechanisms which are not easily distinguished from one another. Nevertheless, it is evident that this complex dynamics plays an important role in promoting fast-ion conductivity.
