(Received 14 April 2022; accepted 2 August 2022; published 22 August 2022)

Recent discoveries of charge order and electronic nematic order in the iron-based superconductors and cuprates have pointed towards the possibility of nematic and charge fluctuations playing a role in the enhancement of superconductivity. The $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ system, closely related in structure to the BaFe_2As_2 system, has recently been shown to exhibit both types of ordering without the presence of any magnetic order. We report single-crystal x-ray diffraction experiments on $\text{Ba}_{0.35}\text{Sr}_{0.65}\text{Ni}_2\text{As}_2$, providing evidence that the previously reported incommensurate charge order with wave-vector $(0, 0.28, 0)_{\text{tet}}$ in the tetragonal state of BaNi_2As_2 vanishes by 65% Sr substitution together with nematic order. Our measurements suggest that the nematic and incommensurate charge orders are closely tied in the tetragonal state and show that the $(0, 0.33, 0)_{\text{tri}}$ charge ordering in the triclinic phase of BaNi_2As_2 evolves to become $(0, 0.5, 0)_{\text{tri}}$ charge ordering at $x = 0.65$ before vanishing at $x = 0.71$.

DOI: [10.1103/PhysRevB.106.054107](https://doi.org/10.1103/PhysRevB.106.054107)

High-temperature superconductivity in the cuprate [1,2] and iron pnictide families [3–5] has prompted wide research efforts aiming to uncover the origins of their unconventional pairing mechanisms. Although long-range magnetic fluctuations have long been suggested as responsible for the pairing, recent research into electronically driven nematicity in the iron pnictides [6,7] as well as charge order and nematic order in the cuprates [8–14] suggests that these electronic degrees of freedom may also play important roles in stabilizing the superconducting phases in these systems.

Theoretical work has shown that fluctuations associated with an electronically nematic quantum critical phase can enhance superconducting phases with few requirements [15,16]. The proximity of magnetism in the cuprates and iron pnictides prevents a straightforward study investigating the potential enhancement effects of electronic nematic fluctuations to superconductivity. Our recent studies of the tunable superconducting pnictide material $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ revealed a strong sixfold enhancement of T_c from 0.6 to 3.5 K in proximity to an increase of nematic fluctuations, suggesting strong evidence of a pairing enhancement [17]. Furthermore, with evidence of charge [18] and nematic [17] orders in proximity to the enhancement, $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ is positioned as a good candidate for exploring the interplay of charge and nematic degrees of freedom in the absence of magnetism within superconducting systems.

The parent compound BaNi_2As_2 is tetragonal and isostructural to its famous iron-based counterpart BaFe_2As_2 at room temperature. Unlike the latter, BaNi_2As_2 undergoes a first-

order tetragonal to triclinic structural phase transition at $T_s = 135$ K. Additionally, neutron measurements of BaNi_2As_2 have shown no evidence of a magnetic structure in its low-temperature phase or anywhere else [19]. The tetragonal and triclinic phases of $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ are denoted by sets of distinct Bragg peaks that index to the space groups of $I4/mmm$ and $P1$, respectively. Here we use $(H, K, L)_{\text{tet}}$ and $(H, K, L)_{\text{tri}}$ separately to describe positions in momentum space for each phase. X-ray measurements have revealed a bidirectional incommensurate charge-density wave (IC-CDW) on setting just above T_s at $T_{IC} = 148$ K at a wave vector of $Q_{\text{tet}} = 0.28$ in a “4Q” state on the ab plane [20]. At T_s , the incommensurate CDW vanishes and gives way to a unidirectional commensurate CDW (C-CDW1) at wave-vector $(0, 0.33, 0)_{\text{tri}}$ in the triclinic phase [18]. BaNi_2As_2 also becomes superconducting at $T_c = 0.7$ K [21], and thermal conductivity measurements suggest that this superconducting state is fully gapped [22]. The other end member SrNi_2As_2 shows no evidence for a structural distortion or magnetic order, but also superconducts below $T_c = 0.62$ K [23]. Isovalent substitution of Sr for Ba in $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ has been shown to suppress T_s toward absolute zero temperature and enhance T_c up to a maximum value of 3.5 K at $x = 0.71$ [17].

Elastoresistivity measurements of $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ probing the B_{1g} channel, corresponding to the symmetry-breaking strain along the [100] and [010] tetragonal crystallographic directions, have revealed a large nematic susceptibility throughout the range of Sr substitution [17]. In addition, this experiment also revealed striking nonreversible hysteretic behavior in the nematic response just above the triclinic distortion between $x = 0$ and $x = 0.5$, implying the presence of an ordered electronic nematic phase that coexists with IC charge order in the tetragonal structural phase. In BaNi_2As_2 at

*paglione@umd.edu

temperatures just above T_s , the area of hysteresis in elastoresistance from nematic order sharply increases with a profile that matches the sharp intensity growth of the IC-CDW. With increasing Sr content, this nematic order begins to fade until a crossover to electronically driven nematic fluctuations occurs in the intermediate region around $x = 0.5$. The correlation between the $Q_{\text{tet}} = 0.28$ charge order and nematic order in both scaled intensity and crystallographic direction suggests that the two phases are closely linked. In this paper, we provide evidence for the vanishing of the incommensurate charge order that lives above the triclinic distortion at $x = 0.65$, matching the disappearance of nematic order at the same concentration. The absence of this incommensurate charge order in a region void of nematic order further supports the notion that these two phases are linked.

Single-crystal x-ray diffraction measurements were carried out using a Xenocs GeniX three-dimensional (3D) Mo $K\alpha$ (17.4-keV) source which delivers 2.5×10^7 photons per second with a beam spot of $130 \mu\text{m}$. The sample was cooled using a closed-cycle cryostat to reach a base temperature of 11 K. The sample was kept inside a Be dome, used for vacuum and radiation shielding. Sample motion was performed using a Huber four-circle diffractometer and x-ray detection was captured using a Mar345 image plate to allow for 3D mapping of momentum space of with a resolution of $\Delta q = 0.01$ to 0.08 \AA^{-1} depending on the cut [18]. Single crystals of $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ were grown using a NiAs self-flux solution technique [21]. Resistivity measurements were performing using a Quantum Design physical property measurement system.

Charge order in the $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ system develops in a complex manner with different phases coexisting [20]. Just as nematic fluctuations undergo changes in character across the phase diagram, so too does the charge order. BaNi_2As_2 develops a complex $4Q$ bidirectional IC-CDW with a wave vector at $(0.28, 0.28, 0)_{\text{tet}}$ that onsets at 148 K [20], distinctly above the first-order triclinic transition (cf. Fig. 1). The IC-CDW order grows in x-ray intensity as temperature is lowered until the structural transition occurs where this order abruptly disappears and a new unidirectional commensurate charge (C-CDW1) order forms at $(0, 0.33, 0)_{\text{tri}}$ in the triclinic phase and is maintained down to base temperature [18]. For increasing Sr concentrations on the order of $x = 0.4$ to $x = 0.5$, the IC-CDW's window of existence above the triclinic order narrows closer to the triclinic onset temperature [20]. Additionally, in the triclinic phase, a new unidirectional commensurate charge order forms at $(0, 0.5, 0)_{\text{tri}}$ (C-CDW2) about 20 K below the triclinic onset [20]. For a narrow range of Sr concentration, about $x = 0.4$, both C-CDW1 and C-CDW2 coexist down to base temperature with C-CDW2 being largely dominant in scattering intensity [20].

Each charge order peak and structural transition is detectable by x-ray diffraction. At a Sr concentration of $x = 0.65$, we report that there is no IC-CDW or any other charge order observed within the tetragonal phase, as presented in Fig. 2. When the system undergoes the triclinic distortion, now at a reduced temperature of 60 K, only the C-CDW2 $Q = 0.5$ order is observed (Fig. 3). Increasing Sr content slightly further to $x = 0.71$ has previously shown a vanishing of the

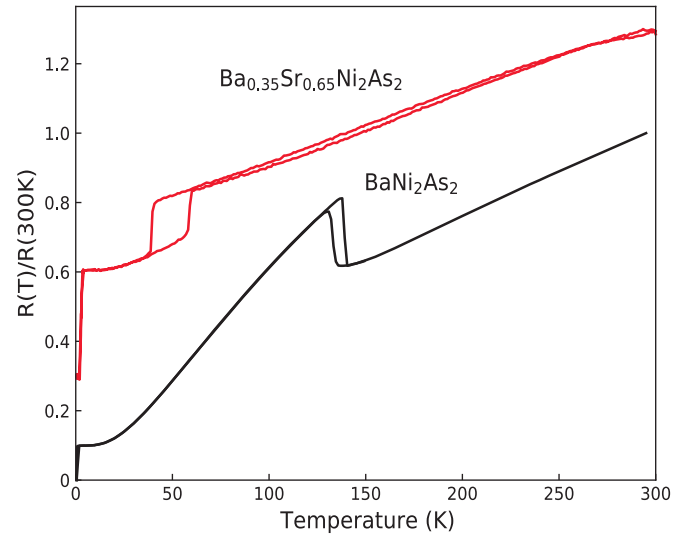

FIG. 1. Resistance of BaNi_2As_2 and $\text{Ba}_{0.35}\text{Sr}_{0.65}\text{Ni}_2\text{As}_2$ normalized to 300-K data. $\text{Ba}_{0.35}\text{Sr}_{0.65}\text{Ni}_2\text{As}_2$ has been offset from BaNi_2As_2 . The triclinic distortion in BaNi_2As_2 can be seen in resistance at 135 K on cooling and at 138 K on warming and in $\text{Ba}_{0.35}\text{Sr}_{0.65}\text{Ni}_2\text{As}_2$ at 40 K on cooling and at 58 K on warming. The T_c of BaNi_2As_2 and $\text{Ba}_{0.35}\text{Sr}_{0.65}\text{Ni}_2\text{As}_2$ is measured at 0.6 and 3 K respectively.

triclinic and C-CDW2 order along with an enhancement of T_c up to 3.6 K [17,20]. The vanishing of the IC-CDW at $x = 0.65$ in the tetragonal phase, along with the shift of commensurate order from C-CDW1 to C-CDW2 in the triclinic phase, indicates that the charge-ordered phases of $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$ develop in a complex way and are not simply tuned to zero temperature.

The charge order of $x = 0.65$ has quite different behavior than that of $x = 0$. Pure BaNi_2As_2 has a triclinic distortion at 135 K that coincides with the destruction of the $Q_{\text{tet}} = 0.28$ incommensurate charge order and the emergence of a $Q_{\text{tri}} = 0.33$ commensurate charge order [18]. In the absence of a precursor incommensurate order for $x = 0.65$, we observe at triclinic distortion at 60 K that, in this case, is accompanied by commensurate charge order with wave-vector $(0, 0.5, 0)_{\text{tri}}$ (Fig. 3). The absence of incommensurate order in the tetragonal phase is likely associated with the absence of nematic order as they are closely tied in $\text{Ba}_{1-x}\text{Sr}_x\text{Ni}_2\text{As}_2$. Elastoresistance measurements for BaNi_2As_2 have shown a hysteresis as a function of applied strain along the B_{1g} symmetry channel (Fig. 2), which operates along equivalent crystallographic directions of the IC-CDW. At low-Sr concentrations, the hysteresis in elastoresistance is thought to arise due to domain formation in an ordered nematic phase present in the system and appears simultaneously with the onset of the bidirectional IC charge order [17].

As Sr concentration increases, the window for nematic order above the triclinic distortion begins to narrow and vanishes around $x = 0.5$ with a transition to electronically driven nematic fluctuations [17]. Concurrently, the window of existence of the IC-CDW also narrows, and the IC-CDW has an intensity profile with temperature that scales

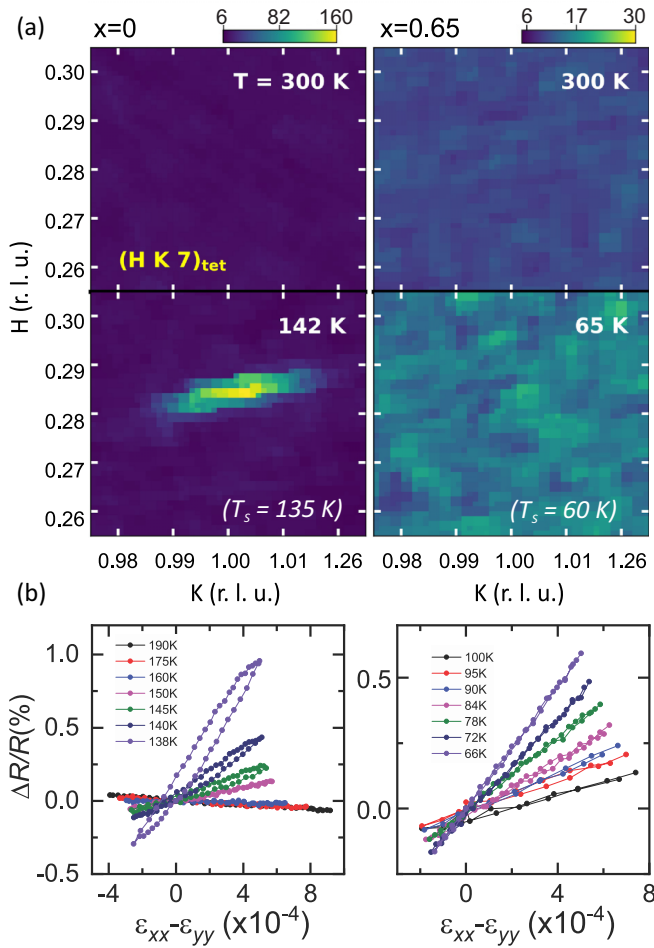

FIG. 2. (a) (H, K) cuts through momentum space centered on $(0.28, 1.7)_{tet}$ at room temperature and relative temperatures above the triclinic structural distortion for $x = 0$ and $x = 0.65$ Sr concentrations. Data taken from Supplemental Material Fig. S3 of Ref. [17]. At room temperature for both concentrations no CDW is present. At $x = 0$ the IC-CDW is observed at 142 K. At $x = 0.65$, the IC-CDW is no longer observable above background levels. No other CDW peaks were detected in tetragonal phase for $x = 0.65$ in all other regions of observed momentum space. X-ray data taken from Supplemental Material Fig. S3 of Ref. [17]. (b) Elastoresistivity ratios for $x = 0$ and $x = 0.63$ for temperatures just above the triclinic distortion. In $x = 0$, the signal is hysteretic with strain, indicating nematic order. In $x = 0.63$, the signal is reversible with strain. The observation of nematic order and the IC-CDW occur simultaneously for $Ba_{1-x}Sr_xNi_2As_2$.

with the hysteretic area profile seen in elastoresistance [17]. For $x = 0.65$, we show that no IC-CDW or any other charge order exists above the triclinic distortion. A prior study has shown a completely reversible nematic susceptibility for this region of Sr concentration and, therefore, no signal of nematic order [17]. We claim that charge order and nematic order not only scale together throughout $Ba_{1-x}Sr_xNi_2As_2$, but also mutually exist together throughout the entire phase diagram. Together with prior elastoresistivity measurements [17], our x-ray data (Fig. 2) suggest there is an intimate tie between the two orders requiring further study to elucidate.

FIG. 3. (H, K) momentum space cuts in the triclinic space at $x = 0.65$ for selected temperatures. The $Q_{tri} = 0.5$ C-CDW2 observed via superstructure reflections at $(1, 0.5, 3)_{tri}$ and $(-1, 0.5, 4)_{tri}$. An example triclinic Bragg reflection onset is shown at $(3, 1, 0)_{tri}$. At 75 K, above the triclinic distortion, no scattering is found in these selected spaces. Intensity from each reflection is first observed starting at 60 K and continues to be observed down to 11 K (not shown).

In conclusion, we report x-ray, transport, and magnetometry measurements showing an absence of long-range charge order in $Ba_{0.35}Sr_{0.65}Ni_2As_2$ within the tetragonal phase that is consistent with the absence of nematic order found previously. Together with the observation of a unique commensurate charge order with the wave vector of $(0, 0.5, 0)_{tri}$ below the triclinic distortion, which evidences a complex evolution of charge-ordered phases with Sr substitution, these data help elucidate the rich evolution of electronic degrees of freedom in the $Ba_{1-x}Sr_xNi_2As_2$ system.

X-ray experiments were supported by the U.S. Department of Energy, Office of Basic Energy Sciences grant No. DE-FG02-06ER46285 (P.A.) and the Institute for Complex Adaptive Matter (J.C.). Low-temperature measurements were supported by the National Science Foundation Grant No. DMR1905891 (J.P.), and J.P. and P.A. acknowledge the Gordon and Betty Moore Foundation's EPiQS Initiative through Grants No. GBMF9071 and No. GBMF9452, respectively.
