We analyze the micromagnetics of short longitudinal modulations of a high-magnetization material in cylindrical nanowires made of a soft-magnetic material of lower magnetization such as permalloy, combining magnetic microscopy, analytical modeling, and micromagnetic simulations. The mismatch of magnetization induces curling of magnetization around the axis in the modulations, in an attempt to screen the interfacial magnetic charges. The curling angle increases with modulation length, until a plateau is reached with nearly full charge screening for a specific length scale Δ_{mod} , larger than the dipolar exchange length of any of the two materials. The curling circulation can be switched by the Oersted field arising from a charge current with typical magnitude 10^{12} A/m² for a diameter of ~ 100 nm, and reaching a maximum for Δ_{mod} .

I. INTRODUCTION

Cylindrical magnetic nanowires can be synthesized rather easily by electrodeposition in insulating templates with pores, such as ion-track-etched polycarbonate membranes [1] and anodized aluminum foils and thin films [2]. Such wires have attracted intense and continuous interest over the past three decades, partially for being a realization of a nearly one-dimensional magnetic system and thus a textbook case to understand fundamental phenomena. A wealth of phenomena have been investigated in cylindrical magnetic nanowires: current-perpendicular-to-plane giant magnetoresistance and measurements of spin diffusion length [3–5], ferromagnetic resonance [6], competition between shape and magnetocrystalline anisotropy [7], dipolar interactions in a dense and complex medium [8–10], nucleation at their apex [11–14], statics and dynamics of domain-wall motion both under a magnetic field and under a spin-polarized current [5,15–19].

The versatility of cylindrical nanowires is high, with free choice of the composition and geometry, with diameters ranging from a few nanometers up to hundreds of nanometers, and lengths from a few tens of nanometers to tens of micrometers [1,2,20]. In addition, it is possible to vary features along

their length, either through the modulation of their diameter [21–32] or through modulation of their composition [33–43]. The latter is particularly interesting for engineering the longitudinal energy landscape and controlling domain-wall motion. From a fundamental point of view, this provides textbook cases of domain-wall (DW) pinning on different types of defects [44,45], related to the long-standing problem called the Brown paradox [44,45]. For applications it may provide ways to enhance coercivity, contributing to the search for rare-earth-free permanent-magnet materials [46], design nonreciprocal ratchet-type devices [47], or provide a building block material for the concept of a domain-wall-based racetrack memory [48,49].

For spintronics, modulations of composition are preferable to modulations of diameter as they avoid local changes in the current density [28]. There are already several theoretical and experimental investigations of nanowires modulated in composition, addressing the physics of magnetization reversal [37,47,50–54], domain-wall pinning [33,50,55], or field-driven domain-wall motion [35,36,47,55]. Yet the underlying general physics of these modulations has not been examined in detail.

Here, we report the micromagnetics of chemical insertions within cylindrical nanowires. Although the insertions have higher magnetization than the rest of the nanowire, all materials considered are magnetically soft. Thus the materials of choice for the segments out of the chemical insertions are typically composed of Ni-rich, CoNi or FeNi alloys, which

*lualv10@ucm.es

†lucas.perez@ucm.es

‡olivier.fruchart@cea.fr

come with rather low magnetization. The nanowires are uniformly magnetized along their axis outside the modulations; that is, we are not considering domain walls. We consider the practical case of $\text{Fe}_{80}\text{Ni}_{20}$ chemical modulations periodically inserted in permalloy ($\text{Ni}_{80}\text{Fe}_{20}$); yet we draw conclusions in terms of reduced magnetic quantities when applicable, for the sake of generality. We combine simulations, micromagnetic modeling, and experiments aiming to provide a comprehensive view, which we hope can be useful as a firm ground for the understanding of more complex situations involving chemical modulations, such as their interaction with magnetic domain walls.

II. METHODS

A. Experimental methods

Permalloy ($\text{Fe}_{20}\text{Ni}_{80}$) cylindrical nanowires with nanometer-sized modulations of composition $\text{Fe}_{80}\text{Ni}_{20}$ were synthesized by template-assisted electrochemical deposition. Two different nanoporous anodic aluminum oxide (AAO) templates were prepared. First, AAO templates with pore diameter ranging between 100 and 140 nm were prepared by one-step hard anodization of Al disks (Goodfellow, 99.999% purity) in a water-based solution of oxalic acid (0.3 M) and ethanol (0.9 M), applying 140 V of anodization voltage at 0–1 °C for 2.5 h. Second, AAO templates with pore diameter below 100 nm were prepared by two-step anodization in oxalic acid (0.3 M), applying 60 V of anodization voltage at 20 °C for 15 and 3 h for the first and second anodization, respectively. In both cases, the remaining Al was etched with an aqueous solution of CuCl_2 (0.74 M) and HCl (3.25 M), the oxide barrier was removed, and the pores were opened to the final diameter with H_3PO_4 (5 vol %). In some cases we performed 5 nm HfO_2 atomic layer deposition (ALD) coating of the pores to optimize the synthesis and prevent sample oxidation. However, this is not a key step because all the nanowires, also the ones without coating, have an oxidized CrO layer created by the solution used to release the nanowires from the alumina template. Therefore, at the end, all the samples are protected from strong oxidation due to this.

The nanowires were grown using pulse-plating electrodeposition under conditions similar to those described in Ref. [55]. The width of the pulses was varied to change the length ℓ of the chemical modulation from 20 to 150 nm, and the length of the permalloy segments is a few hundreds of nanometers to several micrometers. Following growth, the templates were dissolved in H_3PO_4 (0.4 M) and H_2CrO_4 (0.2 M). Then, the nanowires were dispersed on Si substrates, either bulk or with a Si_3N_4 window to allow for transmission microscopy. Nanowires were contacted electrically using laser lithography in order to allow current injection. Resistivity values obtained are as low as 20 $\mu\Omega$ cm at room temperature in comparison with 15 $\mu\Omega$ cm of bulk permalloy despite the material interfaces, allowing the injection of currents much higher than 10^{12} A/m². The residual resistivity value measured at low temperature is 10 $\mu\Omega$ cm.

We used several types of magnetic microscopy techniques in order to access three-dimensional magnetization

textures, all based on x-ray magnetic circular dichroism (XMCD): photoemission electron microscopy (PEEM) in shadow mode [16,56,57] and transmission x-ray microscopy (TXM) [58] at the CIRCE and MISTRAL beamlines of the ALBA synchrotron and scanning transmission x-ray microscopy (STXM) [59] and ptychography [60–62] at the HERMES beamline of the SOLEIL synchrotron. Unless otherwise stated, we set the photon energy at the Fe L_3 absorption edge. The x-ray beam direction was typically nearly transverse to the nanowire axis, in order to be mostly sensitive to nonlongitudinal components of the magnetization. For PEEM and TXM microscopy, series of about 64 images per polarity were taken and registered to increase the signal-to-noise ratio, while keeping under control the loss of spatial resolution due to drift during long acquisitions. For STXM, an image is reconstructed from a single scan. In the case of ptychography, an overlap of 30% of the illumination spots allowed a rather fast convergence of the iterative algorithm and a reconstructed amplitude image of sub-15-nm resolution. Ptychographic reconstruction was carried out using the open-source PYNX software developed at the European Synchrotron Radiation Facility [63]. Complementary measurements were performed by atomic and magnetic force microscopy (AFM and MFM, respectively), as well as by scanning transmission electron microscopy (STEM) and holography.

B. Theoretical methods

Micromagnetic simulations were performed using FEELL-GOOD [64–66], a homemade finite-element-based code that uses tetrahedrons for the discrete mesh. The system considered is a cylindrical nanowire made of two permalloy segments of 100 nm (for a diameter $d = 90$ nm) or 150 nm (for $d = 130$ nm) length each, separated by a $\text{Fe}_{80}\text{Ni}_{20}$ chemical modulation with length ℓ varied between 20 and 120 nm. In order to mimic an infinite wire, the magnetic charges at the wire ends are removed numerically. The mesh size used was 4 nm. The following material parameters were used: spontaneous magnetization $M_1 = 8 \times 10^5$ A/m for the permalloy segments, $M_2 = 14 \times 10^5$ A/m for the $\text{Fe}_{80}\text{Ni}_{20}$ modulation, $M_2 = 12.5 \times 10^5$ A/m for the $\text{Fe}_{65}\text{Ni}_{35}$ modulation, single exchange stiffness for all materials $A = 1.3 \times 10^{-11}$ J/m, and zero magnetocrystalline anisotropy. The reason to use a single value for exchange stiffness is to highlight the impact of the variation of M_s on the micromagnetics, which is the driving force for the phenomena reported here. The resulting dipolar exchange lengths $\Delta_d = \sqrt{2A/(\mu_0 M_s^2)}$ are 5.6, 3.3, and 3.7 nm, respectively. Finally, a damping coefficient equal to 1 was used for faster relaxation and dynamics. When considering the effect of an Oersted field, we consider a uniform and steady charge current flowing along the wire axis z , disregarding spin-transfer torque effects.

Postprocessing scripts were used to extract quantitative information on the magnetization components from simulated and experimental data. From magnetic contrast images the degree of tilt of magnetization was extracted based on the Beer-Lambert law as described in Ref. [67] (see Supplemental Material for a detailed description [68]).

FIG. 1. (a) Atomic force microscope (AFM) image of a chemically modulated nanowire with $d = 130$ nm and $\ell = 60$ nm. (b) Magnetic force microscope (MFM) of (a). Each modulation is highlighted by a dark-light bipolar contrast. Orange dashed lines indicate the location of the chemical modulations. (c) Combination of STEM and holographic image of the nanowire in (a). Black lines inside the wire show a continuous induction field. The modulation is noticed by the black segment due to the difference in Z contrast. Stray field lines arise from the modulation (directions sketched in the inset).

III. RESULTS

A. Experimental evidence of stray field

The insertion of chemical modulations with high magnetization within a permalloy nanowire is expected to affect the magnetostatics of the system. Indeed, when the magnetization of the nanowire lies along its axis, as expected for soft-magnetic materials in elongated structures, surface magnetic charges appear at the interface between the two materials, due to the mismatch of magnetization.

Figures 1(a) and 1(b) show an AFM image and a MFM image of a nanowire with $d = 130$ nm and $\ell = 60$ nm, in a remanent state. In the MFM image, a bipolar magnetic contrast is observed at each modulation. This suggests the existence of opposite directions of the vertical magnetic stray field on either side of the modulation, which is consistent with the expectation of opposite magnetostatic charges at the two interfaces.

The stray field can be visualized directly with electron holography. The location of the modulations was determined first, by imaging in STEM, highlighting the Z contrast. The stray field, imaged by electron holography, takes the form of a flux leakage at the modulation, opposite to the direction of magnetization in the wire [Fig. 1(c)]. In this specific case, the stray field is slightly shifted to the left due to a slight synthesis-induced structural asymmetry of the modulation in this particular wire (which has been avoided for later-stage synthesis processes). Note the continuity of the magnetic induction field \mathbf{B} inside the wire, expected from Maxwell's equations. Yet magnetic induction results both from magnetization and from the magnetostatic field, so that the details of the magnetization distribution cannot be easily obtained from this image. More is reported in the next section with

FIG. 2. X-ray imaging of $\text{Fe}_{20}\text{Ni}_{80}$ cylindrical nanowires with $\text{Fe}_{80}\text{Ni}_{20}$ chemical modulations. (a) Top: chemical contrast image obtained by subtracting two shadow-PEEM XAS images taken at the Fe and Ni L_3 edges, for wire with $d = 120$ nm and $\ell = 40$ nm (black lines in the shadow). The microscope focus was set at the shadow, and the x-ray direction is almost perpendicular to the wire axis. The orange dashed lines guide the location of two chemical modulations. Bottom: XMCD corresponding to the top image, taken at the Fe L_3 edge. The straight blue arrow indicates the magnetization direction. (b) Reconstructed amplitude ptychographic XAS (top) and XMCD (bottom) of a wire with $d = 160$ nm and $\ell = 150$ nm.

other imaging techniques that are directly sensitive to the magnetization.

B. Experimental evidence of curling

Imaging techniques based on x-ray magnetic dichroism are complementary to electron holography. Indeed, the latter is sensitive to the two components of magnetic induction perpendicular to the beam, while the former directly probes the magnetization component along the beam. Therefore the combination of both provides a pretty good view of the three-dimensional distribution of magnetization.

Figure 2(a) shows a shadow PEEM image of a nanowire with $d = 120$ nm and $\ell = 40$ nm. This specific wire is incidentally lying on top of two other wires, making its shadow fully visible. Shadows are stretched by about a factor of 3.5 along the beam direction due to the near grazing x-ray incidence (angle of 16°). The sample was rotated to have the nanowire almost perpendicular to the x-ray beam.

The top image in Fig. 2(a) is the subtraction of two x-ray absorption spectroscopy (XAS) images at the Fe and Ni L_3 edges, highlighting the changes in chemical composition. The Fe-rich chemical modulations appear bright (more electrons emitted) and dark (fewer photons transmitted) on the wire and the shadow, respectively. The bottom image is the corresponding XMCD image. The lack of magnetic contrast in the permalloy segments reveals that the magnetization lies along the wire axis, consistent with the electron holography results [Fig. 1(c)]. However, magnetic contrast is observed at the modulations, mostly in the shadow as surface oxidation masks magnetic contrast at the wire surface. The bipolar dark and bright contrast at the modulations reflects components of magnetization parallel and antiparallel to the x-ray beam on opposite sides of the wire. Such features are often called curling [69] in micromagnetism. The curved blue arrows in Fig. 2(a) show that the sign of curling, which we will call circulation, can be either positive or negative in the same wire. The distribution of magnetization in the chemical modulations

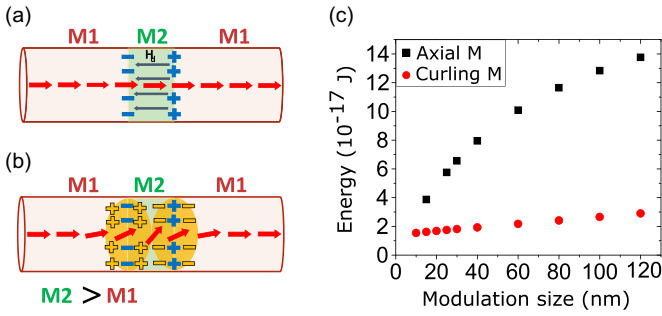

FIG. 3. Scheme of the magnetic charge distribution at a chemical modulation for (a) axial and (b) curling magnetization states, for $M_2 > M_1$. The volume charges are shown in yellow, while the surface ones are shown in blue. (c) Total magnetic energy of the axial and curling magnetization states, vs the modulation length for a diameter of 130 nm.

observed with higher spatial resolution by XMCD ptychography is shown in Fig. 2(b). Note that in this case the aspect ratio along the transmitted x-ray beam is equal to 1. We imaged nanowires with $d = 70\text{--}160$ nm and $\ell = 20\text{--}150$ nm and evidenced curling in all of them. It should be noted that curling magnetization at the chemical modulations cannot be viewed as a 360° domain wall since the integration of change of magnetization angle along the axial direction is zero instead of 2π , which is the expected value for a 360° domain wall.

C. Analytics to explain the physics of curling

Curling around the axis is a well-known feature of wires: For d above typically seven times the dipolar exchange length, a mostly uniformly magnetized wire ends up with such a curling feature at each end [11,14,70,71]. Similar to the curling reversal mode from which the name was first coined [69], this results from the driving force of surface charges, which appear at each end of the wire with areal density M_s in the case of uniform axial magnetization. For the following discussion, it is important to realize that curling does not remove magnetic charges from the system, whose integrated value is fixed by topology. Instead, curling converts part of the surface charges into volume charges $-\text{div}\mathbf{M}$. These are on average farther apart from each other than surface charges, thereby lowering the total magnetostatic energy of the system. In practice, the amount of curling is determined by the balance of gain in magnetostatic energy versus the cost in exchange energy. Another analogous situation is that of the vortex state in disks and short cylinders.

A chemical modulation with high magnetization can be described in similar terms. The mismatch of spontaneous magnetization across the interfaces gives rise to surface charges of areal density $\sigma = \pm(M_2 - M_1)$ at the interfaces [Fig. 3(a)]. As a result, magnetization tends to curl at the modulation, thus reducing longitudinal magnetization, its interfacial mismatch, and the associated dipolar energy. The volume density of charge ρ resulting from the gradient of longitudinal magnetization has a sign opposite to that of the nearby interfacial charges [Fig. 3(b)], which can be understood as a screening effect. The initially dipolar nature of magnetostatics at the modulation tends to be replaced by an

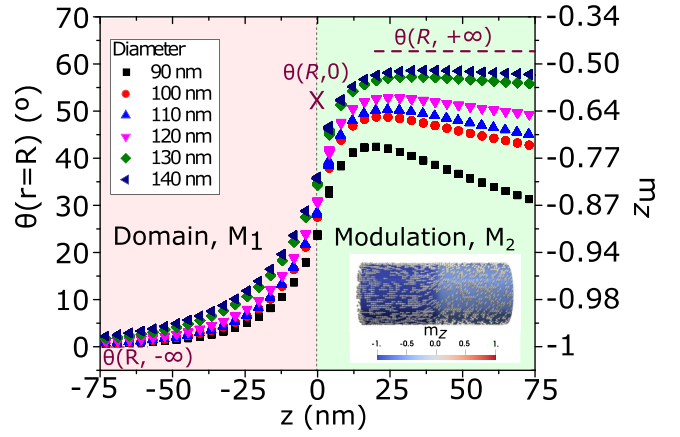

FIG. 4. Curling angle at the surface of the nanowire $\theta(R, z)$ obtained by micromagnetic simulations for various wire diameters. The prediction by the analytical model for curling at the interface and inside the modulation far from the interface are highlighted by a cross and a horizontal dashed line, respectively. The considered system is a permalloy segment for $z < 0$ and a $\text{Fe}_{80}\text{Ni}_{20}$ chemical modulation for $z > 0$. Inset: magnetization state at the wire surface.

octopole, largely decreasing the extent of the resulting magnetostatic field and thus its energy. It is important to remark that this occurs when the chemical modulation has a higher magnetization than the rest of the nanowire ($M_2 > M_1$). For the opposite case, no screening mechanism may occur since surface and volume charges have the same sign (for more details, see Supplemental Material).

We propose several assumptions in order to model the physics of charge screening analytically in a simple manner and predict general features. In a first stage we consider just one interface, which would stand for a very long modulation: the domain material for $z < 0$ and modulation material for $z > 0$. Second, we consider a system with large diameter ($d \gg \Delta_d$), which allows us to neglect the radial and azimuthal contributions to exchange. The corollary of the second hypothesis is that the dominating contribution to the energy of the system is magnetostatics, so that as a third hypothesis we assume complete screening, i.e., exact compensation of the total amount of surface charge with volume charges of opposite sign. This is expected to bring the magnetostatic energy to a minimum. Fourth, we neglect any radial magnetization component.

We define the curling angle θ as the angle of magnetization away from the axial direction and towards the azimuthal direction [inset of Fig. 5(a)]. As magnetization must remain longitudinal on the axis, the curling angle must be dependent on the distance to the axis. We use an ansatz to describe the variation of the curling angle θ along r :

$$\theta(r, z) = \theta(R, z) \sin\left(\frac{\pi r}{2R}\right), \quad (1)$$

where R is the wire radius, r is the distance to the axis, and z is the coordinate along the wire axis. This ansatz accurately describes the spatial variation of θ along r [67,72], minimizing the (residual) exchange energy. The magnetization state of the system is then fully determined by the function $\theta(R, z)$, with $\theta(R, -\infty) = 0$ in the axially magnetized domain. In this

FIG. 5. Micromagnetic simulations of permalloy nanowires with a $\text{Fe}_{80}\text{Ni}_{20}$ chemical modulation, at rest. (a) Outer view and (b) cross-section view at the center of the modulation, for $d = 90$ nm and $\ell = 60$ nm. (c) Line profiles of unitless longitudinal magnetization m_z along the z direction at the surface of the wire with chemical modulation lengths $\ell = 10$ – 120 nm for $d = 90$ nm (left) and $d = 130$ nm (right). The gray dashed line marks the start of the chemical modulation.

simplified example, $\theta(R, +\infty)$ stands for the final curling angle at the surface at a distance z sufficiently far from the interface.

The Appendix provides the details of the model. In short, we use the following procedure: (i) We set $\theta(R, 0)$ to a given value, not known at this stage. From this we compute the total surface charge at the interface and the integrated volume charges on the left-hand side of the modulation. (ii) We assume an equal share of volume charges on either side of the interface, which allows us to derive the peripheral curling angle far inside the modulation, away from the interface, $\theta(R, +\infty)$, needed to establish these volume charges. This assumption is made with the aim of maximizing the gain provided by the screening of surface charges or, in other words, to obtain the largest screening for a given number of surface charges. (iii) We impose full screening of charges in a quadrupolar fashion, i.e., the integrated interfacial and volume charges compensate. This sets the values $\theta(R, 0)$ and $\theta(R, +\infty)$ self-consistently. In the end we find

$$\theta(R, 0) \approx \sqrt{2.85 \frac{M_2 - M_1}{M_2 + M_1}}, \quad (2)$$

$$\theta(R, +\infty) \approx \sqrt{2.85 \frac{M_2 - M_1}{M_2}}. \quad (3)$$

Based on the expansion $m_z(r = R, z) = \cos \theta(R, z) \approx 1 - \theta^2(R, z)/2$, we can rewrite these two equations for the longitudinal magnetization:

$$m_z(R, 0) \approx 1 - 1.42 \frac{M_2 - M_1}{M_2 + M_1}, \quad (4)$$

$$m_z(R, +\infty) \approx 1 - 1.42 \frac{M_2 - M_1}{M_2}. \quad (5)$$

Note that the model yields the curling angle at the interface and deep inside the modulation ($z = +\infty$ in the model) but

it does not yield the full function $\theta(R, z)$. Also, the above expressions depend only on M_s , because the model disregards exchange. Before assessing the validity of the model and hence its physical basis with micromagnetic simulations, let us make a few sanity checks. (i) There is no curling without a material modulation, i.e., for $M_2 = M_1$. (ii) $M_1 = 0$ mimics the situation of the apex of a cylindrical nanowire. In this situation we get $\theta(R, 0) \approx 1.69$, which is slightly more than $\pi/2 \approx 1.57$, the expectation to cancel surface charges. This comes from the hypothesis of the global compensation of charges: As no volume charge is created close to the axis for which magnetization remains longitudinal, more charges need to be created away from the axis. We will come back to this when comparing the model with numerical micromagnetics.

Coming back to the specific case of permalloy segments with modulations of inverted composition, on the basis of our model we expect the following: $\theta(R, 0) \approx 51^\circ$ [$m_z(R, 0) \approx 0.63$] and $\theta(R, +\infty) \approx 61^\circ$ [$m_z(R, +\infty) \approx 0.45$].

D. Micromagnetic simulation of curling

The model reported in the previous paragraph intends to highlight the main physical ingredients driving curling and to allow a quick estimation of the resulting angle. Here, we report a series of micromagnetic simulations to assess the validity of the model, refine its predictions quantitatively, and address the situation of a finite-length modulation, which cannot be tackled as easily through analytic modeling.

Figure 4 shows the curling profile at the surface $\theta(R, z)$, across a single interface between two materials with semi-infinite length derived from micromagnetic simulations. This is the situation considered in the model, whose predictions are indicated with a horizontal dashed line and a cross. It is clear that the model overestimates the curling angle; yet the agreement is better for larger diameter. This is because the model disregards exchange, while the energy cost coming from radial exchange decreases for larger diameter. We expect that other effects limiting curling are the fact that screening is nonlocal, as mentioned in the previous paragraph, balancing volume versus surface, and that magnetization cannot curl close to the wire axis. Yet the very good quantitative agreement for curling inside the modulation for large diameter confirms that charge screening is indeed the key ingredient driving curling. The agreement for curling at the interface is not as good, although in both cases $\theta(R, 0) > \theta(R, +\infty)/2$. The reason is that volume charges are related to the variation of longitudinal magnetization, which does not scale linearly with the curling angle, as the right y axis in the plot reflects. Finally, note that curling tends to decrease in the modulation, when moving away from the interface. The reason is that the radial exchange cost of curling scales linearly with ℓ once the curling angle has reached a plateau, while it provides no further screening benefit. In the case of a semi-infinite medium, magnetization would progressively turn back to being fully axial for $z \rightarrow +\infty$, an effect that is not reflected by the analytical model due to the disregard of exchange. The faster decay of curling for smaller diameter is consistent with this picture.

We now turn to the case of practical interest: a material modulation with finite length. Figures 5(a) and 5(b)

illustrate the surface and cross-sectional views of a simulated micromagnetic state at rest. The graphs in Fig. 5(c) show the peripheral $m_z(R, z)$ profile and curling angle, $\theta(R, z)$, versus axial position for two wire diameters, 90 and 130 nm, each for a series of ℓ values. The gray dashed line indicates the start of the chemical modulation at $z = 0$.

For long modulations the curling angle reaches a plateau, with a value very similar to the case of a single interface (Fig. 4). Yet the curling angle tends to decrease as ℓ increases due to an increasing cost of exchange. Thus a maximum curling angle is found for a given modulation length: $\ell = 60$ nm for $d = 90$ nm, with $|m_z(R, z)| = 0.53$; and $\ell = 80$ nm for $d = 130$ nm, with $|m_z(R, z)| = 0.47$. Note that $m_z(R, z)$ curves have nearly an inversion symmetry across each interface, unlike $\theta(R, z)$ curves. Since volume magnetic charges are related to the variation of m_z , this inversion symmetry shows that screening is largely symmetric.

The curling angle plateau is not reached for modulations shorter than typically 30–40 nm. There is no energy dependence of the chirality of the system, i.e., circulation versus longitudinal magnetization, so that both circulations have the same energy, which requires a certain distance to rotate magnetization. This competition defines the dipolar exchange length Δ_d , dictating a maximum gradient of the magnetization direction. More precisely, with the definition $\Delta_d = \sqrt{2A/(\mu_0 M_s^2)}$, magnetization may rotate by 1 rad over a distance Δ_d . It can be seen in Fig. 5(c) that all $m_z(z)$ curves overlap at their rising stage in the permalloy segment, even if the plateau is not reached. From the angular gradient in Fig. 4, we derive the characteristic length scale specific to a modulation as the distance that would be required to rotate the magnetization by 1 rad, $\Delta_{\text{mod}} \approx 22$ nm, much larger than the dipolar exchange length of any of the two materials. We believe that the reason for this is twofold: First, the charges scale as $M_2 - M_1$, not with the full magnetization; second, the screening effect on both sides of the interface further decreases the effective charge and thus the magnetostatic energy, which is driven by the longitudinal variation of magnetization.

Micromagnetic simulations also allow us to derive the energy of the system for any distribution of magnetization. Figure 3(c) shows the total micromagnetic energy versus modulation length, for longitudinal uniform magnetization and for the relaxed curling state for a 130-nm-diameter wire. It is clear that curling allows a decrease in energy, which, however, has a lower limit imposed by the residual magnetostatic energy and the resulting exchange energy. The graph also illustrates how the gain is less for short modulations, consistent with the decrease in curling (Fig. 5).

E. Curling controlled by applied magnetic fields

1. Response to an axial magnetic field

We performed high-spatial-resolution magnetic imaging by XMCD-ptychography in order to experimentally confirm the predictions of the previous section. Since the magnitude of curling depends on the materials' parameters and the modulation length, which may all suffer from experimental errors, we studied both the curling angle at rest and its response to an external static magnetic field along the wire axis for a more robust comparison. We conducted experiments under a

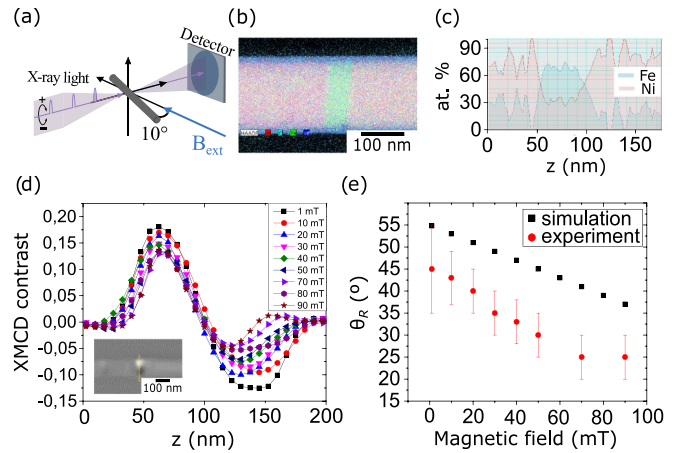

FIG. 6. Curling strength vs axial static magnetic field. (a) STXM and ptychography setup for a 10° rotation of the nanowire with respect to the incident x-ray beam. (b) and (c) EELS map across the modulation. (d) XMCD contrast line profile across the modulation for several values of applied axial magnetic field. The inset shows the XMCD-ptychography image and the line profile (yellow). The nanowire has $d = 130$ nm and $\ell = 60$ nm. (e) Curling angle resulting from the analysis of the line profiles (red) and from micromagnetic simulations (black).

magnetic field of up to 90 mT applied perpendicular to the x-ray beam and thus almost along the nanowire's axis. A small angular offset of 10° was chosen in order to have a small dichroic contribution from the axial magnetization and thus distinguish the magnetization direction in the domains [Fig. 6(a)].

The nanowire chosen for this study has $d = 130$ nm and $\ell = 60$ nm. The experimental results and their analysis are summarized in Fig. 6. In Fig. 6(d), we show the line profile of the XMCD contrast across the wire, centered on the modulation (yellow line in the inset), for several applied magnetic fields. Its noncentrosymmetric shape results from sample rotation away from the plane perpendicular to the x-ray beam. The conversion of these curves into the curling angle is performed taking into account the intrinsic features (exponential absorption along the x-ray path, three-dimensional magnetization texture) and the experimental considerations (finite size of the probe, background intensity) as explained in the Supplemental Material and in Ref. [67]. A crucial parameter of the model is the absorption coefficient of the material that depends on composition, which was independently obtained by electron-energy-loss spectroscopy (EELS) measurements [Figs. 6(b) and 6(c)] as $\text{Fe}_{65}\text{Ni}_{35}$ at the modulation on this specific nanowire. In Fig. 6(e), the evolution of $\theta(R)$ as a function of the applied magnetic field is shown for data extracted from the experiments (red symbols) and from micromagnetic simulations (black symbols). Curling decreases with applied field; however, it does not go to zero, owing to the large magnetostatic energy involved.

2. Oersted field

We have seen experimentally that curling in the modulations may be either clockwise or anticlockwise [Fig. 2(a)]. There is no energy dependence of the chirality of the system,

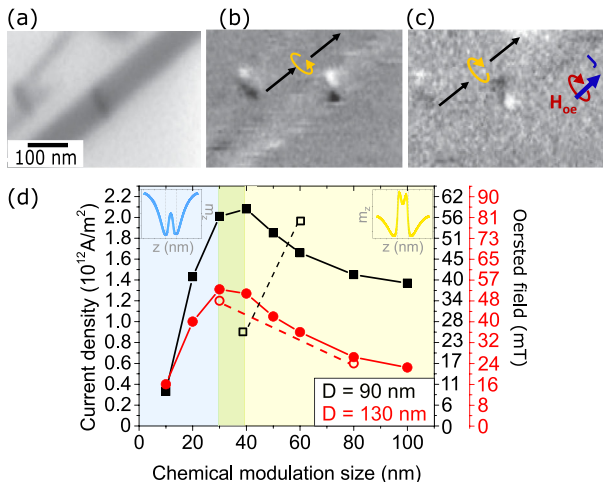

FIG. 7. Switching of the curling circulation in the modulation, driven by the Oersted field. (a) XAS Fe L_3 STXM image of a permalloy nanowire electrically contacted, with $d = 90$ nm and $\ell = 40$ nm. The nanowire at the top is not electrically contacted. (b) XMCD image of (a) in the initial state, revealing that curling in the modulation has negative circulation C^- (yellow arrow) with respect to the axial magnetization (black arrow). (c) XMCD image after the application of a current pulse with density $j = -1.6 \times 10^{12}$ A/m² and duration 5.6 ns. The circulation switched to positive C^+ circulation (yellow arrow), which fits the circulation of the Oersted field during the pulse of current (red arrow). (d) Threshold of current density to switch circulation, vs length of the chemical modulation. Simulation and experimental data are displayed with solid and open symbols, respectively, for a system with $d = 90$ nm (black) and $d = 130$ nm (red). The y axis at the right shows the corresponding Oersted field at the external surface for $d = 90$ nm (values in black) and $d = 130$ nm (values in red). The green segment separates two regimes of switching. The insets in the first and second regime (blue and yellow background) show m_z vs z at the periphery of the wire before switching the circulation.

i.e., circulation versus longitudinal magnetization, so that both circulations have the same energy. We expect that this degeneracy is lifted upon application of an electric current flowing along the wire, which gives rise to an Oersted magnetic field that couples directly with curling, either parallel or antiparallel. This situation is analogous to the case of azimuthal curling around Bloch-point domain walls in nanowires, for which the Oersted field has been proven to be crucial for the dynamic stability and switching [19,72].

We conducted experiments on electrically contacted nanowires, injecting current pulses of magnitude around 10^{12} A/m², variable sign, and duration up to a few nanoseconds. The images were taken using XMCD-STXM or TXM, under static conditions before and after application of every current pulse. We evidence the existence of a threshold for the current density, above which the sign of curling in the modulation switches deterministically, if not initially parallel to the Oersted field. The switching is illustrated in Fig. 7 for a wire with $d = 90$ nm and $\ell = 40$ nm. Figure 7(a) shows an absorption image, highlighting the position and width of the modulation. The initial state, revealed by XMCD in Fig. 7(b), has a negative circulation C^- (yellow arrow) with respect to

magnetization direction (black arrow). After the application of a current pulse with magnitude $j = -1.6 \times 10^{12}$ A/m² and duration 5.6 ns, the circulation has switched to a positive circulation state C^+ [Fig. 7(c), yellow arrow]. This is consistent with the sign of the Oersted field associated with the charge current (red arrow). We evidenced no dependence of the switching on pulse duration in the range 1–20 ns. Open black and red symbols in Fig. 7(d) show the experimental dependence of the threshold current versus modulation length ℓ for $d = 90$ nm and $d = 130$ nm, respectively. The calculation of the current density that flows through the wire was done taking into account the attenuation and losses of the electric pulse (see Supplemental Material).

We performed micromagnetic simulations to shed light on the switching mechanism. We considered only the effect of the Oersted field, disregarding spin-transfer torque (which was previously shown to be negligible [72]), as well as Joule heating, which plays a key role in magnetization dynamics for high current density values or long pulses. In our experiment we estimated a temperature rise of 100 °C for a current density of magnitude $j = 1 \times 10^{12}$ A/m², pulse duration 5 ns, and 90 nm diameter. The initial magnetization state prepared has a negative circulation with respect to the axial magnetization direction m_z , as in Fig. 5(a), antiparallel to the Oersted field that will be applied. We need a criterion to determine the minimum current density j_c required to switch the circulation. Indeed, since any computation time is finite, a long incubation time may be misinterpreted as the absence of circulation switching. A standard method in micromagnetism to address this issue is to rely on the scaling of a parameter, such as the switching time t_{sw} above the threshold, versus the driving parameter, here the current density j . The switching time was defined by the first occurrence of $\theta = 0$ at the surface of the wire, which reflects the transition towards positive circulation. We expect and indeed evidence that $1/t_{sw}$ scales nearly linearly with $|j - j_c|$ [72], from which j_c is determined.

We considered lengths ℓ ranging from 20 to 100 nm and two diameters: $d = 90$ nm and $d = 130$ nm. The results are summarized in Fig. 7(d), along with the experimental results. One can see that the switching current is higher for smaller diameter. While the micromagnetic energetics may play a role, the dominant effect is probably the magnitude of the Oersted field. Indeed, it rises linearly with radius for a given density of current, thus promoting switching. In addition, the variation with modulation length is nonmonotonous, displaying a maximum of switching current around $\ell = 40$ nm for $d = 90$ nm and around $\ell = 30$ nm for $d = 130$ nm. This hints at the existence of two distinct switching regimes, which we understand as follows. For short modulations, the curling angle (Fig. 5) as well as the energy barrier [Fig. 3(c)] decrease, so that switching is easier. For long modulations, the curling angle presents a minimum at the center of the modulation, which we understand as follows: While curling at the interfaces is driven by significant magnetostatic energy and the tendency for charge screening, curling at the center is imposed only through exchange with the two interfacial regions, which decays with modulation length once the plateau is reached. Thus the central region is expected to be a weak locus for nucleation. Examination of snapshots of the magnetization distribution during the switching process confirms that it occurs largely as

a coherent process in cylindrical coordinates for short modulations, in terms of $\theta(r, t)$, while for long modulations the switching process is not coherent but rather with a profile $\theta(r, z, t)$ that indicates nucleation at the center of the modulation. Insets in Fig. 7(d) show m_z profiles at the periphery of the wire before the circulation reversal. In the short-modulation regime (blue background), m_z decreases more rapidly at the edges of the modulation than at the center (gray dashed lines in the inset), whereas in the long-modulation regime (yellow background) this occurs at the center of the modulation. The high value of m_z out of the modulation reflects the tilt of the permalloy domains due to the Oersted field (for more details, see Supplemental Material). We pointed out in the micromagnetics of the modulation at rest that the characteristic length scale here is $\Delta_{\text{mod}} \approx 22$ nm, in the case of $\text{Fe}_{80}\text{Ni}_{20}$ modulations within $\text{Fe}_{20}\text{Ni}_{80}$ segments. This means that the magnetization may rotate by 180° over a distance $\approx \pi \Delta_{\text{mod}}$. As the plateau for curling reaches $60^\circ = \pi/3$ rad, so that the total rotation is twice this value, we expect that the length required is $(2 * \pi/3) \Delta_{\text{mod}} \approx 46$ nm. This is consistent with the modulation width giving rise to the maximum switching current [Fig. 7(d)], which confirms the relevance of a specific length scale for modulations, Δ_{mod} .

The order of magnitude for the switching current is consistent between simulations and experiment. However, while the experimental trend for $d = 130$ nm is consistent with the above, for $d = 90$ nm it is found to be the opposite. The reasons for this can be severalfold. First, in the simulations we did not consider a distinct value for exchange stiffness in the modulation material, while a larger exchange is expected in practice for $\text{Fe}_{80}\text{Ni}_{20}$, which shall increase Δ_{mod} . Second, we have neglected thermal activation (expected to have more impact for shorter modulations and smaller diameters) as well as heating during the current pulse. Third, the modulation length and the materials' composition suffer from experimental uncertainties.

IV. CONCLUSION

Combining experiments, analytical modeling, and micromagnetic simulations, we provide a rather consistent qualitative and quantitative view of the micromagnetics of high-magnetization longitudinal material modulations in cylindrical nanowires. Their key feature is the spontaneous occurrence of curling around the axis, driven by the need to create volume magnetic charges and screen the interfacial charges between different materials. This replaces a net charge by a quadrupolar distribution for an interface, and the dipole of the total modulation by an octopole, thereby sharply decreasing the magnetostatic energy of the system. An analogy can be drawn with vortex states in disks and short cylinders, sharing the same feature of magnetization distribution, however, with different quantitative energetics. We evidence a specific length scale, Δ_{mod} , a few times larger than the dipolar exchange length of any of the two materials and expected to scale with $\sqrt{2A/\mu_0(M_2 - M_1)^2}$. For modulations shorter than typically $2\Delta_{\text{mod}}$ the charge screening is partial, and switching of the curling sign with an Oersted field occurs in a coherent fashion. For modulations longer than this, the charge screening is nearly complete, the curling reaches an angle that can

be predicted analytically, and switching of the curling sign with an Oersted field occurs incoherently, nucleating from the center of the modulation and expanding towards its interfaces. The switching current reaches its maximum at the crossover between the two regimes. We believe that this knowledge of the micromagnetics at modulations is important in order to understand more complex situations, such as their interaction with magnetic domain walls.

Associated data are also available [73].

APPENDIX

Here, we detail intermediate steps supporting the analytical model, whose main features are described in Sec. III C.

Throughout the derivation of the analytical model, we make use of the following integrations:

$$\int r \sin^2\left(\frac{\pi r}{2R}\right) dr = \frac{r^2}{4} - \frac{Rr}{2\pi} \sin\left(\frac{\pi r}{R}\right) - \frac{R^2}{2\pi^2} \cos\left(\frac{\pi r}{R}\right), \quad (\text{A1})$$

$$\int r \cos\theta(r, z) dr = \frac{r^2}{2} - \frac{\theta^2(R, z)}{2} \left[\frac{r^2}{4} - \frac{Rr}{2\pi} \sin\left(\frac{\pi r}{R}\right) - \frac{R^2}{2\pi^2} \cos\left(\frac{\pi r}{R}\right) \right], \quad (\text{A2})$$

$$\langle m_z(r, z) \rangle_r \approx 1 - \theta^2(R, z) \left(\frac{1}{4} + \frac{1}{\pi^2} \right), \quad (\text{A3})$$

$$\langle m_z^2(r, z) \rangle_r \approx 1 - \frac{\theta^2(R, z)}{2} \left(1 + \frac{4}{\pi^2} \right). \quad (\text{A4})$$

The latter two equations relate to the radial areal average and make use of the expansion of $\cos\theta$ to second order, i.e., up to θ^2 .

The distribution of magnetic charges at the interface between the two materials reads

$$\sigma(r) = (M_2 - M_1) \cos\theta(r, 0). \quad (\text{A5})$$

Upon integration on the full disk cross section, we find the resulting total charge, expanding the cosine up to second order:

$$\Sigma = -\pi R^2 (M_2 - M_1) \left[1 - \theta^2(R, z) \left(\frac{1}{4} + \frac{1}{\pi^2} \right) \right]. \quad (\text{A6})$$

The distribution of volume magnetic charges reads

$$\rho = -\frac{\partial M_z(z)}{\partial z} = -M_{1,2} \frac{\partial[\cos\theta(r, z)]}{\partial z}. \quad (\text{A7})$$

Upon integration along both the radius r and the longitudinal coordinate z , we derive the total volume charge:

$$P = \pi R^2 \left(\frac{1}{4} + \frac{1}{\pi^2} \right) \times \{M_1 \theta^2(R, 0) + M_2 [\theta^2(R, +\infty) - \theta^2(R, 0)]\}. \quad (\text{A8})$$

In the above, the first term in brackets on the right-hand side stands for volume charges in material 1, while the second term stands for charges in material 2. We now make the assumption that volume charges are equally shared on either side of the interface, to achieve a quadrupolar distribution and minimize the energy of the system. This sets the condition

$$\theta^2(R, 0) = \frac{M_2}{M_1 + M_2} \theta^2(R, +\infty) \quad (\text{A9})$$

and allows us to simplify the expression for the total volume charges:

$$P = \pi R^2 \left(\frac{1}{4} + \frac{1}{\pi^2} \right) \times \frac{2M_1 M_2}{M_1 + M_2} \theta^2(R, +\infty) \\ = \pi R^2 \left(\frac{1}{4} + \frac{1}{\pi^2} \right) \times 2M_1 \theta^2(R, 0). \quad (\text{A10})$$

We now set equal the total interface and volume charges in terms of absolute value [Eqs. (A6) and (A10)], assuming full screening. This leads to the following expressions:

$$\theta^2(R, +\infty) = \frac{M_2 - M_1}{M_2} \frac{1}{\frac{1}{4} + \frac{1}{\pi^2}}, \quad (\text{A11})$$

$$\theta^2(R, 0) = \frac{M_2 - M_1}{M_2 + M_1} \frac{1}{\frac{1}{4} + \frac{1}{\pi^2}}. \quad (\text{A12})$$

Equations (2) and (3) directly derive from the above, with a numerical approximation for $1/(1/4 + 1/\pi^2)$.
