The mixed-valent iridate $\text{Ba}_3\text{InIr}_2\text{O}_9$ has been discussed as a promising candidate for quantum spin-liquid behavior. The compound exhibits $\text{Ir}^{4.5+}$ ions in face-sharing IrO_6 octahedra forming Ir_2O_9 dimers with three t_{2g} holes per dimer. Our results establish $\text{Ba}_3\text{InIr}_2\text{O}_9$ as a cluster Mott insulator. Strong intradimer hopping delocalizes the three t_{2g} holes in quasimolecular dimer states while interdimer charge fluctuations are suppressed by Coulomb repulsion. The magnetism of $\text{Ba}_3\text{InIr}_2\text{O}_9$ emerges from spin-orbit entangled quasimolecular moments with yet unexplored interactions, opening up a new route to unconventional magnetic properties of $5d$ compounds. Using single-crystal x-ray diffraction we find the monoclinic space group $C2/c$ already at room temperature. Dielectric spectroscopy shows insulating behavior. Resonant inelastic x-ray scattering reveals a rich excitation spectrum below 1.5 eV with a sinusoidal dynamical structure factor that unambiguously demonstrates the quasimolecular character of the electronic states. Below 0.3 eV, we observe a series of excitations. According to exact diagonalization calculations, such low-energy excitations reflect the proximity of $\text{Ba}_3\text{InIr}_2\text{O}_9$ to a hopping-induced phase transition based on the condensation of a quasimolecular spin-orbit exciton. The dimer ground state roughly hosts two holes in a bonding $j = \frac{1}{2}$ orbital and the third hole in a bonding $j = \frac{3}{2}$ orbital.

I. INTRODUCTION

The spin-orbit-assisted Mott-insulating character of iridates provides a very active playground for quantum magnetism [1–12]. For $5d^5$ and $5d^4$ configurations, spin-orbit coupling $\lambda = \zeta/2S$ lifts the degeneracy of the t_{2g} orbitals and yields electronic bands which in many compounds are sufficiently narrow for a moderate on-site Coulomb interaction U to result in Mott insulators with local $j = \frac{1}{2}$ and $j = 0$ moments, respectively. Particular attention has been paid to $j = \frac{1}{2}$ moments in compounds with corner-sharing or edge-sharing IrO_6 octahedra, such as Sr_2IrO_4 or Na_2IrO_3 with dominant isotropic Heisenberg exchange or bond-directional Kitaev exchange couplings, respectively [13]. The experimental realization of Kitaev couplings has triggered an intense quest for novel quantum spin-liquid states in so-called Kitaev materials [4,8,9,12,14–16].

The rich physics encountered in the iridates is based on the subtle balance of U , ζ , and hopping t . Compared to corner-

edge-sharing IrO_6 octahedra, the less intensively studied case of *face-sharing* octahedra features enhanced hopping [17], opening access to unexplored regions in U - ζ - t space. We focus on the structural motif of two face-sharing octahedra that form Ir_2O_9 units or dimers, as realized in the $\text{Ba}_3X\text{Ir}_2\text{O}_9$ family with the layered (6H)- BaTiO_3 structure formed for a wide variety of mono-, di-, tri-, or tetravalent X ions [11,18–29]; see Fig. 1. Within the layers, the Ir_2O_9 units are arranged on a triangular lattice. In total there are 12 neighbors in three dimensions, analogous to a *hcp* lattice of Ir_2O_9 units. In $\text{Ba}_3\text{InIr}_2\text{O}_9$ with $\text{Ir}^{4.5+}$ ions and three holes per dimer, no long-range magnetic order is observed but persistent spin dynamics were reported down to 20 mK using thermodynamic measurements, nuclear magnetic resonance, and muon spin resonance [25]. This promisingly points toward a possible gapless spin-liquid ground state.

An essential step for the understanding of the magnetism of $\text{Ba}_3X\text{Ir}_2\text{O}_9$ is the determination of the character of the magnetic moments. To this end, one has to resolve the

FIG. 1. Left: Sketch of the crystal structure of $\text{Ba}_3\text{InIr}_2\text{O}_9$ with triangular layers of well-separated Ir_2O_9 units. Bold blue lines connect Ir ions within a dimer. Olive/gray/red: Ba/In/O. Right: Permittivity ϵ' (black) and dielectric loss ϵ'' (red) at 20 K in the microwave range. The small ϵ'' demonstrates the insulating character of $\text{Ba}_3\text{InIr}_2\text{O}_9$.

electronic structure of the Ir_2O_9 units. In the limit of dominant U , one expects spin-orbit entangled moments localized on each Ir site with strong exchange interactions [30]. For mixed-valent compounds such as $\text{Ba}_3\text{InIr}_2\text{O}_9$, this limit may, e.g., feature charge ordering of $5d^5 \text{Ir}^{4+}$ and $5d^4 \text{Ir}^{5+}$ sites with $j = \frac{1}{2}$ and $j = 0$ moments coexisting on a dimer. However, depending on the choice of X ions the Ir_2O_9 units exhibit a very short Ir-Ir distance of 2.5–2.6 Å [18,25], shorter than the value realized in Ir metal, 2.7 Å. This suggests an alternative scenario in which the large intradimer Ir-Ir hopping yields quasimolecular orbitals with possibly quenched orbital moments [31], as proposed for Na_2IrO_3 [32,33]. For iridate dimers, the formation of quasimolecular orbitals was claimed in $\text{Ba}_5\text{AlIr}_2\text{O}_{11}$, $\text{Ba}_3\text{BiIr}_2\text{O}_9$, and $\text{Ba}_3\text{CeIr}_2\text{O}_9$ [34–37]. For the latter compound, it has been shown that resonant inelastic x-ray scattering (RIXS) measurements of the dynamical structure factor are particularly well suited to nail down a quasimolecular orbital character of the electronic states as well as to unravel the role of spin-orbit coupling [37]. In $\text{Ba}_3\text{CeIr}_2\text{O}_9$ with two holes per dimer, the comparison of RIXS and theory established that the quasimolecular states are predominantly built from spin-orbit entangled $j = \frac{1}{2}$ states, giving rise to a pseudospin $j_{\text{dim}} = 0$ character as opposed to a spin-singlet dimer [37]. The compound $\text{Ba}_3\text{InIr}_2\text{O}_9$ with three holes per dimer has been discussed as being close to a phase transition [38] between a $j_{\text{dim}} = \frac{1}{2}$ state with dominant spin-orbit coupling and a $j_{\text{dim}} = \frac{3}{2}$ state for larger hopping; see Fig. 2. This phase transition is related to van Vleck-type excitonic magnetism [39], also known as singlet magnetism [40], in nominally nonmagnetic $d^4 j = 0$ compounds in which magnetic moments arise from the hopping- or exchange-induced condensation of excited states. Similarly, the condensation of spin-orbit excitons has been discussed in one-dimensional t_{2g} systems [41]. The quasimolecular dimer orbitals provide a different flavor of this mechanism. Condensation of the $j_{\text{dim}} = \frac{3}{2}$ excitation occurs on the dimer level based on strong intradimer hopping, while exchange between

FIG. 2. Quasimolecular orbitals based on local single-hole states with $j = \frac{1}{2}$ and $\frac{3}{2}$. In the hole picture, bonding (antibonding) orbitals are depicted in red (blue). In this j basis, hopping is block-diagonal for $t_{e_g^\pi} = -t_{a_{1g}}$ (see main text). For three holes, increasing hopping yields a phase transition from $j_{\text{dim}} = \frac{1}{2}$ (left) to $j_{\text{dim}} = \frac{3}{2}$ (right) [38]. In the latter state, all three holes occupy bonding orbitals. In $\text{Ba}_3\text{InIr}_2\text{O}_9$, the hopping parameters deviate from the idealized case $t_{e_g^\pi} = -t_{a_{1g}}$ depicted here, but this sketch still provides a good starting point for an intuitive understanding of the electronic structure.

the dimer moments is related to interdimer hopping with a smaller energy scale.

Here, we study the crystal structure and the electronic structure of $\text{Ba}_3\text{InIr}_2\text{O}_9$, which represents a model system for Ir dimers with unpaired electrons. We find a rich RIXS spectrum of intra- t_{2g} excitations and demonstrate their quasimolecular nature by the observation of a sinusoidal RIXS interference pattern, i.e., the dynamical structure factor of a dimer, similar to the two-hole case of $\text{Ba}_3\text{CeIr}_2\text{O}_9$ [37]. A comparison of RIXS spectra with exact diagonalization calculations establishes a $j_{\text{dim}} = \frac{3}{2}$ nature of the ground state, while the observation of RIXS features below about 0.3 eV supports that $\text{Ba}_3\text{InIr}_2\text{O}_9$ is close to the phase transition to a $j_{\text{dim}} = \frac{1}{2}$ state.

The existence of quasimolecular magnetic moments in dimers with an odd number of charge carriers clearly establishes that $\text{Ba}_3\text{InIr}_2\text{O}_9$ belongs to the class of cluster Mott insulators [42–44]. Due to strong intradimer Ir-Ir hopping, charge carriers are delocalized inside the dimer-type cluster in quasimolecular orbitals. The Mott gap in this case refers to *inter*dimer charge excitations which are suppressed by Coulomb repulsion. In comparison, the two holes per dimer in the sister compound $\text{Ba}_3\text{CeIr}_2\text{O}_9$ fully occupy the lowest-lying molecular orbital, leading to a nonmagnetic ground state. Cluster Mott insulators offer a new route to tailor spin-orbit entangled quasimolecular magnetic moments. In this spirit, our RIXS results reveal the local quasimolecular orbital structure of the spin-liquid candidate material $\text{Ba}_3\text{InIr}_2\text{O}_9$, providing an essential step toward a thorough understanding of its magnetic properties.

II. EXPERIMENTAL

Single crystals of $\text{Ba}_3\text{InIr}_2\text{O}_9$ were grown at 1200 °C in air using a BaCl_2 flux, as described in Ref. [38]. We first synthesized polycrystalline material using stoichiometric amounts of In_2O_3 , BaCO_3 , and Ir powder [25]. This polycrystalline material was used to grow the single crystals. Single-crystal x-ray diffraction measurements were carried out using a Bruker AXS Kappa APEX II four-circle diffractometer that operates with a wavelength of 0.7 Å (Mo K_α radiation). The studied

crystal was shaped like a hexagonal prism and a numerical absorption correction is based on a model with eight faces at distances from the center of about $100 \mu\text{m}$.

RIXS measurements were performed at beamline ID20 at the ESRF [45]. The crystal studied in RIXS had the shape of a hexagonal prism with a size of about 0.3 mm and a thickness of roughly 0.05 mm . The RIXS intensity of intra- t_{2g} excitations was resonantly maximized by choosing an incident energy of 11.215 keV at the Ir L_3 edge. Data were collected at 10 K . At low temperature, a monoclinic distortion with a monoclinic angle $\beta = 90.854(3)^\circ$ was reported based on powder neutron diffraction data [25]. Orienting the sample on the RIXS spectrometer with a spot size of the incident beam of about $(20 \times 10) \mu\text{m}^2$, we found that the measurement averages over different monoclinic domains. With $\sin \beta \approx 0.9999$, we neglect the small distortion for the sake of simplicity and assume hexagonal $P6_3/mmc$ symmetry for the RIXS measurements. We studied the (001) surface in horizontal scattering geometry with the c axis in the scattering plane and the a axis along the vertical direction. The incident photons were π polarized. Combining a Si(844) backscattering monochromator and $R = 2 \text{ m}$ Si(844) spherical diced crystal analyzers, an overall energy resolution of 25 meV was achieved [46]. Replacing the Si(844) backscattering monochromator with a Si(311) channel cut yields a lower resolution of 0.36 eV but a larger signal-to-noise ratio. RIXS spectra were measured with the high-resolution setup by scanning the energy loss at constant transferred momentum \mathbf{q} . The spectra were normalized by the incident flux and the acquisition time. Additionally, we collected \mathbf{q} scans at constant energy loss, both with the low- and the high-resolution setup. For comparison, we measured RIXS on $\text{Ba}_3\text{CeIr}_2\text{O}_9$ using the same setup and the same sample orientation as for $\text{Ba}_3\text{InIr}_2\text{O}_9$, as described previously [37].

III. RESULTS

A. Insulating behavior

We probe the conductivity of $\text{Ba}_3\text{InIr}_2\text{O}_9$ by dielectric spectroscopy in the microwave range. A 4-point measurement of the dc resistivity was unfeasible since the size of our single crystals does not exceed 0.3 mm . We employ a 2-point approach in which case extrinsic contact effects have to be considered. These can be reduced by measuring at frequencies that are high enough to short out the contacts. The crystal was contacted in capacitor geometry on a microstrip waveguide with the electric field parallel to the c axis. Using a vector network analyzer (Rhode & Schwarz ZNB8) in the frequency range from 300 kHz to 30 MHz , the permittivity of $\text{Ba}_3\text{InIr}_2\text{O}_9$ was measured at 20 K ; see Fig. 1. A significant uncertainty in the absolute values is caused by the high relative error in the determination of the small effective area $A_s = 0.02 \text{ mm}^2$ and thickness $d_s = 0.04 \text{ mm}$. However, the experimental result corresponds to a real part of the conductivity $\sigma \approx 10^{-6} / \Omega \text{ cm}$, which firmly establishes the insulating character of $\text{Ba}_3\text{InIr}_2\text{O}_9$. Independent of the exact absolute values, this result is supported by the observation that the dielectric loss ϵ'' is much smaller than the permittivity ϵ' , as expected for an insulator.

B. Single-crystal structure refinement

In single-crystal x-ray diffraction at 295 K , we collected the intensities of 69971 Bragg reflections, yielding 877 independent reflections with respect to the hexagonal space group $P6_3/mmc$. The integration yields an internal R value [47] of $R^2(\text{int}) = 6.53\%$ after absorption correction. Using the software JANA [48], three refinements were carried out in space group $P6_3/mmc$. One assumes the ordered structure, with In (Ir) atoms located on the Wyckoff sites $2a$ ($4f$). The second refinement considers a statistical distribution of In and Ir atoms, with the $2a$ and $4f$ sites both occupied by $1/3$ In and $2/3$ Ir. The third refinement assumes partial disorder, allowing free occupations of these sites with the constraint that each site is fully occupied. We employ isotropic atomic displacement parameters for all atoms and Gaussian isotropic Becker-Coppens extinction correction [49]. For the refinements with In and Ir sharing a site, these atoms are constrained to have the same atomic displacement parameters.

The best result was obtained for the partially ordered model. It yields $R(\text{obs}) = 5.96\%$, $wR(\text{obs}) = 8.41\%$, $R(\text{all}) = 5.96\%$, and $wR(\text{all}) = 8.41\%$. We find that the $2a$ site is occupied by $98.5(1.1)\%$ In atoms and $1.5(1.1)\%$ Ir atoms, while the $4f$ sites are occupied by $92.7(1.4)\%$ Ir atoms and $7.3(1.4)\%$ In atoms. For comparison, the fully disordered model can be ruled out, $wR(\text{all}) = 19.56\%$, while the ordered model yields $wR(\text{all}) = 9.14\%$. In total, the single-crystal data point toward a small surplus of In ions with about 7% of In ions on the Ir $4f$ dimer sites while the In $2a$ sites are almost completely occupied by In. This has to be compared with the powder data which indicate In-Ir disorder of about $2.8(5)\%$ [25] in a refinement with fixed In to Ir total occupation ratio.

We have searched for a breaking of the translational symmetry by analyzing half-integer indexed Bragg reflections with respect to the hexagonal lattice. In standard operation of the x-ray generator with 50 kV voltage many of these reflections were observed with statistically significant intensities. At 30 kV , which is below the voltage required to generate photons with half wavelength, 0.35 \AA , these signals are suppressed although we significantly enhanced the counting time to 2000 seconds/degree. All half-indexed reflections can thus be attributed to $\lambda/2$ contamination that possesses a greater impact in x-ray diffraction experiments on highly absorbing materials like iridates. The comparison of all observed half-indexed reflections with their doubled integer-indexed partners further corroborates this conclusion.

The space group $P6_3/mmc$ exhibits the selection rule $hh2hl : l = 2n$ caused by the c glide plane. At room temperature, we observed several such forbidden reflections for which a $\lambda/2$ contamination was excluded by scanning with reduced generator voltage. Typical reflections are $(6 \bar{3} \bar{3})$, $(\bar{3} \bar{3} \bar{3})$, or $(\bar{6} 3 1)$. The breaking of hexagonal symmetry can be described in the monoclinic space group $C2/c$ that was proposed for other members of the $\text{Ba}_3\text{XM}_2\text{O}_9$ family [18,19]. The overall structure in this family corresponds to the $6H$ - BaTiO_3 phase, which can be considered as a mixing of cubic and hexagonal perovskite arrangements. The XO_6 octahedra form a single layer and share a corner with neighboring MO_6 octahedra as in the cubic perovskite; see Fig. 1. In contrast, the M sites in the double-octahedron dimer layer share faces as in hexagonal perovskites. In the high-symmetry arrangement in space

TABLE I. Results of the refinements of the crystal structure in $\text{Ba}_3\text{InIr}_2\text{O}_9$ in monoclinic space group $C2/c$ with room-temperature x-ray single-crystal diffraction data. The lattice parameters are $a = 5.829(3)$ Å, $b = 10.096(5)$ Å, and $c = 14.487(7)$ Å for $\beta = 90^\circ$ (see main text). The parameters U_{iso} are given in 10^{-4} Å². Errors are given in parentheses for the last digits; if no errors are given, parameters are fixed by symmetry or were constrained.

group $P6_3/mmc$ all oxygen ions in a plane between two metal planes are on the same height and there are only two distinct O positions (one on the common face of the double octahedra, one in between X and M ions). Since the arrangement around the X sites resembles the cubic perovskites it is not surprising to find the main structural instability of these materials, i.e., the rotation of the $X\text{O}_6$ octahedra. This already has been proposed for several $\text{Ba}_3XM_2\text{O}_9$ compounds [18,19] including $\text{Ba}_3\text{InIr}_2\text{O}_9$ at low temperature [25]. The observation of the corresponding superstructure reflection however shows that the distortion is already present at room temperature in our single crystal.

We have refined the crystal structure in space group $C2/c$ by taking the twinning into account; see Table I. The symmetry reduction from hexagonal to monoclinic symmetry results in six different twin orientations, whose contributions need to be summed up in the analysis. The refinement indicates a nearly equal distribution of these twins which results in correlations of the parameters describing the distortion. Furthermore the lattice constants determined on the single crystal cannot show the monoclinic distortion due to the twinning, so that we fix $\beta = 90^\circ$. The number of positional parameters is considerably enhanced from 7 in $P6_3/mmc$ to 20 in $C2/c$. We have used the low-temperature structure [25] as starting parameters in the refinement with strong damping. We find a considerable improvement of the fit when applying the lower symmetry: wR_{all} (R_{all}) decreases from 8.41% (5.96%) to 5.01% (5.13%) and the goodness of fit parameter is reduced from 5.39 to 1.87. There is thus no doubt that the single crystal of $\text{Ba}_3\text{InIr}_2\text{O}_9$ exhibits the structural distortion as described in space group $C2/c$ already at room temperature. The main element of this distortion consists of the rotation of the InO_6 octahedron: the In-O-Ir bond angle amounts to 178.2° in the hexagonal refinement and to 171.1° , 169.8° , and 172.2° in the distorted structure. The structural phase transition involves the condensation of a Γ_6^+ phonon mode [50] associated with the rotation of the octahedra around an axis parallel to the

layers. Due to the degeneracy of this mode in the hexagonal high-temperature space group several low-temperature symmetries are possible. In $C2/c$ the octahedra rotate around a $[210]$ direction of the hexagonal lattice, which corresponds to the monoclinic b axis. There is also some distortion in the InO_6 octahedron with the O-In-O bond angle deviating by up to 5° from 90° , which is also frequently observed in cubic perovskites [51]. Furthermore, there is some buckling in the O layers arising from the octahedron rotation. However there is little impact on the bond distances. For the intradimer Ir-Ir distance we find 2.648 Å at room temperature.

C. RIXS spectra

High-resolution RIXS spectra of $\text{Ba}_3\text{InIr}_2\text{O}_9$ are shown in Fig. 3 for selected values of the transferred momentum \mathbf{q} . Note that we use reciprocal lattice units (r.l.u.) for indices (h, k, l) while reciprocal space vectors are given in absolute units. The RIXS data are analyzed in the hexagonal lattice with $P6_3/mmc$ symmetry, as discussed in Sec. II. Iridates are known to show a large cubic crystal-field splitting $10 Dq \approx 3$ eV between t_{2g} and e_g^σ orbitals due to the spatially extended character of the $5d$ states. Accordingly, the RIXS features observed below 1.5 eV can be attributed to intra- t_{2g} excitations. Excitations to e_g^σ orbitals set in at about 2.5 eV, see right panel of Fig. 3, and the increase above 4.5 eV can tentatively be identified with charge-transfer excitations between Ir and O sites. Around zero energy loss, the data are dominated by the elastic line. For π polarization of the incident photons, the elastic line can be suppressed by choosing a scattering angle of $2\theta = 90^\circ$. Figure 3 shows data for $\mathbf{q} = (0.3 \ 0 \ l)$ r.l.u. that were measured with $2\theta = 51^\circ, 65^\circ, 80^\circ$, and 97° , and the strongest elastic line is observed for $l = 11.2$ with $2\theta = 51^\circ$.

The RIXS spectrum of intra- t_{2g} excitations is very rich in $\text{Ba}_3\text{InIr}_2\text{O}_9$. Figure 3 shows the effect of changing q_c , the component of the transferred momentum parallel to the c axis, and Fig. 4 addresses a possible dispersion within the hexagonal plane, perpendicular to c , showing data for different high-symmetry points for two different values of q_c . We find that the intensity of the intra- t_{2g} excitations strongly varies with q_c , while the peak energies do not depend considerably on \mathbf{q} . For constant q_c , the data basically fall on top of each other in Fig. 4. The largest effect of \mathbf{q} on the peak energy is observed for the feature at about 0.45 eV, which sets an upper limit of 10 meV for a possible dispersion; see the inset of Fig. 4. This reflects the fact that interdimer hopping of the excited states is small. Since such interdimer hopping interactions form the microscopic basis for magnetic exchange interactions, a dispersion smaller than 10 meV suggests that also exchange interactions between dimers are small. This agrees with the small Curie-Weiss temperature $\Theta_{\text{CW}} = -6.8$ K derived from an analysis of magnetic susceptibility data and the small temperature scale of about 2 K for the occurrence of correlated spin-liquid-like behavior [25], which suggests interdimer exchange interactions of less than 1 meV.

D. RIXS interference patterns and quasimolecular orbitals

The absence of strong dispersion shows that interdimer hopping is small. In the following, we address the role of

FIG. 3. High-resolution RIXS spectra of $\text{Ba}_3\text{InIr}_2\text{O}_9$ at 10 K for $\mathbf{q} = (0.3 \ 0 \ 2.8n)$ r.l.u. with integer n and $2.8 \times 2\pi/c \approx \pi/d = Q_d$, where d denotes the intradimer Ir-Ir distance. Left: The intra- t_{2g} excitations below about 1.5 eV show a pronounced even/odd behavior with respect to n . The intensity is modulated with the period $2Q_d = 2\pi/d = 5.56(2) \times 2\pi/c$; cf. Fig. 5. We use a finite $h = 0.3$ to avoid fulfilling the Bragg condition and the concomitant enhancement of the elastic line. Right: Excitations involving e_g^σ orbitals are observed above 2.5 eV.

intradimer hopping for the electronic structure. RIXS provides an unambiguous tool to distinguish different limits. For dominant U and small intradimer hopping t , the presence of local $j = \frac{1}{2}$ or $j = 0$ moments can be detected via characteristic narrow features in the RIXS spectra [52–61]. For the opposite limit of dominant intradimer hopping, the observation of sinusoidal double-slit-type RIXS interference patterns provides a litmus test for a quasimolecular electronic structure [37]. As described in the following, the pronounced modulation of the RIXS intensity $I(q_c)$ depicted in Figs. 3, 4, and 5(a) is caused by such a double-slit-type interference and demonstrates the quasimolecular dimer character. To explain the occurrence of such interference patterns, we address the RIXS process at the Ir L_3 edge [62], in which an incident x-ray photon excites an electron out of a strongly localized $2p$ core level into an empty $5d$ level. In particular, the choice of 11.215 keV for the incident energy resonantly enhances absorption into a t_{2g} orbital in the $5d$ shell. This intermediate state decays by emitting a photon with lower energy, and the $2p$ core hole is filled by a $5d$ valence electron. The resonance enhancement particularly boosts the sensitivity to intra- t_{2g} excitations, which may show orbital or magnetic character. In other words, resonant inelastic scattering proceeds from the ground state via an intermediate state with a strongly localized $2p$ core hole to a final state with an excitation that may be delocalized, for instance a magnon. For a given excitation, the total RIXS amplitude is a coherent sum running over the scattering processes on all Ir sites over which this final excited state is delocalized [63,64]. If the excited state is a quasimolecular orbital excitation in which electrons are delocalized over two Ir sites, the interference between x-ray photons emitted from these dimer sites yields a sinusoidal interference pattern as a function of the transferred momentum \mathbf{q} , in close analogy to the case of a double-slit experiment [65]. The same applies to,

FIG. 4. RIXS spectra of $\text{Ba}_3\text{InIr}_2\text{O}_9$ at the high-symmetry points Γ , M , and K for two different values of q_c , the component of the transferred momentum parallel to the c axis. For Γ , the data were measured with a small offset in \mathbf{q} to avoid strong elastic scattering. We find a striking insensitivity to the in-plane components of the transferred momentum. Within the experimental energy resolution, the RIXS features do not show any considerable dispersion. The largest change of up to 10 meV is found for the peak at 0.45 eV (see inset). The data are dominated by the strong dependence of the intensity on q_c , very similar to the behavior shown in Fig. 3. The integer values $l = 17$ and 20 were chosen since they are close to extrema of the intensity modulation at $6Q_d$ and $7Q_d$; see Fig. 5(a). Compared to Fig. 3, the larger overall intensity stems from the difference in h ; see Fig. 5(b).

e.g., magnetic excitations if spin correlations are restricted to two adjacent sites, and the corresponding sinusoidal interference pattern was observed in RIXS on the honeycomb Kitaev materials Na_2IrO_3 and $\alpha\text{-Li}_2\text{IrO}_3$ [66].

This explains the strong dependence of the intensity on $\mathbf{q} \cdot \mathbf{d} = q_c d$, cf. Fig. 3, where $\mathbf{d} = (0, 0, d)$ is the vector connecting two Ir sites within a dimer. The sinusoidal character of the intensity modulation,

$$I(q_c) \propto \sin^2(q_c d/2) + \text{const.}, \quad (1)$$

is revealed by measurements of the RIXS intensity $I(q_c)$ for fixed energy loss; see Fig. 5(a). The observed period $2Q_d = 2\pi/d = 5.56(2) \times 2\pi/c$ yields an Ir-Ir distance $d = 2.601(9) \text{ \AA}$ at 10 K, in excellent agreement with the neutron diffraction result $2.599(4) \text{ \AA}$ at 3.4 K [25]. The sinusoidal form of the modulation and the value of the period $2Q_d$ unambiguously prove that the intra- t_{2g} excitations are delocalized over the two sites of an Ir dimer; hence the electronic structure of $\text{Ba}_3\text{InIr}_2\text{O}_9$ needs to be described in a quasimolecular picture.

The $\sin^2(q_c d/2)$ interference pattern deviates from the $\cos^2(q_c d/2)$ behavior well known from a conventional elastic double-slit experiment. For RIXS on dimers, the observation of a $\cos^2(q_c d/2)$ or $\sin^2(q_c d/2)$ interference pattern contains information on the symmetry of the investigated states [37]. This can be explained by the dipole selection rules for both photon absorption and photon emission. Consider, e.g., an even ground state. In the limit $\mathbf{q} = 0$, RIXS excitations are allowed via an odd intermediate state to an even final state. For

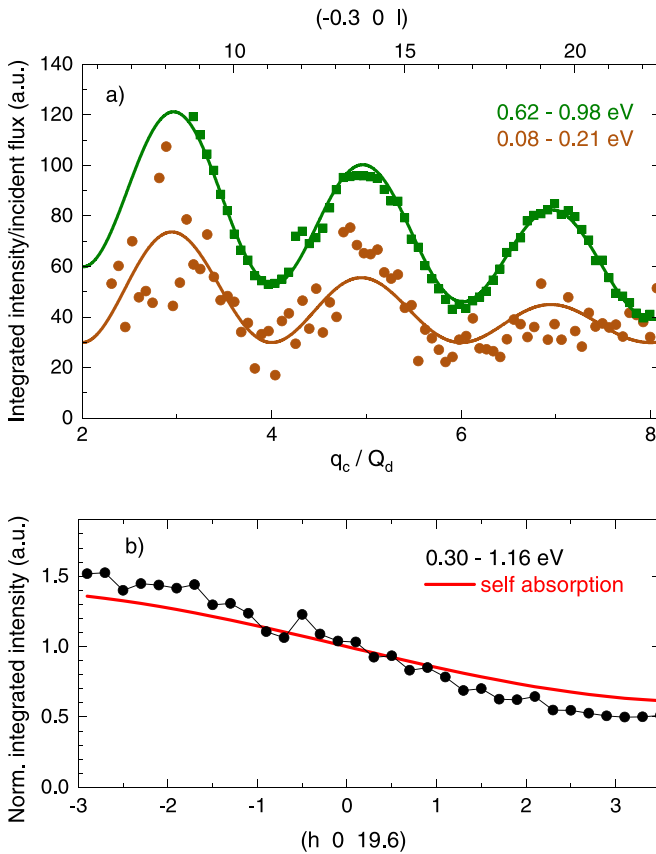

FIG. 5. RIXS intensity $I(\mathbf{q})$ of $\text{Ba}_3\text{InIr}_2\text{O}_9$ at 10 K. (a) Data for $\mathbf{q} = (-0.3 \ 0 \ l)$ r.l.u. (top axis) reveal a sinusoidal intensity modulation that unambiguously demonstrates the quasimolecular dimer character of the electronic structure. The bottom axis emphasizes the period $2Q_d = 2\pi/d = 5.56 \times 2\pi/c$ which is incommensurate with the Brillouin zone. Solid lines show damped sinusoidal fits; see Eq. (1). Green symbols: Low-resolution data, $\Delta E = 0.36$ eV, covering the range 0.62–0.98 eV. Integration time was 10 s per \mathbf{q} point. Brown symbols: Data integrated from 0.08 to 0.21 eV with the high-resolution setup, $\Delta E = 25$ meV, and 20 s integration time per \mathbf{q} point. The advantage of the low-resolution setup is the enhanced signal-to-noise ratio. Data were normalized by the incident flux. (b) As a function of h , the RIXS intensity, integrated from 0.3 to 1.16 eV, shows monotonic behavior. Data were normalized to the value at $h = 0$. The solid red line depicts the expected behavior due to self-absorption.

finite \mathbf{q} , we additionally have to consider the geometrical path difference for scattering events on the two adjacent Ir sites. Together, this yields a $\cos^2(q_c d/2) [\sin^2(q_c d/2)]$ interference pattern for even (odd) final states in the case of an even ground state.

The Ir_2O_9 dimers show mirror symmetry but no inversion symmetry, as the two face-sharing octahedra are rotated with respect to each other by π around c . Parity therefore is not a good quantum number of the eigenstates. This results in interference patterns with mixed behavior, $I(q_c) \propto u \sin^2(q_c d/2) + v \cos^2(q_c d/2)$; cf. Eq. (1). In RIXS on $\text{Ba}_3\text{InIr}_2\text{O}_9$, the $\sin^2(q_c d/2)$ behavior strongly prevails for the intra- t_{2g} excitations below about 1 eV, similar to the case of $\text{Ba}_3\text{CeIr}_2\text{O}_9$ [37]. Figure 5(a) demonstrates this dominant

$\sin^2(\pi q_c/2Q_d)$ behavior for the integrated intensity plotted as a function of q_c/Q_d , and the spectra depicted in Figs. 3 and 4 corroborate this behavior for energies below about 1.1 eV. These spectra were recorded for values of $q_c \approx nQ_d$ that correspond to extrema of the interference pattern. RIXS spectra for, e.g., odd n agree with each other over almost the entire range of energy loss. Below about 1.1 eV, the intensity is higher for odd n and the data strongly differ from the spectra for even n . Even though parity is not a good quantum number, we find that excitations from bonding to antibonding orbitals, as defined in Sec. IV, predominantly show $\sin^2(q_c d/2)$ behavior. The experimental result hence agrees with a $j_{\text{dim}} = \frac{3}{2}$ ground state as depicted in Fig. 2, where all three holes occupy bonding orbitals and most of the excitations correspond to transitions to antibonding ones. This conclusion is supported by the analysis in Sec. IV.

Wang *et al.* [34] reported on RIXS data of $\text{Ba}_5\text{AlIr}_2\text{O}_{11}$ which also shows face-sharing IrO_6 octahedra that form Ir dimers with three holes. However, these Ir dimer sites are crystallographically nonequivalent, resulting in charge disproportionation [35]. The formation of quasimolecular orbitals, predicted by Streltsov, Cao, and Khomskii [35], has been derived from the RIXS spectra by arguing that they deviate from those of local moments and by comparing with cluster calculations. Data addressing the RIXS intensity as a function of $\mathbf{q} \cdot \mathbf{d}$ were not reported. Measured with an energy resolution of 80 meV, the RIXS spectra of $\text{Ba}_5\text{AlIr}_2\text{O}_{11}$ show five broad peaks at 0.18, 0.32, 0.57, 0.74, and 1.13 eV. They resemble our results obtained at an interference minimum assuming a somewhat reduced energy scale.

E. In-plane momentum dependence

In contrast to the pronounced sinusoidal dependence of $I(q_c)$, the RIXS intensity shows a moderate, monotonic intensity change as a function of h ; see Fig. 5(b). Any change of \mathbf{q} for fixed incident energy requires to change the experimental geometry. This affects matrix elements and self-absorption effects. The latter can be described by [67] $1/(1 + \sin \theta_{\text{in}}/\sin \theta_{\text{out}})$, where θ_{in} and θ_{out} denote the angle between the sample surface and the incident and emitted beams, respectively. For grazing incidence, i.e., small θ_{in} , the incident photons are absorbed close to the surface. This facilitates the escape of the reemitted photons and results in an enhanced signal. The overall h dependence of the intensity agrees with this expectation, as depicted by the red line in Fig. 5(b).

Additional matrix-element effects are revealed by comparing spectra for different h ; see top panel of Fig. 6. For the same value of l , the intensity is larger for $h = -2.5$ than for $h = 0.3$, but this effect is most pronounced around 0.7 eV. Remarkably, a similar behavior is observed from 0.5 to 1.1 eV in the sister compound $\text{Ba}_3\text{CeIr}_2\text{O}_9$ [37] with two holes per dimer; see bottom panel of Fig. 6. In $\text{Ba}_3\text{CeIr}_2\text{O}_9$, the two prominent peaks at about 0.7 eV and 0.9 eV show $\sin^2(q_c d/2)$ behavior [37], very similar to $\text{Ba}_3\text{InIr}_2\text{O}_9$. In reasonable approximation, these two peaks of $\text{Ba}_3\text{CeIr}_2\text{O}_9$ can be described in a single-particle picture as excitations from the bonding quasimolecular orbital formed from local $j = \frac{1}{2}$ states to bonding quasimolecular orbitals built from

FIG. 6. Comparison of RIXS spectra of $\text{Ba}_3\text{InIr}_2\text{O}_9$ (top) and $\text{Ba}_3\text{CeIr}_2\text{O}_9$ (bottom). The Ce compound has two holes per dimer, i.e., no partially filled quasimolecular orbitals, and exhibits a clear onset of RIXS intensity at about 0.5 eV. The different Ir-Ir distance $d_{\text{Ce}} = c_{\text{Ce}}/5.83$ gives rise to a slightly different period $2Q_{\text{Ce}}$ of the interference pattern.

local $j = \frac{3}{2}$ states [37]. For the 0.7 eV peak in $\text{Ba}_3\text{InIr}_2\text{O}_9$, the similar energy range and the similar dependence on h suggest a related character. Our analysis supports a contribution of such states but finds also further excitations in this energy range; see Sec. IV.

F. Low-energy behavior

In $\text{Ba}_3\text{CeIr}_2\text{O}_9$, the RIXS intensity vanishes below 0.5 eV, which in a single-particle picture reflects the energy difference between filled and empty quasimolecular orbitals [37]. In contrast, $\text{Ba}_3\text{InIr}_2\text{O}_9$ exhibits finite RIXS intensity also at low energy; see Fig. 7. Previously, the existence of excitations at about 10 meV and 40 meV has been estimated from an analysis of the magnetic susceptibility [25]. To better resolve the low-energy features, we suppressed the elastic line by choosing a scattering angle $2\theta = 90^\circ$ with incident π polarization; see Fig. 7(b). Dashed lines with small symbols estimate the inelastic contribution after subtraction of the remaining elastic line. With the given energy resolution of 25 meV, the data in Fig. 7(b) show that the RIXS intensity remains finite for any energy loss below 0.3 eV. The data for $l = 17$ appear continuum-like but the result for $l = 18.5$ points toward peaks at about 0.03 eV, 0.10 eV, and 0.23 eV.

Within a dimer, low-energy excitations occur in the vicinity of the phase transition from $j_{\text{dim}} = \frac{1}{2}$ to $j_{\text{dim}} = \frac{3}{2}$; see Sec. IV. The peak energies and the RIXS resolution are much larger than the interdimer magnetic energy scale given by the peak in the specific heat at about 2 K [25]. Therefore a direct connection between the observed low-energy excitations and the magnetic fluctuations of a possible spin-liquid ground state can be ruled out. However, it is tempting to speculate that a small but finite magnetic contribution to the low-energy

FIG. 7. Low-energy RIXS spectra of $\text{Ba}_3\text{InIr}_2\text{O}_9$ at 10 K. (a) Zoom-in on two data sets shown in Fig. 3, measured with 10 meV step size for q_c values on extrema of the interference pattern; see Fig. 5. Integration time was 20 s per detector image. (b) Data collected with $2\theta = 90^\circ$ to suppress the elastic line. With the given incident energy, this fixes $|\mathbf{q}|$. With this restriction, we can reach $q_c = 18.5 \times 2\pi/c \approx 6.7Q_d$, reasonably close to the interference maximum at $7Q_d$, and $\mathbf{q} = (-2.66 \ 1/3 \ 17)$ r.l.u. with $q_c \approx 6Q_d$, an interference minimum. For a quantitative comparison, one has to take into account that the intensity at $6.7Q_d$ (dark red symbols) is roughly 10% smaller than at $7Q_d$; see Fig. 5(a). Self-absorption has been corrected. Dashed lines with small symbols show an estimate of the inelastic contribution obtained by subtracting the already suppressed elastic line. Dark blue (dark red): 5 meV (10 meV) step size and 40 s (30 s) integration time.

RIXS intensity may arise due to In/Ir site mixing. Sakamoto *et al.* [19] studied powder samples of $\text{Ba}_3\text{XIr}_2\text{O}_9$ for different metals X including In and found that X -Ir cation disorder is only relevant for $X = \text{Ti}^{4+}$ and Sc^{3+} . This can be explained by the similar ionic radii of Ir^{4+} , Ti^{4+} , and Sc^{3+} [19]. Larger X ions such as Ce^{4+} or In^{3+} as well as the different valence of In and Ir suppress cation disorder. For $\text{Ba}_3\text{InIr}_2\text{O}_9$, Dey *et al.* [25] discussed that the structural data of powder samples are well described by fully ordered structure models without cation disorder, while deliberately adding site mixing yields an estimate of 2.8(5)%. Our single-crystal x-ray diffraction data indicate about 1%–2% of Ir ions on the In $2a$ site *between* dimers; see Sec. III B. Even though the estimated density of such Ir moments is small, their contribution may be relevant since each of them is coupled to six neighboring dimers. The $2a$ sites are connected with the $4f$ dimer sites in a corner-sharing configuration with close to 180° Ir-O-Ir bonds, and Ir moments on the $2a$ sites are expected to enhance interdimer coupling. The bonding geometry is closely related to the case of Sr_2IrO_4 which shows large exchange interactions and magnetic excitations up to about 0.2 eV [68,69]. In $\text{Ba}_3\text{InIr}_2\text{O}_9$, the sinusoidal modulation observed for integration from 0.08 to 0.21 eV demonstrates the existence of dimer excitations at low energy; see Fig. 5(a). However, the l dependence is small

FIG. 8. Oscillator fit (solid lines) of RIXS data averaged over the spectra measured at about Γ , M , and K ; cf. Fig. 4. We distinguish $l \approx 20$ and 17 which roughly correspond to the extrema of the interference pattern at $q_c = 7Q_d$ and $6Q_d$; cf. Fig. 5(a). The elastic line has been subtracted. Parameters are given in Table II. Vertical bars denote the excitation energies found in the fit.

between 0.2 eV and 0.3 eV; see Fig. 7(b). A small magnetic contribution caused by In-Ir site disorder hence cannot be ruled out.

IV. DISCUSSION

Having established the quasimolecular nature of the electronic states, we aim to achieve a microscopic understanding of the electronic structure of $\text{Ba}_3\text{InIr}_2\text{O}_9$. To this end, we compare our RIXS data with exact diagonalization results. Typical for iridates and other $5d$ compounds, the electronic structure is governed by the interplay of Coulomb interactions, spin-orbit coupling, hopping interactions, and the noncubic part of the crystal field. However, for the cluster Mott insulator $\text{Ba}_3\text{InIr}_2\text{O}_9$ the focus is in particular on the competition between hopping and spin-orbit coupling. Is hopping strong enough to counteract the effects of spin-orbit coupling? In general, individual $5d^5$ Ir^{4+} sites show local moments with $j = \frac{1}{2}$ and $\frac{3}{2}$. In the case of two holes per dimer as in $\text{Ba}_3\text{CeIr}_2\text{O}_9$ with Ir^{4+} , (anti)bonding states of these spin-orbit entangled j states provide a good starting point for the description [37]. Below we show that the same applies to $\text{Ba}_3\text{InIr}_2\text{O}_9$, as sketched in Fig. 2, giving rise to the rich excitation spectrum observed in RIXS.

First, we determine the peak energies by fitting the RIXS data using Pearson VII oscillators [70]. For the fit, we considered the dispersion as negligible, as discussed above, and averaged the data of Fig. 4 over Γ , M , and K for constant q_c to improve statistics. Motivated by the intensity modulation depicted in Fig. 5(a), we focus on $q_c/(2\pi/c) \approx 20$ and 17, i.e., close to a maximum and a minimum of interference. In the fit, only the peak intensities are allowed to change as a function of q_c ; all other parameters are treated as independent of q_c . The fit describes the RIXS spectra very well; see Fig. 8. The corresponding parameters are summarized in Table II, and the peak energies are plotted as symbols in the middle panel of Fig. 9.

TABLE II. Parameters of the fit depicted in Fig. 8, where only the peak intensities are allowed to vary with q_c . The Pearson VII oscillator describes a Lorentzian (Gaussian) line shape for $\mu = 1$ (∞) [71]. Above about 1 eV it is not possible to distinguish different features. The lowest excitation energy of 0.03 eV is estimated from the data in Fig. 7(b).

energy (eV)	I_{6Q_d}	I_{7Q_d}	$\frac{I_{7Q_d} - I_{6Q_d}}{I_{7Q_d} + I_{6Q_d}}$	width (meV)	μ

The interaction Hamiltonian with on-site Coulomb repulsion U and Hund's coupling J_H reads [72]

$$\begin{aligned}
 H_C = & U \sum_{i,\alpha} n_{i\alpha\uparrow} n_{i\alpha\downarrow} + \frac{1}{2} (U - 3J_H) \sum_{i,\sigma,\alpha \neq \alpha'} n_{i\alpha\sigma} n_{i\alpha'\sigma} \\
 & + (U - 2J_H) \sum_{i,\alpha \neq \alpha'} n_{i\alpha\uparrow} n_{i\alpha'\downarrow} \\
 & + (U - 2J_H) \sum_i \left(15 - 5 \sum_{\alpha,\sigma} n_{i\alpha\sigma} \right) \\
 & + J_H \sum_{\alpha \neq \alpha'} (c_{\alpha\uparrow}^\dagger c_{\alpha\downarrow}^\dagger c_{\alpha'\downarrow} c_{\alpha'\uparrow} - c_{\alpha\uparrow}^\dagger c_{\alpha\downarrow} c_{\alpha'\downarrow}^\dagger c_{\alpha'\uparrow}),
 \end{aligned}$$

with $n_{i\alpha\sigma}$ being the number operator for the t_{2g} orbitals $\alpha \in \{a_{1g}, e_g^{\pi+}, e_g^{\pi-}\}$ [17] at site i , $j \in \{1, 2\}$ and $\sigma \in \{\uparrow, \downarrow\}$, and the operators $c_{\alpha\sigma}^\dagger$ create holes. We stick to $P6_3/mmc$ symmetry for the analysis of our RIXS data and consider the trigonal crystal field via $\Delta_{CF} L_z^2$, splitting the t_{2g} level into a_{1g} and e_g^π orbitals, and the intersite hopping amplitudes $t_{a_{1g}}$ and $t_{e_g^\pi}$. For D_{3h} symmetry of the Ir_2O_9 dimer, hopping is diagonal in the $a_{1g}-e_g^\pi$ basis. Finally, we employ spin-orbit coupling $\zeta \mathbf{I} \cdot \mathbf{s}$.

Discussing three t_{2g} holes on two Ir sites, we start from vanishing hopping $t = t_{a_{1g}} = t_{e_g^\pi} = 0$ and a cubic crystal field; i.e., we neglect the noncubic part by choosing $\Delta_{CF} = 0$. States with all three holes on the same site are about $2U$ above the ground state and can be neglected. For $t = 0$ we hence are facing simple product states $|t_{2g}^5\rangle_i |t_{2g}^4\rangle_j$ of single-site multiplets with one and two holes. Their joint excitation energies as function of ζ are depicted in the left panel of Fig. 9 for $U = 1.5$ eV and $J_H = 0.33$ eV. Energies are plotted up to $\zeta = 0.43$ eV, a realistic value for iridates [73]. While t_{2g}^5 systems in cubic approximation show a single intra- t_{2g} excitation at $\frac{3}{2}\zeta \approx 0.7$ eV [52–58] the dominant RIXS features in t_{2g}^4 compounds are observed at roughly 0.4 and 0.7 eV [59–61]; see dashed lines in top panel of Fig. 10.

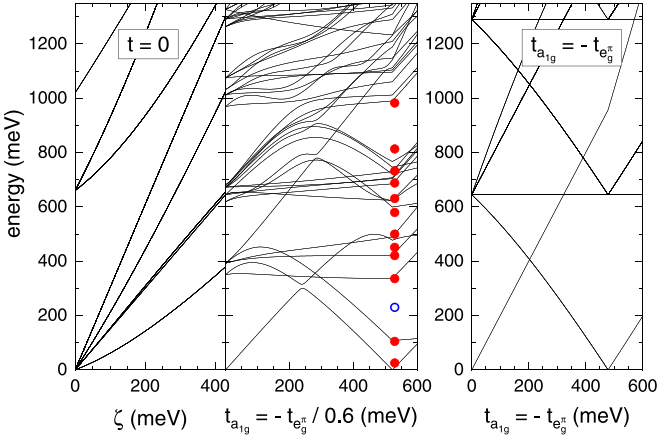

FIG. 9. Excitation energies of the many-body states calculated by exact diagonalization for $U = 1.5$ eV. Left: Dependence on ζ for $t = \Delta_{\text{CF}} = 0$ and $J_H = 0.33$ eV. For $\zeta = 0.43$ eV, the lowest excitation energies of about 0.4 eV and 0.7 eV agree with the dominant characteristic RIXS features of t_{2g}^4 iridates [59–61] and with the spin-orbit exciton of t_{2g}^5 iridates at $\frac{3}{2}\zeta$. Right: Effect of hopping in the simplified case $t = t_{a_{1g}} = -t_{e_g^*}$ for $\zeta = 0.43$ eV and $J_H = \Delta_{\text{CF}} = 0$, where hopping is block-diagonal in the j basis. Notably, several excitation energies are independent of t . Middle: Excitation energies as a function of hopping $t_{a_{1g}}$ for the realistic parameter set with $\zeta = 0.43$ eV, $J_H = 0.33$ eV, $\Delta_{\text{CF}} = 0.1$ eV, and $t_{e_g^*}/t_{a_{1g}} = -0.6$. For these parameters, the ground state changes at about 0.52 eV, and good agreement with the experimental peak energies (symbols) is obtained for $t_{a_{1g}} = 0.53$ eV. The weak RIXS feature at 0.23 eV (open blue symbol) is tentatively attributed to Ir/In site disorder; see Sec. III F.

Hopping is diagonal in the single-particle $a_{1g}-e_g^\pi$ basis and mixes the local multiplets. We therefore skip a more detailed discussion of the t_{2g}^4 multiplets but mention in passing that the local t_{2g}^4 ground state shows $j = 0$. In contrast to the t_{2g}^4 states, the single-hole t_{2g}^5 states with $j = \frac{1}{2}$ and $\frac{3}{2}$ are still important for an intuitive picture of the electronic states of a dimer. In particular, most of the characteristic features of the electronic structure already become apparent when considering an idealized system with $\Delta_{\text{CF}} = J_H = 0$ and $t_{e_g^*}/t_{a_{1g}} = -1$. The latter makes hopping block-diagonal in the $j = \frac{1}{2}$ and $\frac{3}{2}$ basis, so that j (but not j_z) remains a good quantum number. In this case, the eigenstates can be built from bonding and antibonding states

$$|j_\pm^m\rangle \equiv \frac{1}{\sqrt{2}}(|j, m\rangle_1 \pm |j, m\rangle_2), \quad (2)$$

where m denotes suitable linear combinations of $j_z = \pm\frac{1}{2}$ or $j_z = \pm\frac{3}{2}, \pm\frac{1}{2}$, and the definition of states on sites 1 and 2 takes into account that the IrO_6 are rotated with respect to each other [17]. Product states of these simple states form a very good starting point for the discussion of the many-body eigenstates, even though $t_{e_g^*}/t_{a_{1g}}$ is closer to $-\frac{1}{2}$ in $\text{Ba}_3\text{InIr}_2\text{O}_9$ and Coulomb interaction is strong.

For the idealized case with $t = t_{a_{1g}} = -t_{e_g^*}$, the right panel of Fig. 9 depicts the effect of hopping on the excitation energies. We employ $\zeta = 0.43$ eV and $U = 1.5$ eV, keeping $\Delta_{\text{CF}} = J_H = 0$ for simplicity. For not too large t , the doubly degenerate ground state shows two holes in the bonding $j = \frac{1}{2}$

FIG. 10. Exact diagonalization results for RIXS spectra at $(0\ 0\ nQ_d)$. Top and middle panels show data on opposite sides of the phase transition for $t_{a_{1g}} = 0.52$ eV and 0.53 eV, respectively. All other parameters are identical, i.e., $\zeta = 0.43$ eV, $U = 1.5$ eV, $J_H = 0.33$ eV, $\Delta_{\text{CF}} = 0.1$ eV, and $t_{e_g^*}/t_{a_{1g}} = -0.6$, as used in the middle panel of Fig. 9. Bottom: Result for larger $t_{a_{1g}} = 0.62$ eV and $U = 3.0$ eV. To take into account the finite In-Ir site disorder, all spectra contain the small contribution of individual t_{2g}^4 sites depicted by dashed lines in the top panel (see main text), using the parameters given above.

orbital $|\frac{1}{2}_+^\sigma\rangle$ and the third hole in the antibonding orbital, resulting in $j_{\text{dim}} = \frac{1}{2}$,

$$|\frac{1}{2}_{\text{dim}}\rangle_\sigma = |\frac{1}{2}_+^\uparrow\rangle|\frac{1}{2}_+^\downarrow\rangle|\frac{1}{2}_-^\sigma\rangle, \quad (3)$$

as sketched in the left panel of Fig. 2. In contrast, the first excited state at small t has two holes in the antibonding orbital,

$$|1\rangle_\sigma = |\frac{1}{2}_+^\sigma\rangle|\frac{1}{2}_-^\uparrow\rangle|\frac{1}{2}_-^\downarrow\rangle. \quad (4)$$

The absolute energies of $|\frac{1}{2}_{\text{dim}}\rangle_\sigma$ and $|1\rangle_\sigma$ vary like $\pm t$, and hence the excitation energy of $|1\rangle_\sigma$ rises with a slope $2t$. Even though U is large, this perfectly agrees with a simple picture of noninteracting holes since hopping for these three-particle states does not affect double occupancy.

The further low-energy states show one hole in either a bonding or an antibonding $j = \frac{3}{2}$ orbital,

$$|\frac{3}{2}_{\text{dim}}\rangle_m = |\frac{1}{2}_+^\uparrow\rangle|\frac{1}{2}_+^\downarrow\rangle|\frac{3}{2}_+^m\rangle, \quad (5)$$

$$|2\rangle_m = |\frac{1}{2}_+^\uparrow\rangle|\frac{1}{2}_+^\downarrow\rangle|\frac{3}{2}_-^m\rangle, \quad (6)$$

$$|3\rangle_{\sigma\sigma'm} = |\frac{1}{2}_+^\sigma\rangle|\frac{1}{2}_-^{\sigma'}\rangle|\frac{3}{2}_+^m\rangle. \quad (7)$$

For $t = 0$, all of these states lie at $\frac{3}{2}\zeta$. For $U = 0$, their energies are given in the simple noninteracting picture described above; i.e., each bonding (antibonding) state contributes $-t$ ($+t$) to the excitation energy. In this limit, the energy of state $|\frac{3}{2}_{\text{dim}}\rangle_m$ decreases with a slope $-3t$, which corresponds to an excitation energy $\frac{3}{2}\zeta - 2t$. Accordingly, $|\frac{3}{2}_{\text{dim}}\rangle_m$ becomes the ground state for t larger than a critical value, as sketched in

the right panel of Fig. 2. For finite U , the slope is reduced and the behavior is not perfectly linear anymore; see right panel of Fig. 9. The reduced slope reflects the Coulomb interaction between holes in the bonding orbitals for $j = \frac{1}{2}$ and $\frac{3}{2}$ which compete for the same space between the two Ir sites.

In contrast to the behavior of $|\frac{3}{2}_{\text{dim}}\rangle_m$, the energies of $|2\rangle_m$ and $|3\rangle_{\sigma\sigma'm}$ vary like $-t$, independent of U . Therefore, their excitation energy remains constant, $\frac{3}{2}\zeta$. With this we collected the main ingredients to describe the general properties observed in the RIXS spectra of $\text{Ba}_3\text{InIr}_2\text{O}_9$. For realistic parameters, the simple states described above are split into a multitude of levels, see middle panel of Fig. 9, but the main features of the RIXS spectra can still be explained in an intuitive picture, as described in the following and depicted in Fig. 2.

First of all, the insensitivity of the excitation energy to hopping roughly remains valid for many states. This applies to the phase observed for small hopping but still is valid above the phase transition. This explains that the main RIXS intensity in $\text{Ba}_3\text{InIr}_2\text{O}_9$ is found in the energy range where single-site-like d^4 and d^5 iridates show RIXS features based on ζ and J_H [52–61], i.e., around 0.4 eV and 0.7 eV. Note that this does not imply that the character of these states is the same as for vanishing hopping. It rather signifies that these states in terms of bonding/antibonding have the same character as the ground state. For instance for small hopping, they are mainly built from two bonding and one antibonding orbital and hence show a very similar dependence on hopping as the state $|\frac{1}{2}_{\text{dim}}\rangle_\sigma$.

Second, the observation of distinct low-energy RIXS features below 0.3 eV suggests that $\text{Ba}_3\text{InIr}_2\text{O}_9$ is close to the phase transition [38] where—in the simple picture given in the right panel of Fig. 9 and sketched in Fig. 2—the ground state changes from $|\frac{1}{2}_{\text{dim}}\rangle_\sigma$ to $|\frac{3}{2}_{\text{dim}}\rangle_m$. The energies of the low-energy features strongly disperse as a function of hopping and hence restrict the possible range of $t_{a_{1g}}$ and $t_{e_g^\pi}$. However, the slope of these states is renormalized by Coulomb interaction, as discussed above. Therefore the relevant range of hopping parameters depends on U [38]. Deviations from the idealized case $t_{e_g^\pi}/t_{a_{1g}} = -1$ mix states with different j and thereby lift the fourfold degeneracy in Eq. (5), giving rise to two Kramers doublets. For the parameters used in the middle panel of Fig. 9, this splitting is of the same order of magnitude as the noncubic crystal-field splitting Δ_{CF} .

With $\text{Ba}_3\text{InIr}_2\text{O}_9$ being close to the phase transition, the central question to be answered concerns the ground state. We address this issue via the RIXS matrix elements and calculate RIXS spectra in the dipole approximation as described in Ref. [37]. In the top and middle panels of Fig. 10, we compare results for $t_{a_{1g}} = 0.52$ eV and 0.53 eV, located on opposite sides of the phase transition. All other parameters are kept fixed. In contrast to the excitation energies that are very similar in the two cases, the RIXS matrix elements sensitively depend on the ground state, which is reflected in the RIXS intensity of different features as well as in their dependence on q_c . In the experiment, we find that the RIXS intensity is larger for odd values of Q_d (red and orange curves in Figs. 3 and 10). This is reproduced for hopping larger than the critical value, i.e., a ground state related to $|\frac{3}{2}_{\text{dim}}\rangle_m$. The corresponding middle panel of Fig. 10 shows reasonable agreement

with the experimental data concerning the main features of the spectrum. In contrast, the overall RIXS intensity is very similar for even and odd Q_d for $t_{a_{1g}} = 0.52$ eV, i.e., smaller than the critical value where the ground state is based on $|\frac{1}{2}_{\text{dim}}\rangle_\sigma$. We hence conclude that hopping exceeds the critical value while the presence of low-energy features demonstrates that $\text{Ba}_3\text{InIr}_2\text{O}_9$ is still close to the phase transition; see Fig. 2. Concerning the character of the ground state, our result agrees with an exact diagonalization study by Li *et al.* [38] which finds evidence for a $j_{\text{dim}} = \frac{3}{2}$ nature of the ground state of $\text{Ba}_3\text{InIr}_2\text{O}_9$ based on the small anisotropy of the magnetic susceptibility and the small magnitude of the effective magnetic moments. Furthermore, the corresponding sequence with the lowest bonding $j = \frac{3}{2}$ orbital lying below the antibonding $j = \frac{1}{2}$ orbital agrees with a RIXS study on $\text{Ba}_3\text{CeIr}_2\text{O}_9$ with two holes per dimer [37].

Concerning the electronic parameters, we use $\zeta = 0.43$ eV and $J_H = 0.33$ eV, which are typical for iridates [37,73]. Determination of the hopping parameters is more subtle. For given ζ , the critical hopping for the phase transition depends on U [38]. Using $t_{e_g^\pi}/t_{a_{1g}} = -0.6$, we obtain very similar results for the RIXS spectra for $U = 1.5$ eV and 3.0 eV if $t_{a_{1g}}$ is adapted from 0.53 eV to 0.62 eV; see Fig. 10. These values roughly agree with first-principles density-functional theory calculations [74] which yield $t_{a_{1g}} = 0.47$ eV and $t_{e_g^\pi}/t_{a_{1g}} = -0.53$. Finally, the effect of a small crystal-field splitting Δ_{CF} is not pronounced, which prevents an accurate determination. We employ $\Delta_{\text{CF}} = 0.1$ eV.

Both finite Δ_{CF} and $t_{e_g^\pi}/t_{a_{1g}} \neq -1$ split the quartet $|\frac{3}{2}_{\text{dim}}\rangle_m$ into two doublets. For the parameters derived above, the lower-energy doublet forms the many-body ground state, while the first excited state is related to $|\frac{1}{2}_{\text{dim}}\rangle_\sigma$; see middle panel of Fig. 9. We emphasize that 86% of the weight of the ground-state doublet arises from the quartet $|\frac{3}{2}_{\text{dim}}\rangle_m$. The main admixture, carrying about 8%, stems from

$$|4\rangle_m = \left| \frac{1}{2}_- \uparrow \right| \frac{1}{2}_- \downarrow \left| \frac{3}{2}_+ \right\rangle, \quad (8)$$

$$|5\rangle_{\sigma\sigma'm} = \left| \frac{1}{2}_+ \sigma \right| \frac{1}{2}_- \sigma' \left| \frac{3}{2}_- \right\rangle, \quad (9)$$

and a further 3% are contributed by

$$|6\rangle_{\sigma mm'} = \left| \frac{1}{2}_+ \sigma \right| \frac{3}{2}_+ \left| \frac{3}{2}_+ \right\rangle. \quad (10)$$

Similarly, $|\frac{1}{2}_{\text{dim}}\rangle_\sigma$ carries about 83% of the weight of the lowest excited many-body state, and $|2\rangle_m$ and $|3\rangle_{\sigma\sigma'm}$ together contribute 8%. We hence conclude that the spin-orbit entangled bonding and antibonding orbitals capture the dominant physics for realistic parameters.

Finally, we address the possible role of In-Ir site disorder on the RIXS spectra. With one exception, the exact diagonalization calculations describe the experimentally observed peak energies very well; see red symbols in the middle panel of Fig. 9. At low energy, however, theory predicts two excitation energies, and our calculations do not yield any RIXS peak around 0.2 eV. This can be reconciled with the experimental data assuming that the weak RIXS intensity around 0.23 eV, cf. Fig. 7 and blue symbol in Fig. 9, is caused by a magnetic contribution of a few % of Ir ions on In sites that form approximately 180° Ir-O-Ir bonds with Ir on dimer sites, as discussed in Sec. III F. Furthermore, the calculated

spectra contain a small contribution of individual $t_{2g}^4 \text{Ir}^{5+}$ sites; see dashed lines in top panel of Fig. 10. These reflect the presence of 7.3% In^{3+} ions on dimer sites, as derived from our analysis of the crystal structure; see Sec. III B. For simplicity, we assume that an In^{3+} ion on a dimer site is accompanied by an Ir^{5+} ion. This contribution, however, is small and overlaps with dimer features; it is hence not important for our analysis. Around 0.4 eV, the small \mathbf{q} dependence of the intensity of this single-site contribution reflects a corresponding change of the scattering geometry. Such effects are typically much smaller than the \mathbf{q} dependence observed for the quasimolecular dimer contribution.

V. CONCLUSIONS

In spin-orbit entangled iridates, experimental realizations of quantum spin liquids are very limited and hotly debated. The honeycomb iridate $\text{H}_3\text{LiIr}_2\text{O}_6$ for instance does not show magnetic order down to 50 mK [16] but the role of disorder related to the H ions has been pointed out [75–77]. The compound $\text{Ba}_3\text{InIr}_2\text{O}_9$ was discussed as an outstanding case with clear experimental evidence for persistent spin dynamics down to 20 mK from thermodynamic and spectroscopic data [25]. The dimer structure based on face-sharing IrO_6 octahedra requires solving the issue of the microscopic character of the local moments on a quantitative level. Understanding these local moments is a prerequisite for a successful description of magnetism in this compound.

Overall, our results establish that $\text{Ba}_3\text{InIr}_2\text{O}_9$ is a spin-orbit entangled cluster Mott insulator. We prove the insulating character via dielectric spectroscopy and demonstrate that the crystal structure shows a monoclinic distortion already at room temperature. Based on the observation of a double-slit type sinusoidal interference pattern, our RIXS data establish the quasimolecular orbital character of the electronic structure in face-sharing geometry. The three holes are fully delocalized over the two sites of a dimer. The physics is related to the case of the sister compound $\text{Ba}_3\text{CeIr}_2\text{O}_9$ in which two holes per dimer form a spin-orbit entangled nonmagnetic $j_{\text{dim}} = 0$ ground state [37]. In $\text{Ba}_3\text{InIr}_2\text{O}_9$, the many-body dimer ground state can be approximated as a spin-orbit entangled Kramers doublet based on the $j_{\text{dim}} = \frac{3}{2}$ state in which two holes occupy the bonding orbital built from local $j = \frac{1}{2}$ moments, as in $\text{Ba}_3\text{CeIr}_2\text{O}_9$, while the third hole is in a bonding $j = \frac{3}{2}$ state. This character of the ground state explains the dominant $\sin^2(q_c d/2)$ behavior of the RIXS intensity. The simple picture of bonding orbitals of local j states works best in the idealized case $t_{e_g}/t_{d_{1g}} = -1$, where hopping is block-diagonal in the j basis, but it still yields a reasonable description for realistic parameters. Furthermore, the observation of low-energy RIXS features demonstrates that $\text{Ba}_3\text{InIr}_2\text{O}_9$ is close to the phase transition to a $j_{\text{dim}} = \frac{1}{2}$ state [38].

The realization of a new type of a gapless spin liquid based on spin-orbit entangled moments in quasimolecular orbitals would open up a different and very promising perspective on iridates and quantum spin liquids in general. In $\text{Ba}_3\text{InIr}_2\text{O}_9$, the proposed unconventional spin-liquid character is supported by a quadratic behavior found in the specific heat at low temperature, which deviates from the typical spin-liquid scenario of fermionic spinons [25]. However, this has to be taken with a grain of salt since the possible role of a small percentage of cation disorder needs to be further elucidated.

The magnetism in $\text{Ba}_3\text{InIr}_2\text{O}_9$ is based on interdimer exchange interactions which occur on an energy scale that challenges the state-of-the-art energy resolution of RIXS at the Ir L_3 edge, calling for thorough theoretical studies of exchange interactions between quasimolecular states on neighboring dimers and further spectroscopic investigations with other techniques.

Finally, our results demonstrate the promising potential of RIXS interference patterns $I(\mathbf{q})$ to unravel the electronic structure and to determine the character and symmetry of electronic states [63–65]. Using the iridate dimers $\text{Ba}_3\text{CeIr}_2\text{O}_9$ [37] and $\text{Ba}_3\text{InIr}_2\text{O}_9$ as well-defined model systems, the power of this approach has been established. Furthermore, such interference patterns revealed the nearest-neighbor character of magnetic excitations in the honeycomb iridates with dominant Kitaev exchange [66]. However, the technique is expected to apply equally well to trimers or larger clusters as well as to ladders, bilayers, and other superstructures. Analyzing only a few values of \mathbf{q} , this interference effect has also been addressed in the bilayer iridate $\text{Sr}_3\text{Ir}_2\text{O}_7$ [78] as well as in VO_2 [79] and in the context of stripes in nickelates and cuprates [80]. One advantage of the iridates, compared to $4d$ or $3d$ transition metal compounds, is that the Ir L edge is lying in the hard x-ray region, allowing us to cover a large range of \mathbf{q} space and hence to observe the interference pattern over more than a period.

ACKNOWLEDGMENTS

We thank Y. Li, S. M. Winter, and R. Valentí for fruitful discussions and for sharing their DFT results with us.
