Interstitial Stabilization and Color-Center Prodnetjon in KBr

G. Giuliani*

Istituto di Fisica dell'Università, 27100 Pavia, Italy (Received 23 January 1970)

This paper deals with the color-center production in KBr containing alkali impurities (Li, Na, and Rb). It turns out that alkali impurities enhance the color-center production at 80 °K only if their size is smaller than that of the substituted ion. Typically, in sodium- or lithiumdoped samples (1% in the melt) the average α - and F-center production efficiencies are increased by more than an order of magnitude and by a factor of $2-3$, respectively. In KBr:Na, the enhancement of the α - and F-center production is related to the growth of the well-known V_1 and I (interstitial negative ion) bands (not observed at 80 °K in sufficiently pure samples). Similarly, in KBr:Li, the increase of the α - and F-center production is related to the growth of an *I*-type band (peaking at 223 m μ) and of two V₁-type bands (peaking at 390 and 438 m μ). The analysis of the growth- and thermal-decay properties of the I - and V_1 -type bands, with respect to those of the α and F bands, leads to the conclusion that the enhancement of the α - and F-center production is due to the trapping and the stabilization of interstitial halogens by sodium or lithium impurities. Finally, the fact that lithium-trapped interstitials are more stable than 0 those trapped by sodium, along with the fact that rubidium impurities (1% in the melt) do not affect the color-center production, supports an interstitial-stabilization mechanism based on the reduction of the repulsive forces acting on the interstitials when they are trapped near suitable impurities.

I. INTRGDUCTIGN

It has been shown that two types of Frenkelpairs are created in alkali halide crystals exposed to ionizing radiations near liquid-helium temperature: one consisting of an F center and an H center (interstitial halogen atom) and the other consisting of an anion-vacancy (α center) and an interstitial halogen.¹ Provided that the temperature of irradiation is low enough (very close to that of liquid helium), the production of these pairs is an intrinsic process, i. e. , it does not depend on the degree of perfection of the sample.^{2,3} However, when the temperature of irradiation is raised, the production of both the α and F centers is enhanced by positive divalent impurities. $\overset{3,4}{ }$ It has been suggested⁴ that the enhancement of the F -center production at 80 'K is due to the stabilization by divalent impurities of interstitials which wouldotherwise recombine with the corresponding anion vacancies. More recently, it has been shown that the α -center production in the 11-196 °K range (in KCl) can be accounted for in terms of an intrinsic production and of a structure-sensitive recombination of anion-vacancy —interstitial-halogen ion pairs. The structure dependence of the recombination process is easily understood in terms of interstitial stabilization by divalent impurities or other defects.³ However, it must be stressed that though the hypothesis of interstitial stabilization explains several facts on the colorcenter production and stability, further data are needed for considering this hypothesis confirmed

by experiment and for finding out the mechanism by which interstitial stabilization occurs. As already suggested,³ an interstitial may be stabilized by an impurity (or by other defects), if the repulsive forces acting on the interstitial are smaller near the impurity than in a perfect region of the crystal. This condition is expected to be verified in the dilated regions which surround impurities smaller than the substituted ion. For instance, if one chooses KBr as the host crystal, then sodium and lithium will be appropriate impurities. In fact, not only are lithium and sodium ions smaller than the potassium ion, but since they are monovalent, their possible influence on the interstitial stability mill be uniquely due to their smaller size.⁵ In particular, there cannot be any effect associated with extra charges or chargecompensating cation vacancies, which may be true in the case of positive divalent impurities. Furthermore, since the lithium ions are considerably smaller than the sodium ions, lithium-trapped interstitials are expected to be more stable than those trapped by sodium. Finally, on the basis of the above speculations, rubidium impurities (in KBr) cannot act as interstitial traps.

In this paper, we report the results of research suggested by the above considerations.

II. EXPERIMENTAL

The production efficiency and the thermal stability of interstitial halogens in KBr have been studied by looking at the optical-absorption bands

 $\boldsymbol{2}$

464

associated with interstitial halogens or with the complementary defects of interstitial halogens $(\alpha$ and F centers). All the optical-absorption measurements have been carried out at 80 'K using a Hitachi EPS-3T double-beam spectrophotometer. The irradiations have been performed at 80 'K, using an OEG-50T Machlett x-ray tube operated at 45-kV peak and 30 mA. The thermal destruction of the defects produced at 80 'K has been studied by a pulse-annealing method alread described in a previous paper. $^3\;$ (In the presen work, however, the samples were kept only for 5 min at the annealing temperature.) The samples used have been grown in nitrogen atmosphere by the Kyropoulos method. The reported impurity contents refer always to the amounts added to the KBr powder (Merck Suprapur).

III. RESULTS AND DISCUSSION

A. Sodium-Doped Samples

1. Mainly F and V_1 Centers

The first results obtained on KBr: Na have already been published in a previous payer from now on referred to as Paper I.⁶ In Paper I the following was shown: (i) Sodium impurities enhance the production of both the α and F centers at 80'K. (ii) The higher production efficiency of α centers is due to the stabilization of interstitialbromine ions by sodium impurities. (iii) The enhancement of the F -center production is related to the growth of the V_1 band. In this section we report some additional data obtained with sodiumdoped samples.

Provided that the sodium content is high enough, the composite V_1 band is proportional to the F band for low radiation doses (Fig. 1). During the warming of the sample the decrease of both V_1 -band com-

FIG. 1. Relation between the composite V_1 band (414) m μ) and the F band (604 m μ) during the x irradiation at 80 K of KBr samples containing different amounts of sodium impurities.

FIG. 2. Relations between the decreases of the two V_1 -band components and the decrease of the F band during the warming of a sodium-doped (1%) KBr sample x rayed at 80 °K.

ponents is proportional to the decrease of the F band (Fig. 2). However, the percent decrease of the composite V_1 band is higher than the corresponding decrease of the F band (Fig. 3).

The decrease of the $423-m\mu$ component of the V_1 band is accompanied by a proportional increase of the V_4 band (Fig. 4). The decay of the other component of the V_1 band is accompanied by an increase of the long-wavelength component (306 $m\mu$) of the V_4 -band envelope. (In dealing with the V_4 -band envelope, we shall use the nomenclature suggested by Comins. 8)

A discussion of these results involves the structure of the V_1 center. According to recent EPR measurements, the V_1 center in KCl consists of an interstitial-halogen atom $(H$ center) trapped at an alkali impurity. 9 Results supporting the same model for KBr have been obtained by the author.¹⁰ Therefore, in the following discussion we shall assume that the V_1 center in KBr(Na) consists of an H center trapped at a sodium impurity. The fact that the assumed model explains all the experimental data (which we will discuss next) is a further argument in favor of its correctness.

The existence of stabilized H centers $(V_1$ centers) at 80 \degree K shows that F-center-H-center pairs are produced at 80 \degree K, as they are near liquid-helium temperature. In a pure sample, the produced H centers will recombine with the corresponding F centers or will give rise to some complex centers centers or will give rise to some complex cent
responsible for the V_4 -band envelope.^{8,11} However, in sodium-doped samples a fraction of the produced H centers will be trapped and stabilized by sodium impurities and will therefore be observable as V_1 centers. As a consequence, the V_1 band will grow at a rate proportional to that of the F band, provided that the effective concentration of impurities is high enough (Fig. 1).¹² On warming the sample the stabilized interstitial-halogen atoms become mobile and either recombine with F centers (Fig. 2), or form the defects responsible for the V_4 band (Fig. 4) or the 306-m μ com-

ponent of the V_4 -band envelope. This behavior of the mobile intertitial-halogen atoms, along with the fact that the V_1 centers are not the only complementary defects of the F centers produced at plementary delects of the r centers produced at $80\degree\text{K}$, 6 is responsible for the larger decrease of the composite V_1 band as compared to that of the F band (Fig. 3).

2. α -Center-Interstitial-Halogen Ion Pairs

The α centers produced at 80 °K in KBr: Na disappear almost completely in two distinct stages as the sample is warmed at $190\textdegree K$ (Fig. 5, lower curve). As shown in Paper 1, the thermal destruction of α centers is due (at least in the 80-140 °K range) to their recombination with interstitialhalogen ions. In principle, the mobile entity responsible for the recombination process may be either anion vacancy or interstitial. However, in the former case one expects a fraction of the mobile-anion vacancies to be trapped by sodium impurities, i.e., one expects to observe the growth of the α_A band.¹³ This $\alpha \rightarrow \alpha_A$ conver growth of the α_A band.¹³ This $\alpha \rightarrow \alpha_A$ conversion is very likely responsible for the apparent shift of the α -band peak, which is observed after the sample has been warmed at $250 \degree K$ (Fig. 6). On the other hand, since no shift is observed below 190'K, we are led to the conclusion that no detectable migration of anion vacancies occurs below 190 'K and that the mobile entity below this temperature is the interstitial. Finally, owing to the overlapping of the α and the α_A band (Fig. 6), the point corresponding to $250 \degree K$ in Fig. 5 (lower curve) overestimates the remaining α center concentration.

FIG. 6. (a) Absorption spectrum (measured at 80 °K) in the α -band region of a sodium-doped (1%) KBr sample x rayed for 210 min at 80 'K and warmed for ⁵ min at 190 'K; (b) absorption spectrum of the same sample of (a) after it has been warmed for 5 min at 250'K. Both curves of this figure have been obtained by subtracting the absorption curve obtained prior to the x irradiation at 80'K from the measured absorption curves.

B. Lithium-Doped Samples

1. α - and F-Center Production Efficiency at 80 °K

Figure 7 shows that lithium impurities enhance the average α -center production efficiency at 80 K

FIG. 7. α - and \boldsymbol{F} center growth curves for samples of pure or doped KBr. The defect concentrations have been calculated as indicated in Paper I. Owing to the soft x rays used and to the thickness of the samples (0.76-0. 80 mm) the coloration was strongly nonuniform. Therefore, the values reported here for the defect concentrations are average values.

FIG. 8. Absorption curves of three of the four samples of Fig. 7 after the x irradiation at 80 °K. The has been x rayed for 317 min, the rudidium doped for 315 min, and the lithium doped for 270 min. All the curves of this figure have been obtained by subtracting from the measured absorption curves the absorption curves measure prior to the x irradiation.

FIG. 9. Relation between the α and the 223-m μ band in a lithium-doped (1%) KBr sample during the x irradiation at 80 °K (open circles) and the subsequent thermal decay (full circles).

FIG. 10. Relation between the 390- and 438-m μ band in a lithium-doped $(1%)$ KBr sample during the x irradiation at 80 'K.

by a factor of about 17 and enhance the average F -center production efficiency by a factor of about 2. 7. $¹⁴$ The enhancement of the anion-vacancies</sup> production is accompanied by the growth of three absorption bands (at 223, 390, and 438 m μ) not observed in pure samples (Fig. 8). Moreover, while the pure samples exhibit the V_4 -band envelope with a peak at $278.5\ \text{m}\mu,$ the lithium-dope samples show a (composite) band peaking at 307.5 m μ (Fig. 8).

2. α -Center-Interstitial-Halogen Ion Pairs

The proportionality between the α and the 223 $m\mu$ band observed during the x irradiation (Fig. 9) suggests that the 223-m μ band might be due to interstitial-bromine ions created in pairs with

and $438-\mathrm{m}\mu$ bands during the thermal decay occurring above 195 'K in a lithium-doped (1%) KBr sample x rayed at 80 'K.

 α centers and stabilized by lithium impurities. This assignment seems reasonable in spite of the shift of the 223-m μ band with respect to the I band in pure KBr, 15 and in spite of the fact that the proportionality between the α and the 223- m μ band does not seem to be maintained during the warming of the sample (Fig. 9). Generally speaking, the shift of the I (Li) band can be understood on the basis that the environment of the lithiumtrapped interstitial is highly perturbed by the presence of the small Li' ion. On the other hand, the breakdown of the linear relation between the α and the I (Li) band during the warming of the sample (Fig. 9) may be due to the growth of some other band overlapping the I (Li) band. (A similar result occurs also in KBr: Na above 140 °K; see Paper I.)

The thermal decay of α centers in KBr: Li is shown in Fig. 5 (upper curve). It takes place in two main stages. The first one occurs in the same temperature range in which interstitialhalogen ions are released by sodium impurities

FIG. 11. Relation between the 390- and 438-m μ bands and the F band in a lithiumdoped (1%) KBr sample during the x irradiation at 80 'K.

lower curve and Sec. III A 2). This coincidence, however, is accidental. In fact, though some sodium impurities may b um-doped samples, their concentration cannot be camples, their concentration cannot
to be responsible for as much as $\frac{1}{3}$ or
ed interstitials. [Otherwise, the α so mgn as to be l
the stabilized int center production efficiency of the pure sample ut $\frac{1}{3}$ that of the lithium-doped sample but this is not observed $(Fig. 7)$. T are led to suggest that the first stage of the upper
curve of Fig. 5 is due mainly to the migration of nterstitial-halogen ions loosely stabili ium impurities. The second stage occurs above . 5, upper curve). It has been sho III A 2 that though the anion vacancies are not mobile below 190 $\mathrm{^{\circ}K},$ they migrate at temper atures as high as $250^\circ K$. Unfortunately, we do not know at what temperature the migration of anion vacancies becomes appreciable. Thus, we cannot say what is th e contribution of the anion vacancies migration to the second stage of the upper curve of Fig. $5.$ As for the of the interstitials migration, since interstitialhalogen atoms trapped at lithium impurities benalogen atoms trapped at fitmum impurities be-
come mobile above 195 °K (see below) interstitia alogen ions also will be very like. this temperature. Finally, it sho e case of the KBr: Na sample (Sec. III A 2), the α -center concentration corresponding to 250° K in Fig. 5 (upper curve) is overestimate to 250 °K in Fig. 5 (upper curve) is overestim:
owing to the α + α $_{A}$ conversion and to the overlapping of the corresponding absorption bands.

3. F and V_1 Centers

Figures 10 and 11 show that during the x irradiation at 80 \degree K (apart from an initial small curvature¹⁶) the 390- and 438-m μ bands (Sec. III B 1) are proportional to each other and bot are proportional to the F band. During the warmple above 195 °K , the decreases of the 390- and 438-m μ bands are proportional to each other (Fig. 12), and both of them are proportional to the decrease of the F band (Fig. 13). However, the percent decrease of the 390- and 438-m μ bands is higher than the corresponding

decrease of the F band (Fig. 3). Finally, the concomitant thermal bleaching of 438- $m\mu$ bands (Fig. 12) is accompanied by an increase of the 307.5- $m\mu$ band.

The above results show that the behavior of the 390- and 438- $m\mu$ bands in KBr: Li is the same (with some differences to be discussed below) as that of the V_1 bands in KBr; Na (Sec. III A 1). Therefore, we are led to the reasonable conclusion that the 390- and 438-m μ bands in KBr: Li are due to interstitial-bromine atoms (H centers trapped and stabilized by lithium impurities and may, therefore, be referred to as V_1 (Li) bands This statement deserves some discussion. In fact, as already stressed previously in this pape: there are some differences between the propert properties of the $\boldsymbol{V_1}$ (Li) bands. In particular, in contrast to the be-(Li) bands. In particular, in contras
havior of the two components of the c
band in KBr: Na, the two V_1 bands in $\stackrel{\sim}{ }$ thermal stability (Fig. 12). This result, along with the other one which indicate that the two V_1 (Li) bands are proportional to each other during their growth (Fig. 10), introduces the possibility that the two V_1 (Li) bands are due to two different optical transitions of the same center Very recently, this hypothesis has been by means of dichroic-bleaching measurements.¹⁷ Finally, it is worth stressing that the decrease of the V_1 (Li) bands is accompanied by an increase of the 307.5- $m\mu$ band. This result agrees with the fact that the role played in sodium-doped KBr by the 278.5- $m\mu$ band seems to be transferred in KBr: Li to the 307.5-mu band [at least for the x ray doses used in our measurements (see Fig. 8).

C. Rubidium-Doped Samples

As shown in Fig. 7, rubidium impurities do not affect the production efficiency of anion vacancies (with or without a trapped electron) at 80 °K. Furthermore, as shown in Fig. 8, x -irradiated samples of KBr: Rb exhibit the same absorption bands ples of pure KBr. In particular rubidium-doped samples do not show any V_1 -type or I-type band.

FIG. 13. Relation between the decreases of the $390-$ and $438-m\mu$ bands and that of the F band during the thermal decay occurring above 195 'K in a lithiumdoped $(1%)$ KBr sample x rayed at 80 'K.

IV. CONCLUSION

The data reported in Paper I and in the present paper show that alkali impurities in KBr enhance the anion-vacancies production at 80 $\,^{\circ}$ K only if their size is smaller than that of the potassium ion (Secs. IIIAI, IIIBI, and IIIC; see, in particular, Fig. 7). This enhancement is very likely due to the trapping and the stabilization by alkali impurities of interstitial-halogen ions and atoms, which in a perfect lattice would recombine with α and F centers, respectively (Secs. IIIA1, III

A 2, III B 2, and III B 3). The thermal stability of the trapped interstitials (ions or atoms) depends on the size of the impurity and increases as the size of the impurity decreases. 18 Therefore, we can conclude that the above results not Only give further strong support to the hypothesis of interstitial stabilization (Sec. I), but the results are also consistent with a stabilization mechanism based on a reduction of the repulsive forces acting on the interstitial (Sec. I),

²In other words, the V_1 -F linear relation breaks down for lightly-doped samples or for strongly doped samples exposed to high radiation doses, which is exactly the same as far as we are concerned with the number

of impurities effective in trapping.

 13 G. Giuliani, J. Phys. Chem. Solids $30, 217$ (1969). 14 For the reader's convenience, we have reported in Fig. 7 also the growth curves of a sodium-doped Sample. For this sample the average α -center production efficiency is increased by a factor of about 14 and the

average F -center production efficiency is increased by a factor of about 2.

 15 G. Kurz and W. Gebhardt, Phys. Status Solidi 7, 351 (1964).

 16 The curvatures in Figs. 10 and 11 are very likely due to the growth and saturation of the V_K and $V_1(Na)$ bands.

 17 M. Saidoh and N. Itoh, Phys. Letters $31A$, 68 (1970); M. Saidoh and N. Itoh (private communication) have also found that the $V_1(\text{Li})$ centers can be converted into $I(\text{Li})$ centers by electron capture. This result supports the models proposed above for the two centers.

 18 In fact, from Fig. 3 we can see that $V_1(L_i)$ centers are more stable than $V_1(Na)$ centers, i.e., that lithium trapped interstitial-halogen atoms are more stable than those trapped by sodium. A similar conclusion concerning interstitial-halogen ions can be drawn from the thermal-decay curves for the α band reported in Fig. 5, taking into account the fact that the thermal destruction of α centers is due mainly to the migration of the interstitials (Sees. IIIA2 and IIIB2).
