(Received 6 July 1970)

By means of Zeeman anisotropy fluorescence (ZAF) and its field dependence (up to 55.8 kG), the authors have investigated the 4.2 K narrow-line fluorescence of  $\text{KCl}:\text{Sm}^{2+}$  and identified some hitherto unreported  $\text{Sm}^{2+}$  sites. The strong no-field line at 7693.5 Å ( ${}^5D_0 \rightarrow {}^7F_3$ ) and a very weak no-field line at 8742.8 Å ( ${}^5D_0 \rightarrow {}^7F_5$ ) are shown to be of  $C_{3v}$  symmetry origin. The 24.5-kG ZAF pattern observed in the 7696–7700-Å ( ${}^5D_0 \rightarrow {}^7F_3$ ) region has been identified to originate from a type-II  $C_s$  site. The 26.5-kG ZAF patterns of the  $C_{3v}$  no-field line at 7693.5 Å and the type-I  $C_s$  no-field line at 7694.5 Å overlap in the 7693–7695.3-Å region, and are elucidated through the field dependence of their Zeeman components. Characteristic radiative lifetimes of the  ${}^5D_0$  level in several  $\text{Sm}^{2+}$  symmetry types have been determined from dominant transitions to the  ${}^7F_J$  ( $J \leq 4$ ) levels. There are two distinct  $C_{4v}$  sites: one with a lifetime of 9.5 msec, and the other 11.2 msec.  $C_{2v}$  and type-I  $C_s$  sites have lifetimes of 10.5 and 10.8 msec, respectively, which are indistinguishable within the experimental error. The role of  $\text{O}^{2-}$  compensation of  $\text{Sm}^{2+}$  in addition to  $\text{K}^+$  vacancy compensation in KCl is discussed in terms of these findings.

### I. INTRODUCTION

The law of equilibrium distribution which governs the low-temperature pair formation of divalent cations and cation vacancies in alkali halides<sup>1</sup> and that of trivalent cations and interstitial anions in alkaline-earth halides<sup>2</sup> has been useful in the interpretation and prediction of spectroscopic data on compensated lattices<sup>2-7</sup> in which aliovalent cations and lattice defects interact as ions of opposite unit charges in a crystalline solution. Idealized calculations<sup>1</sup> for  $\text{KCl}:\text{Sm}^{2+}$  ions show that at  $T \sim 500$  K, all the  $\text{Sm}^{2+}$  ions are paired with  $\text{K}^+$  vacancies. The dominant pairs, in the order of their relative importance, are the  $C_{4v}(2, 0, 0)$ ,  $C_s(2, 1, 1)$ ,  $C_{2v}(1, 1, 0)$ ,  $C_1(3, 2, 1)$ ,  $C_s(3, 1, 0)$ ,  $C_{2v}(2, 2, 0)$ , and  $C_{3v}(2, 2, 2)$   $\text{Sm}^{2+}$ - $\text{K}^+$  vacancy pairs [where the notations  $C_{4v}$ ,  $C_s$ ,  $C_{2v}$ , and  $C_1$  denote the site symmetry of the  $\text{Sm}^{2+}$  ion, and the integers in parentheses, e.g., (2, 0, 0), give the lattice position of the vacancy with the divalent cation at the origin], of which the first three account for approximately 90% of the  $\text{Sm}^{2+}$  ions. The problem of site distribution is often complicated by possible oxygen contamination, in which case the  $\text{Sm}^{2+}$  ion sees a second site symmetry distribution due to  $\text{Sm}^{2+}$ - $\text{O}^{2-}$  pair formation.<sup>6,7</sup>

There are fourteen dominant (4.2 K narrow-line fluorescence) transitions in  $\text{KCl}:\text{Sm}^{2+}$  spanning the wavelength region 6891–9440 Å.<sup>3</sup> These lines approximately follow the Landé interval rule, and probably arise from the radiative decay of the  ${}^5D_0$  to the  ${}^7F_J$  levels of the  $4f^6$  ground configuration in  $\text{Sm}^{2+}$ .<sup>6</sup> All these fourteen lines, as well as weaker fluorescence lines of  $\text{KCl}:\text{Sm}^{2+}$ , show Zeeman effects under external magnetic fields up to 93.5 kG.<sup>3-7</sup> Through Zeeman anisotropy fluo-

rescence (ZAF) determinations, the no-field lines<sup>7</sup> at 7014.7 Å (0–1) and 7264.4 Å (0–2) have been attributed to  $C_{2v}$  symmetry origin, the no-field lines at 7282.8 Å (0–2),<sup>7</sup> 7304.6 Å (0–2),<sup>7</sup> 8204.9 Å (0–4),<sup>3</sup> and 9439.1 and 9440.0 Å (0–6)<sup>3</sup> have been attributed to  $C_{4v}$  symmetry origin, and the no-field lines at 7031.7 Å (0–1),<sup>7</sup> 7694.5 Å (0–3),<sup>5</sup> and 8778.4 Å (0–5)<sup>5</sup> have been attributed to  $C_s$  site symmetry origin. The 0–0 line at 6891.9 Å as well as the diffuse no-field lines at 7048.2 Å (0–1) and 7327.6 Å (0–2) show Zeeman shifts at high fields, but they do not give rise to discernible ZAF patterns even at 93.5 kG.<sup>7</sup> The sites responsible for these lines thus far remain unknown. The assignment<sup>5</sup> of the no-field line at 7694.5 Å to the  $C_s(2, 1, 1)$  pattern is tentative due to the presence of the no-field line at 7693.5 Å (the symmetry origin of which has yet to be determined) in its close proximity: Additional work is necessary to isolate the overlapping ZAF patterns, which at 26.5 kG occur in the 7693–7695.3-Å region.

There are three main goals in the present work: (i) to determine the site symmetry origin of the thus far unknown no-field line at 7693.5 Å (0–3) which, in turn, will enable us to confirm the  $C_s(2, 1, 1)$  origin of the no-field line at 7694.5 Å; (ii) to examine the possible existence of site symmetries other than  $C_{4v}$ ,  $C_{2v}$ , and  $C_s(2, 1, 1)$ ; and (iii) to propose radiative lifetime measurements as a new technique for the site symmetry determination of lines which do not give rise to discernible ZAF patterns.

In achieving goal (i), we have resorted to field dependence investigations in which ZAF patterns are traced to their original no-field lines. The angular dependence of the Zeeman components in a ZAF pattern is ascertained through their line intensities

as recorded with tracings of the photographic plates from a high-resolution comparator microdensitometer. In accomplishing goal (ii), we have examined the schematic ZAF patterns for all the possible  $\text{Sm}^{2+}$  sites in KCl. A systematic search has been made among the weaker lines in all the  $J$  manifolds for novel site symmetries [ $C_{3v}$ ,  $C_s(\text{II})$ , and  $C_1$ ] which have not been previously observed. Goal (iii) is achieved by establishing the fact that for a given site there is one and only one characteristic radiative decay lifetime from a single excited level. As a result of these investigations, we wish to report (i) the discovery of the  $C_{3v}$  symmetry origins of the no-field line at 7693.5 Å(0-3) and a very weak no-field line at 8742.8 Å(0-5); (ii) the observation of a type-II  $C_s$  ZAF pattern in the 7696-7700-Å region (0-3) which is probably of  $C_s(3, 1, 0)$  origin; and (iii) the observation of two different dominant  $C_{4v}$  sites as well as the probable  $C_{2v}$  assignment of the 6891.9-Å(0-0) line by means of characteristic lifetimes. The complications of the site symmetry distribution by the presence of  $\text{O}^{2-}$  compensation emerge as a result of this investigation, which will be discussed in some detail.

## II. THEORETICAL FRAMEWORK

### A. ZAF Patterns of Allowed $\text{Sm}^{2+}$ Site Symmetries

In the free-ion state, the  $LS$  coupling scheme is usually considered as a good approximation for the  $\text{Sm}^{2+}$  ion. The  $|f^6 \alpha LSJM\rangle$  free-ion states, where  $\alpha$  denotes all other quantum numbers not specified, are employed as the zeroth-order wave functions in our problem. In a crystalline lattice, the crystal field potential contributes a term to the total Hamiltonian of the  $\text{Sm}^{2+}$  ion. The term is usually expanded as a series of spherical harmonics,

$$H_{\text{cf}} = \sum_{l, m, t} A_l^m r_l^t Y_l^m(\theta_l, \phi_l), \quad (1)$$

where the expansion coefficients  $A_l^m$  are determined by the position of the charge compensation in a complex of a given site symmetry. In terms of the Wigner-Eckart theorem, a typical matrix element of the crystal field perturbation matrix can be written<sup>8</sup>

$$\langle f^6 \alpha LSJM | \mathcal{H}_{\text{cf}} | f^6 \alpha SLJM' \rangle = B_l^m C_{M'M}^{J l J} (\alpha SLJ || Y_l || \alpha SLJ), \quad (2)$$

$$B_l^m = \langle r^l \rangle A_l^m,$$

where  $C_{M'M}^{J l J}$  is a Wigner coefficient and  $(\alpha SLJ || Y_l || \alpha SLJ)$  a reduced matrix element. The diagonalization of the crystal field perturbation matrix results in the crystal field states, provided that coefficients  $B_l^m$  are known.

If one assumes the point charge model, the crystal field expansion coefficients  $A_l^m$  are

$$A_l^m = (4\pi/2l+1) \sum_j (q_j e^2/R_j^l + 1) Y_l^{m*}(\theta_j, \phi_j), \quad (3)$$

where  $R_j$  is the distance between the  $j$ th ion and the central ion, the sum extends over all the ions of the lattice, and  $q_j$  is the effective charge of the  $j$ th ion. The point charge model, however, ignores effects arising from charge overlap, covalency, polarization of the lattice about the central ion, as well as the lattice distortion about the divalent cation-compensation pair. Equation (3) is thus often invalid, and the coefficients  $B_l^m$  are best treated as experimental parameters. When only one site symmetry exists or is assumed for the rare-earth ion, it is possible to identify the representation origin of a given transition through conventional spectroscopic techniques such as polarization and group theoretical selection rules, and diagonalization of the  $\mathcal{H}_{\text{cf}}$  matrix can be readily achieved by parameter fitting of the  $B_l^m$  coefficients.

In compensated lattices such as  $\text{KCl}:\text{Sm}^{2+}$  in which the fluorescence is made up of a superposition of  $\text{Sm}^{2+}$  fluorescence lines arising from various sites, the above procedure is not possible unless the site origin of each line is determined. The polarized excitation technique employed by Bron and Heller<sup>9</sup> in the determination of dipole origin, representation origin, and site origin is unique only for the 0-0 transition. For all the other transitions, it is necessary to assume the site origin or the polarization of the excitation, which is not justified in  $\text{KCl}:\text{Sm}^{2+}$ . One unique method for the determination of symmetry origin is the ZAF technique in which characteristic patterns of the angular dependence of energy shifts of the Zeeman components are readily recognizable for each of the site symmetries allowed for the  $\text{Sm}^{2+}$  ion due to geometric restrictions of the fcc KCl lattice.

Under an external magnetic field, an additional term must be added to the total Hamiltonian of the central  $\text{Sm}^{2+}$  ion in the form

$$\mathcal{H}_m = g_\lambda \mu_B H_0 [\cos \theta_H J_Z + \frac{1}{2} \sin \theta_H (e^{i\phi_H} J_- + e^{-i\phi_H} J_+)], \quad (4)$$

where  $\mu_B$  is the Bohr magneton,  $g_\lambda$  the Landé  $g$  factor,  $H_0$  the effective magnetic field strength,  $\theta_H$  the angle between the  $\vec{H}$  field and the  $Z$  axis, and  $\phi_H$  the corresponding azimuthal angle. In axial symmetries such as  $C_{2v}$ ,  $C_{3v}$ , and  $C_{4v}$ ,  $Z$  is taken to be the rotational  $C$  axis. In  $C_s$  symmetries  $Z$  is taken to be the axis  $\perp$  to the reflection ( $XY$ ) plane. In  $\text{KCl}:\text{Sm}^{2+}$  there are, in all, six types of site symmetries in  $\text{K}^+$  vacancy compensation:  $C_{2v}$ ,  $C_{3v}$ ,  $C_{4v}$ ,  $C_s(\text{I})$ ,  $C_s(\text{II})$ , and  $C_1$  which are typified by the  $C_{2v}(1, 1, 0)$ ,  $C_{3v}(2, 2, 2)$ ,  $C_{4v}(2, 0, 0)$ ,  $C_s(2, 1, 1)$ ,  $C_s(3, 1, 0)$ , and  $C_1(3, 2, 1)$   $\text{Sm}^{2+}$ - $\text{K}^+$  vacancy pairs, respectively. The ZAF patterns for  $C_{2v}$ ,  $C_{4v}$ , and  $C_s(\text{I})$  have been described previously.<sup>3,5</sup> Here, we shall consider the theoretical patterns of the  $C_{3v}$  and  $C_s(\text{II})$  sites, which are shown in Fig. 1 along with the schematic ZAF patterns for  $C_{2v}$ ,  $C_{4v}$ ,  $C_s(\text{I})$ , and  $C_1$  sites. No detailed discussion for the  $C_1$  ZAF pattern will be

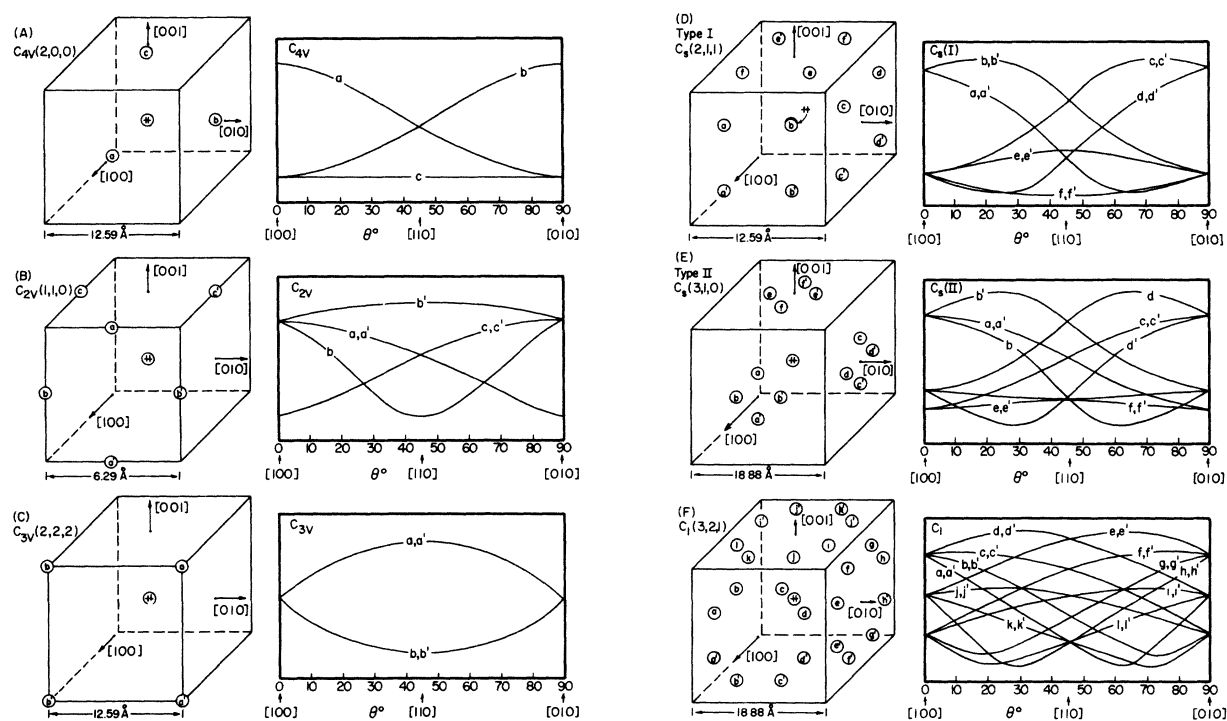

FIG. 1. Equivalent magnetically distinguishable vacancy sites and corresponding schematic ZAF patterns [with  $\vec{H}$  rotating in (001) plane] for the six typical  $\text{Sm}^{2+}$  site symmetries allowed for  $\text{K}^+$  vacancy compensation as exemplified by (a) three equivalent  $C_{4v}(2, 0, 0)$  sites, (b) six equivalent  $C_{2v}(1, 1, 0)$  sites, (c) four equivalent  $C_{3v}(2, 2, 2)$  sites, (d) twelve equivalent type-I  $C_s(2, 1, 1)$  sites, (e) twelve equivalent type-II  $C_s(3, 1, 0)$  sites, and (f) 24 equivalent  $C_1(3, 2, 1)$  sites. The ZAF patterns are deduced on the basis of a transition between two nondegenerate levels.

given in the text since it has not been observed in the present investigation or elsewhere.

For  $C_{3v}(2, 2, 2)$   $\text{Sm}^{2+}$ - $\text{K}^+$  vacancy pairs there are eight equivalent sites, four of which are shown in Fig. 1(c) at the corners of a face of a cube whose center is occupied by the  $\text{Sm}^{2+}$  ion. Each side of the cube measures  $4a$ , where  $a = 3.15 \text{ \AA}$  is the  $\text{K}^+$ -Cl<sup>-</sup> distance of separation. Since the magnetic field is invariant upon inversion, the  $[lmn]$  and  $[\bar{l}\bar{m}\bar{n}]$  crystal axes are equivalent, and the four remaining sites are indistinguishable from the four sites shown through an inversion of coordinates. With  $\vec{H} \parallel [100]$ , all the sites are equivalent, and only one line will arise from them. As  $\vec{H}$  is rotated towards  $[010]$  in the (001) plane, two lines arise due to the two sets of equivalent sites: (i)  $a, a'$ ; (ii)  $b, b'$ . These two lines will reach a maximum separation when  $\vec{H}$  is in the  $[110]$  direction and will merge back together with  $\vec{H}$  in the  $[010]$  direction. [See anisotropy pattern in Fig. 1(c).]

For the type-II  $C_s(3, 1, 0)$  site there are 24 equivalent sites. In Fig. 1(e), twelve of these sites are shown lying on three faces of a cube of  $(6a)^3$ . Each site lies  $+a$  or  $-a$  away from the center of a cube face in one of the six major crystal planes  $\{100\}$ . Again, the remaining twelve sites are obtained

through a coordinate inversion. With  $\vec{H}$  in the  $[100]$  direction there are three sets of equivalent sites: (i)  $a, a'$ ,  $b, b'$ ; (ii)  $d, d'$ ,  $f, f'$ ; and (iii)  $c, c'$ ,  $e, e'$  which give rise to three lines. As  $\vec{H}$  is rotated towards  $[010]$  in the (001) plane, there is splitting of the above three lines into eight lines corresponding to the eight sets of equivalent sites: (i)  $b'$ ; (ii)  $a, a'$ ; (iii)  $b$ ; (iv)  $d$ ; (v)  $f, f'$ ; (vi)  $d'$ ; (vii)  $c, c'$ ; and (viii)  $e, e'$ . When  $\vec{H} \parallel [110]$ , the pattern will merge into three lines according to the groups (i)  $b', d$ ; (ii)  $a, a', c, c'$ ; and (iii)  $b, d', e, e', f, f'$ . As  $\vec{H}$  rotates away from  $[110]$ , eight lines appear due to the same eight sets of equivalent sites as previously mentioned. Finally, when  $\vec{H}$  reaches  $[010]$ , the eight lines merge into three corresponding to the following sets of equivalent sites: (i)  $c, c', d, d'$ ; (ii)  $b, b', e, e'$ ; and (iii)  $a, a', f, f'$ .

It is important to realize that it is possible to identify experimental ZAF patterns according to the schematic patterns shown in Fig. 1 without ever having to solve the matrix equations involving the perturbation Hamiltonians of Eqs. (1) and (4). When the no-field line is intense and its Zeeman components well resolved, it is possible to determine its symmetry origin beyond any doubt. Difficulties arise when the ZAF patterns of two no-field lines

of comparable intensities overlap, particularly when a lower-symmetry (and thus more complicated) pattern is involved. Such difficulties are encountered in the case of the overlapping ZAF patterns of the 7693.5- and 7694.5-Å no-field lines in 0-3. Although the  $C_2(2, 1, 1)$  origin of one of the two lines was apparent,<sup>5</sup> an additional anisotropic Zeeman component was not satisfactorily accounted for. In a detailed analysis given in Sec. IV, we shall overcome these difficulties in arriving at the correct solution.

#### B. Characteristic Radiative Lifetimes

Lifetime measurements on rare-earth ions in ionic crystals have been reported by a number of authors in recent years.<sup>10-13</sup> Usually, these works focused on the temperature dependence or concentration dependence of the lifetimes. In the present work, we shall discuss the use of lifetime measurements as a tool for distinguishing the various symmetry types of  $\text{Sm}^{2+}$  in KCl.

Fluorescence of KCl:  $\text{Sm}^{2+}$  is observed upon optical pumping of the  $4f^5d$  bands, which lie at about  $15\,500\text{ cm}^{-1}$  above the  ${}^7F_0$  level. All the fluorescence lines arise from radiative decay from the  ${}^5D$  multiplet to the  ${}^7F$  multiplet. In general, the effective decay time for a group of  $n$  excited levels in a given site is given by

$$\frac{1}{\tau_{\text{eff}}} = \sum_{i=1}^n g_i A_i \exp\left(\frac{E_1 - E_i}{kT}\right) / \sum_{i=1}^n g_i \exp\left(\frac{E_1 - E_i}{kT}\right), \quad (5)$$

where  $A_i$  is the total Einstein spontaneous-emission probability from the  $i$ th level to all lower levels, and  $g_i$  is the degeneracy of the  $i$ th level. Here, we have assumed that a Maxwell-Boltzmann distribution of the  $n$  excited levels is achieved through rapid phonon processes and that there are no nonradiative transitions to the ground levels. In KCl:  $\text{Sm}^{2+}$  all the radiative decay processes probably initiate from the  ${}^5D_0$  level at 4.2 K,<sup>9</sup> and Eq. (1) simplifies to

$$1/\tau_{\text{eff}} = \sum_J A(0, J) = 64\pi^4(3h)^{-1} \sum_J \nu_{0J}^3 S(0, J), \quad (6)$$

where 0 and  $J$  are the symmetrized crystal states of  ${}^5D_0$  and  ${}^7F_J$  levels in  $\text{Sm}^{2+}$ , respectively,  $\nu_{0J}$  is the frequency of the transition  $0 \rightarrow J$ , and

$$S(0, J) = \sum |\langle \alpha | \vec{V} | \beta \rangle|^2$$

gives the line strength between the two states 0 and  $J$ . Here,  $\alpha$  and  $\beta$  are the components of the symmetrized crystal states 0 and  $J$ , respectively, and  $\vec{V}$  is usually either the magnetic ( $\vec{M}$ ) or the electric ( $\vec{P}$ ) dipole moment operator given by

$$\vec{M} = -e(2mc)^{-1} \sum_i (\vec{L}_i + 2\vec{S}_i)$$

and

$$\vec{P} = -e \sum_i \vec{r}_i,$$

where  $e$  is the electronic charge of the electron and  $m$  is the mass of the electron. For electric dipole transition moments, only opposite parity components of 0 and  $J$  give rise to nonvanishing contributions, while magnetic dipole transition moments arise from matrix elements connecting free-ion states within the  $4f^6$  ground configuration. Since 0 and  $J$  are unique for a given  $\text{Sm}^{2+}$  site according to  $\mathcal{K}_{\text{cr}}$  in Eq. (1), it follows that each type of  $\text{Sm}^{2+}$  site must possess a distinct and characteristic effective radiative decay lifetime. The important experimental handle on the problem of site distribution which emerges from the above argument is that if a given  $\text{Sm}^{2+}$  ion site radiatively decays through several fluorescence transitions, its effective decay time can be determined by monitoring any one of these fluorescence transitions. Conversely, if the characteristic radiative decay lifetimes of the various  $\text{Sm}^{2+}$  symmetry species are known, it is in principle feasible to determine the symmetry origin of any fluorescence transition by measuring its effective decay time and matching it with one of the known characteristic lifetimes. In general, even if the decay process is not purely radiative, and  $1/\tau_{\text{eff}}$  is the sum of all the decay probabilities, radiative and otherwise, the lifetime is still characteristic of the site symmetry. These ideas will be further developed in the following sections as we describe the lifetime measurements and their interpretations.

#### III. EXPERIMENTAL PROCEDURE

KCl:  $\text{Sm}^{2+}$  crystal samples were grown in a  $\text{H}_2$  atmosphere using the Czochralski technique.<sup>14</sup> An EDTA analysis was carried out to show that the crystals contained  $3.6 \times 10^{18}$  ( $\text{Sm}^{2+}$  ions)  $\text{cm}^{-3}$ . All spectra were measured spectrographically at 4.2 K. A 600-W tungsten-halogen lamp was used to pump in the 3800-6000-Å broad bands. The crystal sample was suspended in a narrow Dewar tip and submerged in liquid He. For low magnetic fields (up to 26.5 kG) a Varian V-3900 12-in. low-impedance electromagnet with a  $1\frac{1}{4}$ -in. gap was used. The 4.2 K anisotropy and low field dependence spectra were taken on a 2-m Jarrell-Ash (model 75-174) spectrograph with a grating (102 mm  $\times$  102 mm, 1180 g/mm) blazed at  $1.0\ \mu$ . The spectra were recorded on Eastman Kodak N and hypersensitized M plates. Higher field measurements were made at the Francis Bitter National Magnet Laboratory employing a 2-m Bausch and Lomb grating spectrograph. Reading of the photoplates was accomplished by means of a direct scanning Grant-Daytex comparator microdensitometer which was coupled to a Varian Statos I (model 150) electrostatic recorder. The comparator has a reproducibility of  $\pm 0.25\ \mu$  and is equipped with both a viewing screen and a split-im-

age oscilloscope display which enhances speed and accuracy of photoplate alignment. A photomultiplier takes transmittance ( $T$ ) data and presents them as density values  $(1 - T)$ .<sup>15</sup> Reproducibility was in most cases better than  $0.05 \text{ \AA}$ .

In lifetime measurements, the crystal was pumped with the light from an EGG FX-12 flashlamp. The resulting fluorescence at  $4.2 \text{ K}$ , passed through a  $0.25\text{-m}$  Jarrell-Ash grating monochromator, was registered on a photomultiplier tube (RCA 7265) with an S-20 response. The signal was recorded photographically from an oscilloscope trace. A combination of blue and red filters prevents the pump light from entering the monochromator.

#### IV. EXPERIMENTAL RESULTS AND INTERPRETATIONS

The  $\vec{H} \parallel [100]$  field dependence (up to  $55.8 \text{ kG}$ ) of the Zeeman components from  $0 \rightarrow 3$  transitions in the  $7690\text{--}7702\text{-\AA}$  region is shown in Fig. 2. The salient features of Fig. 2 are (i) The strong (s) zero-field  $7694.5\text{-\AA}$  line splits into two Zeeman components, the shorter wavelength of which crosses over the very strong (vs) line (originating from the  $7693.5\text{-\AA}$  zero-field line) at  $21.6 \text{ kG}$ . (ii) The  $7693.5\text{-\AA}$  line appears to remain as a single component. The very weak (vw) line which appears on its long-wavelength side at fields higher than  $30 \text{ kG}$

FIG. 2. Field dependence ( $\vec{H} \parallel [100]$ ) of the Zeeman components of the no-field ( $0 \rightarrow 3$ ) lines at  $7692.9$ ,  $7693.5$ ,  $7694.5$ , and  $7697.0 \text{ \AA}$ . Intensities are indicated by S = strong, M = medium, W = weak, VW = very weak, and VVW = very very weak. The dashed lines indicate extrapolations to zero field. The open circles indicate that the values correspond to the  $0^\circ$  values of the  $26.5\text{-kG}$  ZAF patterns in Fig. 4.

FIG. 3.  $4.2 \text{ K}$  fluorescence lines in the  $7693\text{--}7695.5\text{-\AA}$  region: no-field and  $\vec{H}$  ( $26.5 \text{ kG}$ ) at  $0^\circ$ ,  $10^\circ$ ,  $20^\circ$ ,  $30^\circ$ ,  $40^\circ$ , and  $45^\circ$  from  $[100]$  in the  $(001)$  plane. Arrows correspond to points plotted in the ZAF patterns of Fig. 4.

most probably originates from the weak no-field at  $7692.9 \text{ \AA}$ . (iii) The lines which appear in the long-wavelength region ( $> 7695 \text{ \AA}$ ) exhibit notable field dependence in their intensities. Their no-field origin is not observed due to vanishingly low intensities. The field dependence of the Zeeman components makes possible an extrapolation to a single no-field origin at  $7697.0 \text{ \AA}$ .

The anisotropic Zeeman splitting (at  $H = 26.5 \text{ kG}$ ) behavior of the two strong no-field lines at  $7693.5$  and  $7694.5 \text{ \AA}$  is shown in Fig. 3. Here  $\vec{H}$  is rotated in the  $(001)$  plane, and angular dependence of the Zeeman components are shown with  $\vec{H}$   $0^\circ$ ,  $10^\circ$ ,  $20^\circ$ ,  $30^\circ$ ,  $40^\circ$ , and  $45^\circ$  away from  $[100]$ . The corresponding peak positions of the resolved lines are plotted against the angle of  $\vec{H}$  rotation in Fig. 4.

With  $\vec{H} \parallel [100]$  ( $H = 26.5 \text{ kG}$ ) three Zeeman components are observed at  $7693.0_4$ ,  $7693.4_8$ , and  $7694.8_8 \text{ \AA}$ . They are shown as open circles in Fig. 2. It is clear from this comparison that the components

FIG. 4. Overlapping  $C_s(\text{I})$  and  $C_{3v}$  26.5-kG ZAF patterns observed for the  $0 \rightarrow 3$  no-field lines (indicated by arrows) at 7694.5 and 7693.5 Å, respectively, with  $\vec{H}$  rotated in the (001) plane.

at 7693.0<sub>4</sub> and 7694.8<sub>8</sub> Å belong to the 7694.5-Å no-field line, a crucial piece of information not available to us without the field dependence data given in Fig. 2. The 7693.4<sub>6</sub>-Å component ( $0^\circ$ ) arises from the 7693.5-Å no-field. In view of its lack of splitting with  $\vec{H} \parallel [100]$  (Fig. 2), it is most probably due to a singlet transition of  $C_{3v}$  origin. [See ZAF pattern in Fig. 1(c).] Upon angular rotation of the magnetic field, it splits into two subcomponents (Figs. 3 and 4), giving rise to a ZAF pattern that is immediately recognizable as a  $C_{3v}$  pattern [Fig. 1(c)]. The  $0^\circ$  component at 7694.8<sub>8</sub> Å splits into three subcomponents as the field angle increases. The  $0^\circ$  component at 7693.0<sub>4</sub> Å must merge into the component at 7694.8<sub>8</sub> Å after  $90^\circ$  rotation of  $\vec{H}$  since both of these two components arise from the same no-field origin (Fig. 2). With this information we readily arrive at the experimental ZAF pattern [which agrees perfectly with the  $C_s(\text{I})$  schematic pattern shown in Fig. 1(d)] arising from the 7694.5-Å no-field line by simply connecting the points observed in addition to these assigned to the  $C_{3v}$  pattern arising from the 7693.5-Å line.

The angular dependence of the Zeeman components (at  $H = 24.5$  kG) in the 7696–7700-Å region ( $0 \rightarrow 3$ ) is shown in Fig. 5(a). These weak Zeeman components arise from a single no-field line which is manifested through extrapolation from field dependence data in Fig. 2. When a single no-field line splits into three components with  $\vec{H} \parallel [100]$ , it must be of either  $C_s(\text{II})$  or  $C_1$  symmetry origin [see Figs. 1(e) and 1(f)]. Although several weak components are missing, a  $C_s(\text{II})$  interpretation of the observed lines gives a reasonable representation of the experimental data. In Fig. 5(b) we present evidence for the observation of a very weak  $C_{3v}$  ZAF pattern which arises from the weak no-field line at 8742.8 Å ( $0 \rightarrow 5$ ).

Because of apparatus limitations, lifetime mea-

surements are restricted to dominant lines in  $0 \rightarrow J$  transitions with  $J \leq 4$ . In addition to the narrow-line  $0 \rightarrow J$  transitions, broad-band transitions are also observed. Typically, the broad-band fluorescence (probably  $d \rightarrow f$ ) lifetimes ( $\sim 10^{-1}$  msec) were observed to be orders of magnitude shorter than those ( $\sim 10$  msec) of the narrow-line fluorescence. The results of lifetime measurements on dominant  $0 \rightarrow J$  lines are given in Table I, along with the corresponding symmetry identifications. The lifetimes have been determined from least-squares fits of exponentials to oscilloscope traces and are given in Table I as averages of three or four trials, along with their standard deviations.

We have found two  $C_{4v}$  lifetimes:  $\sim 9.5$  msec at 7282.8 Å ( $0 \rightarrow 2$ ) and 8204.9 Å ( $0 \rightarrow 4$ );  $\sim 11.2$  msec at 7304.6 Å ( $0 \rightarrow 2$ ). This finding is in agreement with the earlier conclusion<sup>6,7</sup> from ZAF investigations that at least two dominant  $C_{4v}$  sites, most probably the  $C_{4v}(2, 0, 0)$   $\text{Sm}^{2+}$ - $\text{K}^+$  vacancy pair and the  $C_{4v}(1, 0, 0)$   $\text{Sm}^{2+}$ - $\text{O}^{2-}$  pair, are present.

The two lines at 7048 Å ( $0 \rightarrow 1$ ) and 7327.8 Å ( $0 \rightarrow 2$ ) do not give discernible ZAF patterns at magnetic

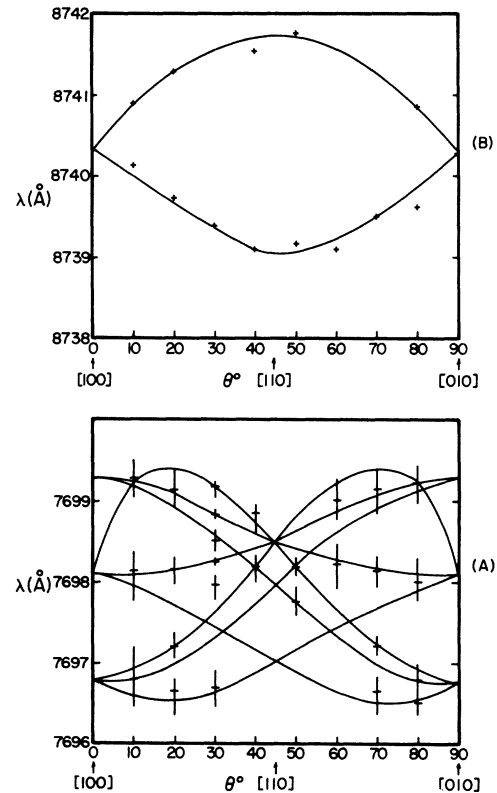

FIG. 5. 4.2 K ZAF patterns with  $\vec{H}$  rotated in (001) plane: (a) 24.5-kG  $C_s(\text{II})$  ZAF pattern for the weak  $0 \rightarrow 3$  transition in the 7696–7700-Å region; and (b) 26.5-kG  $C_{3v}$  ZAF pattern for the weak  $0 \rightarrow 5$  transition in the 8739–8742-Å region.

TABLE I. Symmetry origin determinations of dominant 4.2 K fluorescence lines in KCl:Sm<sup>2+</sup>.

Transition	$\lambda(\text{\AA})$	$\text{cm}^{-1}$	Lifetime (msec)	Symmetry	References on symmetry	Comments
0→0	6891.9	14 509.8	10.2±0.2	$C_{2v}$	Present work	0.16-cm <sup>-1</sup> blue shift at 93.5 kG; no discernible ZAF pattern.

0→5	8778.4	11 391.6		$C_s(I)$	5	ZAF pattern observed at 26.5 kG is not well resolved.
0→6	9439.1	10 594.2		$C_{4v}$	3	Resolved ZAF patterns at 26.5 kG.
	9440.0	10 593.2		$C_{4v}$		

fields up to 93.5 kG.<sup>7</sup> However, their lifetimes show that they arise from either  $C_{2v}$  or  $C_s$  sites, which are indistinguishable within the experimental error.

The  $J=0$  lines contain a dominant component at 6891.9 Å and a weaker component at 6890.7 Å.<sup>7</sup> Their combined effective decay time is 10.2 msec, which lies on the low side of the lifetime range observed (Table I) for known  $C_{2v}$  lines. If we assume the empirical  $\Delta J$  odd selection rule<sup>7</sup> for the  $C_s$  site (dominant  $C_s$  lines are observed only in 0→1, 3, and 5 transitions), the 6891.9-Å (0→0) line is of  $C_{2v}$  origin. This assignment is consistent with the polarized excitation experiment by Bron and Heller,<sup>9</sup> which is unique only for the 0→0 transition.

#### V. DISCUSSION

By means of detailed ZAF analyses and lifetime measurements, we have brought the study of 4.2 K KCl:Sm<sup>2+</sup> fluorescence to a reasonable state of

completion. In an initial paper<sup>3</sup> on ZAF spectroscopic investigation into KCl:Sm<sup>2+</sup>, the dominant transitions in 0→6 and 0→4 were found to be of  $C_{4v}$  symmetry origin, which raised serious doubts to the single  $C_{2v}(1,0,0)$  complex spectroscopic analysis made by Bron and Heller<sup>9</sup> for the same system. A statistical mechanical calculation<sup>1</sup> was subsequently made for an idealized system of divalent cations charge compensated by K<sup>+</sup> vacancies. It was predicted<sup>1</sup> that a distribution of site symmetries must exist and that the third-nearest-neighbor  $C_s(2,1,1)$  site is of great prominence in this distribution, which was confirmed<sup>5</sup> by experimental ZAF observations. Of the fourteen dominant fluorescence transitions, ten have been shown in these previous papers<sup>3-7</sup> to arise from  $C_{4v}$ ,  $C_s(I)$ , and  $C_{2v}$  sites. The symmetry origins of the remaining four lines have been determined in the present work. Results of the various symmetry determinations are tabulated in Table I.

The problem of overlapping ZAF patterns such as those arising from the 7693.5- and 7694.5-Å lines has been dealt with in the preceding paragraphs. There exists still another difficulty which complicates the problem of line symmetry assignment: missing lines in an otherwise well-resolved ZAF pattern. For example, if the isotropic line due to site *c* [Fig. 1(a)] is missing from the  $C_{4v}$  ZAF pattern, the resulting pattern becomes indistinguishable from a  $C_{2v}$  pattern with the latter pattern's lines due to sites *b* and *b'* [Fig. 1(b)] missing. A  $C_s(I)$  pattern [Fig. 1(d)] with the lines due to sites *b*, *b'*, *c*, and *c'* missing could be mistaken for a somewhat distorted  $C_{2v}$  pattern. A  $C_{2v}$  pattern with the lines due to sites *a*, *a'*, *c*, and *c'* missing gives the appearance of a distorted  $C_{3v}$  pattern. These complications are exemplified by the  $C_{4v}$  ZAF pattern of the dominant line at 8204.9 Å (0–4) in which the isotropic line is not observed. Its  $C_{4v}$  symmetry assignment now appears correct in view of the observed lifetime ( $9.7 \pm 0.8$  msec) associated with it, which is in good agreement with the lifetime ( $9.5 \pm 0.5$  msec) associated with the 7282.8-Å (0–2) line for which a definitive  $C_{4v}$  ZAF pattern was observed at 93.5 kG. The  $C_{4v}$  pattern of the line at 7304.6 Å also has its isotropic line missing. Its  $C_{4v}$  assignment is again ascertained by the lifetime measurement; the associated characteristic lifetime is  $11.2 \pm 0.4$  msec which lies outside the range of lifetimes given for all the  $C_{2v}$  lines (see Table I). The possible observation of a dominant  $C_{2v}$  line due to a second  $C_{2v}$  site other than  $C_{2v} \times (1, 1, 0)$  vacancy pair is very unlikely due to the fact that the probability of finding the  $C_{2v}(2, 2, 0)$  vacancy pair is negligibly small<sup>1</sup> and that  $O^{2-}$  ion compensation does not give rise to  $C_{2v}$  sites.

The observation of two dominant tetragonal sites by lifetimes,  $C_{4v}(I)$  with  $\tau_{eff} \sim 9.5$  msec and  $C_{4v}(II)$  with  $\tau_{eff} \sim 11.2$  msec, gives strong support to the earlier conclusion that  $O^{2-}$  compensation of  $Sm^{2+}$  must be present in KCl:  $Sm^{2+}$  giving rise to a second site distribution with the  $O^{2-}$  ion (associated with the divalent cation) occupying various possible inequivalent lattice points in the  $Cl^-$  sublattice. The role of  $O^{2-}$  in charge compensation is further manifested in the observation of the dominant  $C_{3v}$  line at 7693.5 Å. According to the statistical calculation,<sup>1</sup> the sixth-nearest-neighbor  $C_{3v}(2, 2, 2)$  vacancy pair is quite improbable at ordinary room temperatures from which the samples are quenched to cryogenic temperatures for spectroscopic measurements. The observation of a very weak  $C_{3v}$  ZAF pattern such as the one shown in Fig. 5(b) might be attributed to the  $C_{3v}(2, 2, 2)$  site. The observation of the  $C_{3v}$  line at 7693.5 Å, the most dom-

inant line in 0–3, however, can only be interpreted in terms of the observation of the  $C_{3v}(1, 1, 1)$   $Sm^{2+}-O^{2-}$  pair, which corresponds to the second-nearest-neighbor pair in the  $O^{2-}$  compensation site distribution.

Although the earlier  $C_s(I)$  assignment<sup>5</sup> of the no-field line at 7694.5 Å is confirmed in the present paper, the  $C_s(I)$  ZAF pattern given in Fig. 4 differs in one important detail from that given<sup>5</sup> in the earlier paper: The  $0^\circ$  Zeeman component at 7693.04 Å [Figs. (3) and (4)] was previously attributed<sup>5</sup> to the no-field line at 7693.5 Å while that at 7693.48 Å was thought to belong to the  $C_s$  pattern. In Sec. IV of the present paper, we have conclusively shown (Figs. 2–4) that such is not the case. We have thus demonstrated the importance of the field dependence data (Fig. 2) in tracing the origin of a ZAF pattern, particularly when overlapping patterns are involved.

The positive confirmation of the  $C_s(I)$  pattern is of importance, since the prominent presence of the  $C_s(2, 1, 1)$   $Sm^{2+}-K^+$  vacancy pair represents a crucial feature of the vacancy pair distribution theory.<sup>1,5</sup> If the weak  $C_s(II)$  and  $C_{3v}$  patterns shown in Fig. 5 correspond to the observations of the fifth and sixth nearest neighbors  $C_s(3, 1, 0)$  and  $C_{3v}(2, 2, 2)$   $Sm^{2+}-K^+$  vacancy pairs, respectively, the ZAF technique is apparently capable of detecting the perturbing influences of the vacancy on the  $Sm^{2+}$  ion even when the  $Sm^{2+}$  vacancy-separation distance is as large as  $\sim 10$  Å. It is interesting to note that in the electron spin resonance studies on (alkali halide):  $Mn^{2+}$  systems,<sup>16</sup>  $Mn^{2+}$  vacancy pairs beyond the second nearest neighbors were collectively observed as "cubic" sites.

In conclusion, we have definitively shown by means of several spectroscopic methods (ZAF, field dependence, and characteristic lifetime measurements) that a distribution of  $Sm^{2+}$  sites exists in KCl. We have further shown that in addition to  $K^+$  vacancies, apparently  $O^{2-}$  ions participate in the charge compensation of the  $Sm^{2+}$  ions. The method outlined<sup>1</sup> for the divalent cation-vacancy pair distribution can be readily extended to include the presence of  $O^{2-}$  ions in the  $Cl^-$  sublattice. The problem of compensated lattices is thus well defined within the scope of our investigations.

#### ACKNOWLEDGMENTS

We wish to acknowledge the generous help of the management of Francis Bitter Magnet Laboratory where the high-field spectrographic plates were taken (by James C. Bellows). We are grateful to the National Institute of Health for a grant with which the 2-m Jarrell-Ash spectrograph was purchased.

## Experimental and Theoretical Study of the Low-Lying Energy-Level Structure of $\text{Sm}^{3+}$ in $\text{CaF}_2$

H. Nara\* and M. Schlesinger

*Department of Physics, University of Windsor, Windsor 11, Ontario, Canada*

(Received 3 August 1970)

The optical spectrum exhibited by the  $\text{Sm}^{3+}$  ion in  $\text{CaF}_2$  is analyzed assuming both octahedral and trigonal site symmetries. Calculations were performed using a tensor operator technique in the complete intermediate-coupling scheme. The crystal field parameters and the root-mean-square (rms) deviations obtained are  $B^{(4)} = -906 \text{ cm}^{-1}$  and  $B^{(6)} = 618 \text{ cm}^{-1}$ , with rms deviations of  $48.1 \text{ cm}^{-1}$  for the octahedral site symmetry;  $B_0^{(2)} = 118 \text{ cm}^{-1}$ ,  $B_0^{(4)} = -272 \text{ cm}^{-1}$ ,  $B_3^{(4)} = -296 \text{ cm}^{-1}$ ,  $B_0^{(6)} = 38 \text{ cm}^{-1}$ ,  $B_4^{(6)} = -128 \text{ cm}^{-1}$ , and  $B_6^{(6)} = 1556 \text{ cm}^{-1}$ , with rms deviation of  $35.4 \text{ cm}^{-1}$  for the trigonal site symmetry. It is suggested that the sample on which the measurements were carried out contains  $\text{Sm}^{3+}$  ions occupying both octahedral and trigonal symmetry sites. It is also shown that crystal field theory with a single set of  $B_q^{(k)}$  parameters is quite adequate to describe the energy levels lying below  $11\,000 \text{ cm}^{-1}$ , above which a fairly large energy gap follows.

### I. INTRODUCTION

The optical absorption, fluorescence, and paramagnetic resonance spectra of  $\text{Sm}^{3+}$  in  $\text{CaF}_2$  have been investigated by several authors.<sup>1-3</sup> In particular, Rabiner<sup>2</sup> investigated the fluorescence of  $\text{Sm}^{3+}$  in  $\text{CaF}_2$  at tetragonal site symmetry and gave a theoretical interpretation.

The  $\text{CaF}_2:\text{Sm}^{3+}$  system is of special interest as the strength of the crystal field is believed to be comparable to that of the spin-orbit interaction. This situation suggests that, in analyzing the experimental spectra, one should treat the system on the basis of the complete intermediate-coupling scheme. Fortunately, very accurate free-ion energy eigenvectors<sup>4</sup> are now available, and this treatment is possible in principle. This treatment, however, requires that very large matrices be diagonalized.

A fairly large energy gap of about  $7500 \text{ cm}^{-1}$  separates the lower-lying levels from higher ones. Crystal field matrix elements between the lower and upper groups of levels are small compared with the gap of  $7500 \text{ cm}^{-1}$ , and may be neglected. The

lower group of levels may then be treated separately. Therefore one can work with matrices of considerably smaller dimensions, enabling one to perform the calculations of the type above.

Since the  $\text{Sm}^{3+}$  ion substitutes for  $\text{Ca}^{2+}$  ions in the  $\text{CaF}_2$  crystal, there must be some kind of charge compensator so as to preserve charge neutrality. The actual site symmetry of the  $\text{Sm}^{3+}$  in the  $\text{CaF}_2$  matrix will depend on the charge compensation mechanisms, which in turn depend on type and amount of impurities, growing conditions, thermal history, etc. Three main site symmetries<sup>5</sup> are possible for  $\text{Sm}^{3+}$  in  $\text{CaF}_2$ , namely, octahedral ( $O_h$ ), tetrahedral ( $C_{4v}$ ), and trigonal ( $C_{3v}$ ) symmetries. Careful study of the influence of heat treatments<sup>3</sup> along with theoretical calculations enables one to classify the lines in the spectra according to their site symmetries. The heat treatment technique, however, is not practical for absorption lines lying below about  $11\,000 \text{ cm}^{-1}$  because of opaque milkiness which is introduced in the crystals as a result of heat treatment. In this paper, where we are primarily concerned with the energy region up to  $11\,000 \text{ cm}^{-1}$ , we shall at-
