(Received 31 August 2005; revised manuscript received 10 February 2006; published 28 March 2006)

Based on the fact that ionicity exists in chemical bonds between identical atoms in  $\alpha$ -boron, investigation has been performed on the influences of  $X$  atoms on the ionicities of B-B bonds in  $B_{13}C_2$ -like structured  $B_yX$  ( $X=C, N, O, P, \text{ and } As$ ) compounds. For the four types of B-B bonds in the  $B_{12}$  icosahedra of the  $B_yX$  compounds, their overlap population  $P$ , population ionicity  $f_h$ , and Phillips ionicity  $f_i$  have been calculated. Comparing to the overlap population  $P_c$  value for the structure of the regular  $B_{12}$  icosahedron, the difference between  $P$  and  $P_c$  in the distorted  $B_{12}$  icosahedron and its origin have been discussed. Our results have shown that the charge transfer occurs between  $B_p$  and  $B_e$  atoms in the distorted  $B_{12}$  icosahedra of  $B_yX$  crystals, different from the  $\alpha$ -boron. Electronegativity of the  $X$  atom in  $B_yX$  crystals plays an important role in the ionicities of B-B bonds in the icosahedra. Among the five investigated  $B_yX$  crystals, the largest ionicity of 0.449 has been found to exist in the  $B_p$ - $B_e$  bond in the  $B_6O$  crystal, which is comparable to that found in AlN. By taking into account the effect of the ionicities of B-B bonds in the  $B_{12}$  icosahedra on hardness, the calculated hardness is in agreement with the experimental values for  $B_6O$  and  $B_{13}C_2$ . In addition, the calculations of hardness indicate that  $B_6N$  is a potential superhard material, but  $B_6P$  and  $B_6As$  are not.

**I. INTRODUCTION**

As a basic concept for description of the spatially asymmetric charge distribution between two bonded atoms, the ionicity has been broadly used to interpret some essential characters in solid-state physics and chemistry. The ionicity scale, which was developed by Phillips<sup>1</sup> and Van Vechten<sup>2</sup> based on dielectric theory, leads to the successful employment of ionicity in a wide variety of studies on crystal structures and band structures,<sup>1-3</sup> nonlinear optical susceptibilities,<sup>4</sup> ultraviolet reflectance, and valence band photoemission.<sup>5</sup>

Generally, the ionicity is considered to exist only in the chemical bond formed by two different kinds of atoms with the occurrence of charge transfer between them. However, first-principles calculations by He *et al.*<sup>6</sup> have shown that in the  $B_{12}$  icosahedra of  $\alpha$ -rhombohedral boron ( $\alpha$ -B), there exist ionicities in B-B bonds in spite of no charge transfer between the two boron atoms. Using a new ionicity scale (population ionicity scale), they have found that the maximum ionicity in the B-B bonds can be as large as 0.359. By taking into account the ionicity of every B-B bond in the  $B_{12}$  icosahedra and its effect on hardness, they have calculated the hardness of  $\alpha$ -B, which is in good agreement with the experimental value. Thus, the ionicity could be obtained indirectly by the measurement of the hardness.

Boron-rich solids include those allotropes formed completely by elementary boron and compounds containing boron element. With the common building element of the distorted  $B_{12}$  icosahedron, boron-rich compounds exhibit similar crystal structures. Recently, the  $B_{13}C_2$ -like structured boron-rich compounds  $B_yX$  ( $X=Be, C, N, O, Si, S, P, As, \text{ and } Se$ ) have attracted considerable interest because of their po-

tential excellent physical and chemical properties such as great hardness, low mass density, high mechanical strength, high thermal conductivity, excellent wear resistance, and high chemical inertness.<sup>7-11</sup> In particular, boron carbide and boron suboxide are found to be superhard materials with hardness higher than 40 GPa.<sup>11,12</sup> These crystals are made up of the  $B_{12}$  icosahedra and the  $X$ -B- $X$  with  $X=C$  (see Refs. 13 and 14) or  $X$ - $X$  chains with  $X=N, O, P, \text{ and } As$ .<sup>7,9,12</sup> For the  $\alpha$ -B, the ratio of  $c/a$  is 2.55. The introduction of  $X$  atom into the  $B_yX$  crystals leads to the decrease of  $c/a$ , depending on the size of the introduced atom.<sup>7</sup> The larger is the radius of the introduced  $X$  atom, the larger is the decrease of  $c/a$ , thus giving rise to the larger distortion of  $B_{12}$  icosahedron in  $B_6X$ , and different ionicities among B-B bonds in the  $B_{12}$  icosahedron than in the  $\alpha$ -B. Since the physical and chemical properties of crystals are directly related to the characteristics of their chemical bonds, it is important to investigate in detail the effects of the  $X$  atoms on the ionicities of B-B bonds in the  $B_{12}$  icosahedron. In the present work, first-principles calculations have been performed to investigate the effects of  $X$  ( $=C, N, O, P, \text{ and } As$ ) atoms on the ionicities of B-B bonds in  $B_{12}$  icosahedron of five selected  $B_yX$  crystals. Based on the microscopic model of hardness<sup>15</sup> and the obtained ionicities, hardness has been calculated finally for all the five crystals. These results would offer a helpful guide to the future experimental determinations of the boron content and the structures of  $B_yBe, B_ySi, B_yS, \text{ and } B_ySe$ .

**II. METHODS OF CALCULATION**

The first-principles calculations are performed with CASTEP code based on the density functional theory (DFT).<sup>16</sup> The ultrasoft Vanderbilt potentials are used and

the exchange-correlation terms were considered by the Perdew-Berke-Ernzerhof form of the generalized gradient approximation. During the structural optimization, the plane-wave cutoff energy  $E_{\text{cut}}$  (see Ref. 17) is chosen to be 380 eV, and Brillouin zone sampling is performed using a  $6 \times 6 \times 6$  Monkhorst-Pack grid.<sup>18</sup> The structural optimization is performed until the energy change of per atom is less than  $5 \times 10^{-6}$  eV, the forces on atoms are less than 0.01 eV/Å, and all the stress components are less than 0.02 GPa. Mulliken overlap populations were integrated by a distance cutoff of 3 Å. The spin polarized DFT and smearing electronic temperature are used in the calculations of  $\text{B}_{13}\text{C}_2$ .

The calculated Mulliken overlap populations of the B-B bonds in the  $\text{B}_{12}$  icosahedra were used to estimate their ionicity values via the population ionicity scale, which is defined as<sup>6</sup>

$$f_h = 1 - e^{-|P_c - P|/P}, \quad (1)$$

where  $f_h$  is the population ionicity,  $P$  is the overlap population of a bond,  $P_c$  is the overlap population of a bond in a pure covalent crystal with specific coordinate structure or cluster. For the selected 20 known crystals with the zinc blend structure and different overlap population  $P$ , a generalized relation of  $f_h = f_i^{1.36}$  between  $f_h$  and Phillips scale  $f_i$  was obtained in Ref. 6. In the calculations of the hardness and comparison of the ionicities of B-B bonds in the  $\text{B}_{12}$  icosahedron of the five  $\text{B}_y\text{X}$  crystals to those of the chemical bonds in the known crystals, for convenience, the characterization of the ionicity in the present paper was still performed by the Phillips ionicity  $f_i$  converted by the relation with  $f_h$ .

For the chemical bonds outside the  $\text{B}_{12}$  icosahedron, their ionicities were estimated by using Eq. (22b) in Ref. 3:

$$f_i = \frac{(b\Delta Z/4.8)^2}{[1 + (b\Delta Z/4.8)^2]}, \quad (2)$$

where  $\Delta Z$  is the difference of the valence electrons between the two atoms forming the bond, and  $b$  is a coefficient constant that can be estimated by

$$b = (0.089 \pm 10\%)N_c^2, \quad (3)$$

where  $N_c$  is the average coordination number of the two atoms constructing the bond.

### III. IONICITIES OF THE B-B BONDS IN $\text{B}_{12}$ ICOSAHEDRA OF $\text{B}_y\text{X}$ CRYSTALS

The  $\text{B}_{13}\text{C}_2$ -like structured boron-rich compounds  $\text{B}_y\text{X}$  usually have the structures similar to the  $\alpha$ -B. Their common structural character is that they are mainly composed of the  $\text{B}_{12}$  icosahedra network. As shown in Fig. 1(a), the  $\alpha$ -B is constructed with the  $\text{B}_{12}$  icosahedra located at the vertexes of a rhombohedral unit cell.  $\text{B}_4\text{C}$  and  $\text{B}_{13}\text{C}_2$  are the two typical rhombohedral boron carbide compounds in the boron-carbon system. As shown in Fig. 1(b), the accepted structure of  $\text{B}_{13}\text{C}_2$  is built with the  $\text{B}_{12}$  icosahedra clusters linked by a C-B-C chain along the main diagonal of the rhombohedron.

FIG. 1. Structures of  $\alpha$ -B (a), the boron-rich compounds of  $\text{B}_{13}\text{C}_2$  (b) and  $\text{B}_6\text{X}$  ( $X=\text{N}, \text{O}, \text{P}$ , and  $\text{As}$ ) (c). The white spheres represent  $\text{B}_p$  atoms located at the polar sites, and the gray ones are  $\text{B}_e$  atoms at the equatorial sites in a  $\text{B}_{12}$  icosahedron. The black spheres are C or X ( $X=\text{N}, \text{O}, \text{P}$ , and  $\text{As}$ ) atoms at the diagonal chain, and the gray sphere at the center of the diagonal chain is  $\text{B}_m$  atom bonded to two C atoms.

In fact, most studies on boron carbide have dealt with the characterization of the large homogeneity region in the rhombohedral boron carbide compound solutions over a wide range of solubility from about 9 to about 20 at. % carbon.<sup>12,19-21</sup> In  $\text{B}_4\text{C}$ , a boron atom located at the polar site on the  $\text{B}_{12}$  icosahedron is replaced by a carbon atom.<sup>13,22,23</sup> Except for that, it is very similar to  $\text{B}_{13}\text{C}_2$  in structure. Hence,  $\text{B}_4\text{C}$  can be written as  $(\text{B}_{11}\text{C}) + (\text{C-B-C})$ . Because of the appearance of B-C bonds in the  $\text{B}_{11}\text{C}$  icosahedron,  $\text{B}_{13}\text{C}_2$  is chosen for present investigation. In the structure of  $\text{B}_6\text{X}$  ( $X=\text{N}, \text{O}, \text{P}$ , and  $\text{As}$ ) compound, no bond is formed between the X atoms along the main diagonal of the rhombohedron as shown in Fig. 1(c).

For the boron-rich  $\text{B}_y\text{X}$  compounds, there are four kinds of B-B bonds in the  $\text{B}_{12}$  icosahedra as shown in Fig. 2. The first one is the  $\text{B}_p$ - $\text{B}_p$  bond in a  $\text{B}_p$ - $\text{B}_p$ - $\text{B}_p$  triangle with the three B atoms located at three polar sites. The second one is the  $\text{B}_e$ - $\text{B}_e$  bond connecting two neighboring B atoms at the

FIG. 2. The four types of B-B bonds in a  $\text{B}_{12}$  icosahedron. The white spheres represent  $\text{B}_p$  atoms located at the polar sites, and the gray ones are  $\text{B}_e$  atoms at the equatorial sites.

TABLE I. Bond lengths in B<sub>12</sub> icosahedra and lattice parameters for the selected boron-rich compounds.

Crystal	B <sub>p</sub> -B <sub>p</sub> (Å)	B <sub>p</sub> -B <sub>e</sub> <sup>*</sup> (Å)	B <sub>p</sub> -B <sub>e</sub> (Å)	B <sub>e</sub> -B <sub>e</sub> (Å)	<i>a</i> (Å)	<i>α</i> (°)
α-B	1.717	1.773	1.764	1.752	4.973	58.171
B <sub>13</sub> C <sub>2</sub>	1.758	1.789	1.769	1.761	5.128	65.936

B <sub>6</sub> As	1.875	1.754	1.785	1.710	5.247	70.338

equatorial sites. The rest are the two kinds of B<sub>p</sub>-B<sub>e</sub> bonds, which are formed between the polar and equatorial B atoms. One is denoted as the B<sub>p</sub>-B<sub>e</sub><sup>\*</sup> bond, and the other is denoted as the B<sub>p</sub>-B<sub>e</sub> bond. Two B<sub>p</sub>-B<sub>e</sub><sup>\*</sup> bonds and one B<sub>p</sub>-B<sub>p</sub> bond together can form a triangle B<sub>p</sub>-B<sub>e</sub>-B<sub>p</sub>, while two B<sub>p</sub>-B<sub>e</sub> bonds cannot form a triangle with one B<sub>p</sub>-B<sub>p</sub> bond. In a B<sub>12</sub> icosahedron, there are totally 12 B<sub>p</sub>-B<sub>e</sub><sup>\*</sup> bonds, while the numbers of B<sub>p</sub>-B<sub>p</sub>, B<sub>e</sub>-B<sub>e</sub>, and B<sub>p</sub>-B<sub>e</sub> bonds are all equal to 6.

In Table I are listed the calculated bond lengths of the different types of B-B bonds and the lattice parameters in five boron-rich compounds. After structural relaxation, the boron-rich compounds still keep the *R*-3*m* symmetry. The different B-B bond lengths in each boron-rich compound indicate that the B<sub>12</sub> icosahedron on each lattice site is distorted to different extents, thus losing their fivefold rotation axis. The broken geometrical symmetry in icosahedron results in the asymmetric distribution of charge density along the B-B bonds in the B<sub>12</sub> icosahedra. The introduction of the X atoms breaks the three-center B<sub>e</sub>-B<sub>e</sub>-B<sub>e</sub> bond in α-B, leading to the formation of three B<sub>e</sub>-X bonds around each X atom. For the B<sub>y</sub>X unit cells, the ratio of *c/a* decreases and the *α* angle increases with the increase of the covalent radius of the X atom. The B<sub>p</sub>-B<sub>p</sub> bond lengths in the boron-rich B<sub>y</sub>X compounds are longer than those in α-B.

The overlap population *P<sub>c</sub>* of the bond in the B<sub>12</sub> icosahedral structure in the formula (1) has been calculated in the following way. First, a 10 × 10 × 10 Å<sup>3</sup> cubic cell with a regular B<sub>12</sub> icosahedron at its center is constructed. After the geometry optimization, it is found that no bond is formed

between two neighboring icosahedra as long as the size of the built cell is large enough. Thus, the optimized structure of the icosahedron keeps the fivefold symmetry strictly, and the calculated bond length and overlap population of B-B bonds in the icosahedron are 1.676 Å and 0.55, respectively. This overlap population of 0.55 is very close to the *P<sub>c</sub>* value of 0.54 calculated from hardness.<sup>6</sup>

The regular B<sub>12</sub> icosahedron could not be used to construct a perfect crystal because of its fivefold symmetry. In order to form the α-B or B<sub>y</sub>X crystals with the existence of intericosahedral B-B bonds or B-X bonds, the fivefold symmetry of B<sub>12</sub> icosahedra has to be removed via distortion. In the distorted B<sub>12</sub> icosahedra of the α-B and B<sub>y</sub>X crystals, the bond length of each B-B bond is longer than the B-B bond length of 1.676 Å in the regular B<sub>12</sub> icosahedron, and the bond angles deviate from 60°. Comparing to the regular icosahedra, the distortions of icosahedra in α-B result in the redistribution of charge density. The elongations of intraicosahedral B-B bonds and the formations of intericosahedral B<sub>p</sub>-B<sub>p</sub> bonds and B<sub>e</sub>-B<sub>e</sub>-B<sub>e</sub> three center bonds should result in the decrease of bond overlap population for the intraicosahedral B-B bonds in α-B. Table II lists the calculated overlap populations for the B-B bonds in the α-B and B<sub>y</sub>X compounds. In α-B, the overlap populations of all the four types of intraicosahedral B-B bonds are lower than *P<sub>c</sub>*. Among them, the B<sub>p</sub>-B<sub>p</sub> bonds have the lowest overlap population because of the formations of the intericosahedral B<sub>p</sub>-B<sub>p</sub><sup>\*</sup> bonds with the overlap population of as high as 1.14. In the B<sub>y</sub>X crystals, the existence of the X atoms with high charge density induces the redistribution of charge density, leading to the increase of overlap populations of some intraicosahedral B-B bonds in comparison to α-B. The overlap population can be increased so much that it is even higher than *P<sub>c</sub>* of the regular B<sub>12</sub> icosahedral structure. The overlap populations of the B<sub>e</sub>-B<sub>e</sub> bonds between the two B<sub>e</sub> atoms bonded to the X atoms are higher than those in α-B. The overlap populations of all B<sub>p</sub>-B<sub>p</sub> bonds and B<sub>e</sub>-B<sub>e</sub> bonds in B<sub>y</sub>X are higher than those in α-B. For the X atoms in the same row of the periodic table, such as C, N, and O, the overlap population of the B<sub>e</sub>-B<sub>e</sub> bond increases with the increase of electronegativity or the decrease of atomic radius of the X element. For the X atoms of N, P, and As in the same group, the overlap population of the B<sub>p</sub>-B<sub>p</sub> bonds increases with the decrease of electronegativity or the increase of atomic radius of the X element. In comparison to the B<sub>p</sub>-B<sub>p</sub>

 TABLE II. Calculated Mulliken population *P*, population ionicity *f<sub>h</sub>* and Phillips ionicity *f<sub>i</sub>* of the four types of B-B bonds in B<sub>12</sub> icosahedra of the selected boron-rich compounds.

TABLE III. Calculated atomic populations for the atoms located at different sites in the selected boron-rich compounds.

Atom	$\alpha$ -B	B <sub>13</sub> C <sub>2</sub>	B <sub>6</sub> N	B <sub>6</sub> O	B <sub>6</sub> P	B <sub>6</sub> As
B <sub>p</sub>	3.0	3.04	3.03	3.07	3.02	3.13
B <sub>e</sub>	3.0	2.88	2.79	2.75	3.16	3.26
X	—	4.64	5.53	6.55	4.46	3.84
B <sub>m</sub>	—	2.22	—	—	—	—

and B<sub>e</sub>-B<sub>e</sub> bonds in the B<sub>y</sub>X, no similar phenomena have been observed in the overlap populations of the B<sub>p</sub>-B<sub>e</sub> and the B<sub>p</sub>-B<sub>e</sub><sup>\*</sup> bonds. It should be noted that the overlap populations of all B<sub>p</sub>-B<sub>e</sub> bonds in B<sub>y</sub>X are lower than those in  $\alpha$ -B.

Table III gives the calculated atomic populations for the atoms in  $\alpha$ -B and B<sub>y</sub>X. In  $\alpha$ -B, the atomic populations for B atoms are always 3, the same as the neutral B atom, while in B<sub>y</sub>X, the atomic populations for B atoms are quite different due to the existence of X atoms. There exists the charge transfer between the B<sub>p</sub> and B<sub>e</sub> atoms in the B<sub>12</sub> icosahedra as well as between the B<sub>e</sub> and the X atoms, which has never been found in the  $\alpha$ -B. From Table III, we found that the amount of transferred charge for the B<sub>e</sub> atom bonded with the X atom increases with the increase of the electronegativity of the X atom. When X is C, N, or O, the B<sub>e</sub> atom would lose some charge to the X atoms. When X is P or As, the B<sub>e</sub> atom should get some charge from the X atom. However, the B<sub>p</sub> atom always obtains charge no matter what the X atom is. For pure covalent bonds in the regular B<sub>12</sub> icosahedra, the local spatial charges on a bond distribute symmetrically. Whenever the bond population deviates from P<sub>c</sub>, there appears the spatial asymmetric charge distribution. Figure 3 gives the typical contour maps of the charge densities along the B-B bonds. For one B-B-B triangle in a regular B<sub>12</sub> icosahedron, Fig. 3(a) shows a symmetric charge distribution. For one B<sub>p</sub>-B<sub>e</sub>-B<sub>e</sub> triangle in the B<sub>12</sub> icosahedron of the B<sub>6</sub>O, Figs. 3(b) and 3(c) reveal clearly the asymmetric charge distribution.

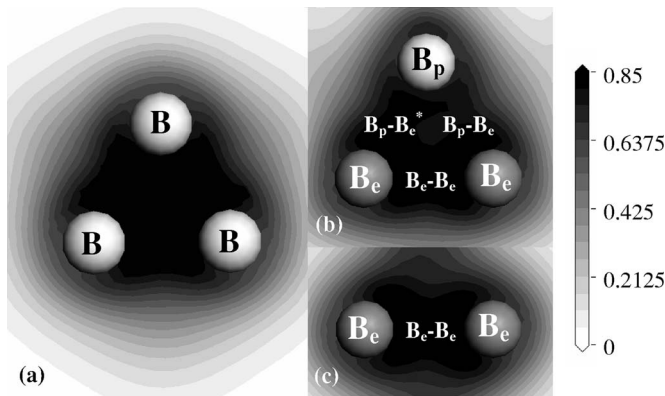

FIG. 3. Typical contour maps of the charge densities for any B-B-B triangle in a regular B<sub>12</sub> icosahedron (a), the B<sub>p</sub>-B<sub>e</sub>-B<sub>e</sub> triangle in the B<sub>12</sub> icosahedron of the B<sub>6</sub>O (b), and the same B<sub>e</sub>-B<sub>e</sub> bond as the bottom one in (b) but at a different projection plane (c).

With the overlap populations of P<sub>c</sub> and P obtained, it is easy to calculate the population ionicity  $f_h$  and Phillips ionicity  $f_i$  using Eqs. (1). For the four types of B-B bonds in the icosahedra of the  $\alpha$ -B and B<sub>y</sub>X compounds, the calculated  $f_h$  and  $f_i$  are listed in Table II. In  $\alpha$ -B, the largest ionicity is found to appear at the B<sub>p</sub>-B<sub>p</sub> bond in the icosahedron. The introduction of the X atom leads to obvious change in the ionicity of the B-B bond in the B<sub>12</sub> icosahedron. First, the calculated ionicity of the B<sub>p</sub>-B<sub>p</sub> bond in the boron-rich B<sub>y</sub>X is lower than in  $\alpha$ -B; Second, the largest ionicity in the selected B<sub>y</sub>X crystals appears at the B<sub>p</sub>-B<sub>e</sub> bond instead of the B<sub>p</sub>-B<sub>p</sub> bond of the icosahedron because of the effect of X atom. From Table II, in addition, we found that the electronegativity of the X atom has a great effect on the ionicities of B-B bonds if the X atom is chosen in the same row. The electronegativities of C, N, and O are 2.55, 3.04, and 3.44, respectively. The ionicity of the B<sub>p</sub>-B<sub>e</sub> bond increases from 0.256 in B<sub>13</sub>C<sub>2</sub> to 0.449 in B<sub>6</sub>O. In the triangle of B<sub>p</sub>-B<sub>e</sub>-B<sub>e</sub> in B<sub>6</sub>O, the B<sub>p</sub>-B<sub>e</sub><sup>\*</sup> bond has no ionicity, while the B<sub>p</sub>-B<sub>e</sub> bond has the largest ionicity and the lowest bond population among all the B-B bonds in B<sub>y</sub>X, and the B<sub>e</sub>-B<sub>e</sub> bond has a larger bond population than P<sub>c</sub> in the regular B<sub>12</sub> icosahedron. The ionicity depends on the charge distribution. The bigger the asymmetry of the charge density distribution is, the bigger the ionicity. Figures 3(b) and 3(c) give the contour map of the charge densities in the triangle B<sub>p</sub>-B<sub>e</sub>-B<sub>e</sub> of B<sub>6</sub>O, displaying distinctly the asymmetric charge distribution. For the B<sub>p</sub>-B<sub>e</sub><sup>\*</sup> bond in B<sub>6</sub>O with the overlap population of 0.55, its contour map of the charge density is the same as that of the B-B bond in the regular B<sub>12</sub> icosahedron as shown in Fig. 3(b). Therefore, no ionicity exists on this bond. For the B<sub>p</sub>-B<sub>e</sub> bond in B<sub>6</sub>O, the charge density around the B<sub>e</sub> atom is much higher than that of B<sub>p</sub> atom, resulting in the highest ionicity on the B<sub>p</sub>-B<sub>e</sub> bond. Obviously, the charge density of the B<sub>e</sub>-B<sub>e</sub> bond is higher than those of the other B-B bonds in the icosahedron. Furthermore, the charge density distributions of the icosahedra in the B<sub>13</sub>C<sub>2</sub>, B<sub>6</sub>N, and B<sub>6</sub>As tend to be uniform, leading to the decrease of the ionicity in the B-B bond of icosahedra.

#### IV. VICKERS HARDNESS OF THE B<sub>y</sub>X CRYSTALS

In the B<sub>6</sub>X (X=N, O, and As) crystals, in addition to the four kinds of B-B intraicosahedral bonds, there exists one kind of B<sub>e</sub>-X bond around the X atom and one kind of B-B bond between the two B<sub>p</sub> atoms in two neighboring B<sub>12</sub> icosahedra. This B-B bond is denoted as B<sub>p</sub>-B<sub>p</sub><sup>\*</sup>. In B<sub>6</sub>P, surprisingly, the population of P-P bond is found to be 0.66, exhibiting that the two P atoms are bonded.<sup>24</sup> In B<sub>13</sub>C<sub>2</sub>, there is one more kind of B<sub>m</sub>-C bond along the C-B-C chain in addition to the six kinds of bonds in B<sub>6</sub>O. In order to calculate the hardness of the selected B<sub>y</sub>X crystals, the Phillips ionicities for the intericosahedral bonds of B<sub>p</sub>-B<sub>p</sub><sup>\*</sup>, B-C, B-N, B-O, B-P, P-P, and B-As have been calculated from Eqs. (2) and (3). The calculated Phillips ionicities and the lengths of these bonds are listed in Table IV.

According to the microscopic model of hardness for the polar covalent compounds,<sup>15</sup> the hardness of these four B<sub>y</sub>X

TABLE IV. Lengths and Phillips ionicities of chemical bonds outside icosahedra in the selected boron-rich compounds.

crystals should be calculated in the same way as for the multicomponent compounds. B<sub>6</sub>N, B<sub>6</sub>As, and B<sub>6</sub>P have an even number of electrons in the unit cell which consists of two formulas of B<sub>6</sub>X (X=N, O, As, and P), while B<sub>13</sub>C<sub>2</sub> has an odd number of electrons. It should be noticed here that B<sub>13</sub>C<sub>2</sub> has been shown to be metallic in the calculations of band structures,<sup>25,26</sup> but experimentally, it has been demonstrated to be semiconducting.<sup>27</sup> The real structure of B<sub>13</sub>C<sub>2</sub> is extremely complex. For the boron carbides in ideal crystals, the electron deficiencies are often compensated by the structural defects. In the case of B<sub>13</sub>C<sub>2</sub>, real crystal with the valence band completely filled is energetically more favorable than the ideal structure of B<sub>12</sub>(C-B-C).<sup>27</sup> Because the lattice parameters of ideal structure is in good agreement with the experimental data for B<sub>13</sub>C<sub>2</sub>,<sup>26</sup> it is proper to use the ideal structure of B<sub>13</sub>C<sub>2</sub> to estimate the hardness instead of the real structure. As an example, a detailed description has been offered below on calculation of the Vickers hardness of B<sub>6</sub>O. In B<sub>6</sub>O, there are 39 bonds in total in its rhombohedral unit cell, 6 B<sub>p</sub>-B<sub>p</sub>, 12 B<sub>p</sub>-B<sub>e</sub>\*, 6 B<sub>p</sub>-B<sub>e</sub> and six B<sub>e</sub>-B<sub>e</sub> bonds in the B<sub>12</sub> icosahedron, 3 B<sub>p</sub>-B<sub>p</sub>\* bonds between the two B<sub>12</sub> icosahedra, and six B<sub>e</sub>-O bonds. Therefore, its Vickers hardness can be expressed as

$$H_v = [(H_v^{B_p-B_p})^6 (H_v^{B_p-B_e^*})^{12} (H_v^{B_p-B_e})^6 \times (H_v^{B_e-B_e})^6 (H_v^{B_p-B_p^*})^3 (H_v^{B_e-O})^6]^{1/39}, \quad (4)$$

where  $H_v^\mu = 350(N_e^\mu)^{2/3} e^{-1.191f_i^\mu} / (d^\mu)^{2.5}$  is the hardness of hypothetical binary compound composed of a  $\mu$  bond. For each B<sub>m</sub>-B<sub>n</sub> bond, its valence electron density  $N_e^{B_m-B_n}$  can be expressed as

$$N_e^{B_m-B_n} = [2Z_B/N_B] \left[ \sum_{\mu} (d^\mu)^3 N^\mu \right] / [V(d^{B_m-B_n})^3], \quad (5)$$

where  $Z_B$  is the valence electron number of the B atom,  $N_B$  is the nearest coordination number of the B atom,  $d^{B_m-B_n}$  is the bond length of the B<sub>m</sub>-B<sub>n</sub> bond, and  $N^\mu$  and  $d^\mu$  are the number and length of the  $\mu$  bond in one unit cell, respectively. For each B-O bond, the valence electron density  $N_e^{B-O}$  can be written as

$$N_e^{B-O} = [Z_B/N_B + Z_O/N_O] \left[ \sum_{\mu} (d^\mu)^3 N^\mu \right] / [V(d^{B-O})^3], \quad (6)$$

where  $Z_O$  and  $N_O$  are the valence electron number and the nearest coordination number of the O atom, respectively,

$d^{B-O}$  is the bond length of the B-O bond. In the structure of the B<sub>6</sub>O crystal, the valence electron numbers of the B and O atoms are 3 and 6, respectively, while their nearest coordination numbers are 6 and 3, respectively. The other parameters used in the hardness calculation and the calculated Vickers hardness for the B<sub>6</sub>O crystal are presented in Table V. The Vickers hardness of the B<sub>6</sub>N, B<sub>6</sub>P, B<sub>6</sub>As, B<sub>13</sub>C<sub>2</sub> and  $\alpha$ -B crystals have been calculated in the same way described above, and the parameters used in the hardness calculations and the calculated Vickers hardness are listed in Table V. The calculated hardness of the B<sub>6</sub>O and B<sub>13</sub>C<sub>2</sub> is 43 and 44 GPa, respectively, in good agreement with the experimental values of 45 GPa (see Ref. 11) or 38 GPa (see Ref. 28) for B<sub>6</sub>O and 45 GPa (see Ref. 12) for B<sub>13</sub>C<sub>2</sub>. For the B<sub>6</sub>N, B<sub>6</sub>P, and B<sub>6</sub>As, their predicted values of the Vickers hardness are 41, 36, and 33 GPa, respectively. These results indicate that the B<sub>6</sub>N crystal is a potential superhard material with the Vickers hardness higher than 40 GPa.

To get a deep insight into the effects of the X atoms on the Vickers hardness of the boron-rich compounds, we have calculated the hardness of icosahedra in these boron-rich compounds using the following equation

$$H_v^{\text{icosah}} = [(H_v^{B_p-B_p})^6 (H_v^{B_p-B_e^*})^{12} (H_v^{B_p-B_e})^6 (H_v^{B_e-B_e})^6]^{1/30}. \quad (7)$$

The calculated results are listed in Table V. It can be seen clearly that the B<sub>12</sub> icosahedron makes a dominant contribution to the hardness of the  $\alpha$ -B. Introduction of the X atom into the diagonal chain leads to an obvious decrease of the hardness of B<sub>12</sub> icosahedron in the rhombohedral cell, especially for X=N and As. For X=C, N, and O, however, the formation of shorter B<sub>e</sub>-X or B<sub>m</sub>-X bond can compensate for the loss of hardness of the B<sub>12</sub> icosahedron, leading to the hardness of B<sub>6</sub>O, B<sub>13</sub>C<sub>2</sub>, and B<sub>6</sub>N higher than 40 GPa. Comparing the contributions of the chemical bonds outside the B<sub>12</sub> icosahedron in the B<sub>6</sub>P and B<sub>6</sub>As on hardness to those in the  $\alpha$ -B, we find that the hardness of the hypothetical binary compounds composed of the B<sub>p</sub>-B<sub>p</sub>\* bonds in the B<sub>6</sub>P and B<sub>6</sub>As is much lower than that in the  $\alpha$ -B. The hardness of the hypothetical binary compounds composed of B<sub>e</sub>-P, P-P, and B<sub>e</sub>-As bonds is also lower than those of icosahedra in the B<sub>6</sub>P and B<sub>6</sub>As. Therefore, it is easy to understand that the hardness of the B<sub>6</sub>P and B<sub>6</sub>As crystals is lower than that of the  $\alpha$ -B. Usually, bulk moduli are correlated to hardness, especially for the materials with the same crystal structures. The calculated bulk moduli for the five boron-rich compounds are listed in Table V. The compounds of B<sub>6</sub>O, B<sub>6</sub>N, B<sub>6</sub>P, and B<sub>6</sub>As have the same crystal structures, so their hardness increases with their bulk moduli. The bulk modulus of B<sub>6</sub>N is almost equal to that of B<sub>6</sub>O, supporting our prediction that B<sub>6</sub>N is also a potential superhard material.

## V. CONCLUSION

In summary, five selected boron-rich B<sub>y</sub>X compounds have been investigated using first principles calculations to understand the influence of the X atom on the ionicities of

TABLE V. Bond parameters, calculated Vickers hardness and bulk moduli of the selected boron-rich compounds.  $H_{v \text{ calc}}$  and  $H_{v \text{ expt}}$  represent the calculated and experimental hardnesses, respectively.

the B-B bonds in the B<sub>12</sub> icosahedra of the B<sub>13</sub>C<sub>2</sub>-like structured B<sub>y</sub>X compounds. It can be concluded that the effect of the X atoms on the bond length, overlap population, population ionicity  $f_h$  and Phillips ionicity  $f_i$  of the B-B bond in B<sub>12</sub> icosahedron is dependent on the electronegativity and the

atomic radius of the X atoms. With the X atoms in the same row of the periodic table, the electronegativity plays a dominant role in the effect; while with the X atoms in the same group, the atomic radius plays a dominant role. Our calculations show that the ionicity of the chemical bond formed by

the identical atoms such as the B-B bond could be quite different even in the same structure. The B<sub>p</sub>-B<sub>e</sub> bond in the B<sub>6</sub>O exhibits the largest ionicity of 0.449 among all of the B-B bonds in the five B<sub>y</sub>X crystals, which is comparable to the ionicity of AlN. There exists the occurrence of charge transfer between the B<sub>p</sub> and B<sub>e</sub> atoms in the distorted B<sub>12</sub> icosahedra of the B<sub>y</sub>X, while no charge transfer occurs between the B atoms in α-B. For B<sub>6</sub>O and B<sub>13</sub>C<sub>2</sub>, the calculated hardness is 43 GPa and 44 GPa, respectively, in good agreement with the experimental values. Our hardness calcu-

lations predict that the B<sub>6</sub>N crystal is a potential superhard material.
