As a possible physical realization of a quantum information processor, a system with stacked self-assembled InAs quantum dots buried in GaAs adjacent to the channel of a spin field-effect transistor has been proposed. In this system, only one of the stacked qubits, i.e., the *edge* qubit (the qubit closest to the channel), is measurable via "spin-blockade measurement." It is shown that the state tomography of the whole chain of the qubits is still possible even under such a restricted accessibility. The idea is to make use of the entangling dynamics of the qubits. A recipe for the two-qubit system is explicitly constructed and the effect of an imperfect fidelity of the measurement is clarified. A general scheme for multiple qubits based on repeated measurements is also presented.

I. INTRODUCTION

Toward realizations of quantum information processors, a variety of physical systems has been proposed and intensively investigated. In particular, solid-state devices with the quantum bits (qubits) realized by the spins of electrons confined in quantum dots in semiconductors[1–3] are supposed to be promising in terms of its compatibility with existing semiconductor technology. Among them, vertically stacked self-assembled InAs quantum dots have the advantage of strong confinement of electrons which allows high-temperature operation of the order of 1 K as opposed to millikelvin in confined two-dimensional electron gas (2DEG) system by Schottky electrode.[2,3] Thus, we have proposed and have been investigating, from both experimental and theoretical aspects, a system with vertically stacked self-assembled InAs dots buried in AlInAs barrier layer adjacent to the channel of a spin field-effect transistor (FET) (see Fig. 1).[4,5]

For quantum information processing, one should be able to perform initialization, quantum gate operations, and readout of the qubits.[6] In the proposed setup depicted in Fig. 1, the qubits evolve under the interactions with the neighboring qubits and each of them would be rotated via electric spin resonance (ESR). Furthermore, it is possible to measure repeatedly the state of the spin of the electron in the edge quantum dot, just above the channel of the FET, by making use of the "spin-blockade effect," as will be recalled in Sec. II.[4,5]

Although the qubits other than the one on the edge are not directly accessible by the proposed measurement scheme, one can still perform useful operations on the chain of qubits. Multiple qubits can be initialized via repeated measurements only on the edge qubits,[4,7] and an entanglement generation was discussed.[4] In the present paper, we show that the *state tomography* (or the *state reconstruction*) is also available.

The determination of the quantum state is a highly nontrivial problem.[8] A wave function, or more generally a density operator, of a quantum system is not an observable and cannot be measured directly. From a practical point of view, one can see the state only through measurable quantities. In order to gain full information on the state of an N-level system, a list of the measured values (expectation values) of N^2-1 independent observables is required, with which all the matrix elements of its density matrix are *reconstructed* and the *tomography* of the state is accomplished.

The state tomography has been carried out for a variety of physical systems to analyze experiments.[9–16] We are going to discuss the state tomography in the present setup. One can measure only the edge qubit; still, it is possible to reconstruct the state of the *whole* chain of the qubits.

II. SPIN FET EMBEDDED WITH QUANTUM DOTS

The proposed device is illustrated in Fig. 1.[4,5] A series of quantum dots is embedded in the FET structure just above the channel. A single electron is confined in each quantum dot and quantum information is encoded on its spin states, $|\uparrow\rangle$ and $|\downarrow\rangle$. Such a situation where only a single electron is stored in each dot is realized by properly adjusting the gate voltage V_G.[3,17] Each qubit would be rotated via ESR to perform single-qubit operations, and the qubits are entangled by the evolution under the interactions between the neighboring qubits.

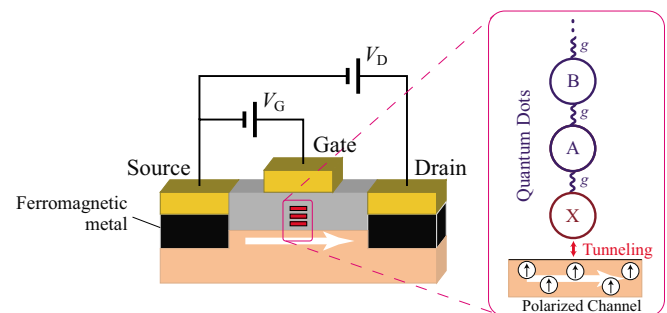

FIG. 1. (Color online) Spin FET embedded with quantum dots.

The FET structure aims at measuring the spin state of the electron confined in the edge quantum dot X. Notice first that one can detect the injection of an electron from the channel into the edge dot X by looking at the channel (source-drain) current I_D as a function of the gate voltage V_G. As the gate voltage V_G is increased, the channel current I_D increases. But if an electron tunnels from the channel into the edge dot in the meanwhile, the edge dot is charged and the channel current is suppressed. As a result, the channel current I_D drops down and exhibits a peak as a function of the gate voltage V_G (Coulomb-blockade effect). Suppose now that the channel electrons are spin polarized in a definite spin state, say $|\uparrow\rangle$. When the edge electron is in the state $|\downarrow\rangle$, a channel electron in $|\uparrow\rangle$ can tunnel into the edge dot at a certain gate voltage V_G, but, on the contrary, when the edge electron is in $|\uparrow\rangle$, the channel electron is not allowed to enter there due to Pauli's exclusion principle. Therefore, if the polarized channel current I_D drops down as the gate voltage V_G is increased, one recognizes that the edge electron is in $|\downarrow\rangle_X$, while the growth of I_D indicates that the edge electron is in $|\uparrow\rangle_X$. In this way, one can measure the spin state of the edge qubit X. We call it "spin-blockade measurement."[4,5]

The feasibility of the present system is discussed in Ref. 5; (i) the selective access to each individual qubit via ESR becomes possible by slightly modifying the compound ratio x of the In$_{1-x}$Ga$_x$As quantum dot, since the g factor of the electron in a dot is altered in this way[18] and the ESR absorption spectra of the electrons in different dots can be separated; (ii) the strength of the exchange interaction energy between qubits and the corresponding characteristic time scale are estimated, showing the feasibility; (iii) the modulation of the channel current by single electron charging in a quantum dot adjacent to the channel has been demonstrated in a trial structure with a single layer of quantum dot with unpolarized channel current. Spin-polarized channel will be available by replacing the normal-metal electrode with a ferromagnet, candidate materials for which are being intensively investigated, see Ref. 19. Spin decoherence time has been reported to be 2 ns for InAs self-assembled quantum dots,[20] while the spin-flipping time is estimated to be 50 ps.[5]

One of the remarkable features of the spin-blockade measurement is that one can measure $|\uparrow\rangle_X$ *repeatedly*. Although one is allowed to measure only the edge qubit X, this feature enables one to perform useful operations on the chain of qubits. The initialization of multiple qubits via repeated measurements on the edge qubit and an entanglement generation are discussed in Refs. 4 and 7. Furthermore, the present paper clarifies that the tomography of the state of the whole qubits $X+A+B+\cdots$ is also possible via the spin-blockade measurements only on the *edge* qubit X.

III. IDEA

In the proposed setup, it is possible to measure the state $|\uparrow\rangle_X$ of the edge qubit X. But at the same time, the measurement of $|\downarrow\rangle_X$ implies that a channel electron in $|\uparrow\rangle$ has been injected into the edge dot and the edge qubit X has been destroyed. Furthermore, qubits other than X are out of reach of the spin-blockade measurement. Still, there is a way to get

the full information about the state of the whole chain of the qubits.

To measure different states of X from $|\uparrow\rangle_X$ without loosing it by the injection of a channel electron, we apply a spin rotation just before a spin-blockade measurement. For instance, finding X in $|\uparrow\rangle_X$ just after rotating X by the angle $\pi/2$ around the y axis is essentially the measurement of the spin X oriented in the x direction [a superposed state $(|\uparrow\rangle_X+|\downarrow\rangle_X)/\sqrt{2}$] before the rotation. In this way, it is possible to measure any state of X.

The idea for getting information about the states of qubits other than X is to make use of the entangling dynamics of the chain of the qubits and the collapse of the state by the measurement on X. Although we are allowed to measure only X, such measurement would reflect the state of the other qubits due to the entanglement between X and the rest

The strategy for the state tomography of the whole chain of the qubits is therefore the following. The qubits $X+A+B+\cdots$ evolve, from a given state ϱ to be reconstructed, under the action of the Hamiltonian

$$H = g_{XA}\boldsymbol{\sigma}^{(X)} \cdot \boldsymbol{\sigma}^{(A)} + g_{AB}\boldsymbol{\sigma}^{(A)} \cdot \boldsymbol{\sigma}^{(B)} + \cdots, \quad (3.1)$$

where $\boldsymbol{\sigma}^{(Q)}$ represents the spin operator of qubit $Q(=X,A,B,\ldots)$. During the evolution, we rotate some qubits and measure $|\uparrow\rangle_X$ a few times at definite timings according to a certain recipe. We prepare the same initial state ϱ and perform such a fixed sequence of operations many times to obtain the probability for every measurement in the sequence to find X in the state $|\uparrow\rangle_X$. (Notice that the measurement at the end of a sequence can be $|\downarrow\rangle_X$, since we do not need to proceed further.)

Consider, for instance, the following series of operations: (rotation of X by an angle θ around the x axis)$\rightarrow$(wait for time τ)$\rightarrow$(measurement of $|\uparrow\rangle_X$)$\rightarrow\cdots\rightarrow$(measurements of $|\downarrow\rangle_X$). The probability of getting the relevant result at every measurement implemented in the series is given by

$$p = \mathrm{Tr}\{P_\downarrow \cdots P_\uparrow U(\tau)R_x^{(X)}(\theta)\varrho R_x^{(X)\dagger}(\theta)U^\dagger(\tau)P_\uparrow \cdots P_\downarrow\}$$
$$= \mathrm{Tr}\{\varrho[R_x^{(X)\dagger}(\theta)U^\dagger(\tau)P_\uparrow \cdots P_\downarrow \cdots P_\uparrow U(\tau)R_x^{(X)}(\theta)]\},$$
$$(3.2)$$

where $R_i^{(Q)}(\theta)=e^{-(i/2)\theta\sigma_i^{(Q)}}$ is the operator that rotates qubit $Q(=X,A,B,\ldots)$ by an angle θ around the $i(=x,y)$ axis, $P_{\uparrow(\downarrow)}=|\uparrow(\downarrow)\rangle_X\langle\uparrow(\downarrow)|$ is the projection operator that represents the measurement of $|\uparrow(\downarrow)\rangle_X$, and $U(\tau)=e^{-iH\tau}$ is the time-evolution operator between two operations and entangles the chain of the qubits. We have set $\hbar=1$.

This is the quantity that we can measure in the present system. It can be viewed as the expectation value $p=\mathrm{Tr}\{\varrho\mathcal{O}\}$ of a Hermitian operator $\mathcal{O}$ in the relevant state ϱ, where $\mathcal{O}$ consists of $P_\uparrow$, $U(\tau)$, $R_x^{(X)}(\theta)$, and so on. Therefore, by suitably arranging the sequences of the operations, we can collect the sufficient number (4^M-1 for an M-qubit system) of expectation values of linearly independent operators that allow us to reconstruct the given state ϱ.

Let us demonstrate how the above procedure works in the simplest case, for two qubits $X+A$. 15 linearly independent sequences of operations that are sufficient to reconstruct a

TABLE I. 15 linearly independent sequences of operations sufficient to reconstruct a state of two qubits. $g=g_{XA}$ is the coupling constant between the two qubits.

$p_{\uparrow(\downarrow)}^{(10)}$	$R_y(\pi) \to P_\uparrow \to U(\frac{\pi}{4g}) \to R_y(\frac{\pi}{2}) \to P_{\uparrow(\downarrow)}$
$p_{\uparrow(\downarrow)}^{(11)}$	$R_y(\pi) \to P_\uparrow \to U(\frac{\pi}{4g}) \to R_x(\frac{\pi}{2}) \to P_{\uparrow(\downarrow)}$
$p_{\uparrow(\downarrow)}^{(12)}$	$R_y(\frac{\pi}{2}) \to P_\uparrow \to U(\frac{\pi}{4g}) \to P_{\uparrow(\downarrow)}$
$p_{\uparrow(\downarrow)}^{(13)}$	$R_x(\frac{\pi}{2}) \to P_\uparrow \to U(\frac{\pi}{4g}) \to P_{\uparrow(\downarrow)}$
$p_{\uparrow(\downarrow)}^{(14)}$	$R_y(\frac{\pi}{2}) \to P_\uparrow \to U(\frac{\pi}{4g}) \to R_x(\frac{\pi}{2}) \to P_{\uparrow(\downarrow)}$
$p_{\uparrow(\downarrow)}^{(15)}$	$R_x(\frac{\pi}{2}) \to P_\uparrow \to U(\frac{\pi}{4g}) \to R_y(\frac{\pi}{2}) \to P_{\uparrow(\downarrow)}$

two-qubit state ϱ are listed in Table I, where $R_i(\theta) = R_i^{(X)}(\theta)R_i^{(A)}(\theta)$ is a "global" rotation, which rotates both X and A at the same time (we can also construct a recipe with "local" rotations, which act separately on X or A). Note that $p_\uparrow^{(n)}$ and $p_\downarrow^{(n)}$ are obtained simultaneously by a common ensemble of experimental data collected for the nth sequence of

operations. By substituting the probabilities $p_{\uparrow(\downarrow)}^{(n)}$ measured for the sequences of operations into the formulas listed in Table II, all of the 16 matrix elements of the two-qubit state ϱ are disclosed and the state ϱ is reconstructed.

The mechanism of the tomography is understood as follows, for relatively simple cases. The curves in Fig. 2 describe the entangling dynamics according to Hamiltonian (3.1). If the result of a measurement on X is "no," two of the four components of the state of $X+A$ are projected out. The survival through such projections corresponds to the event where every measurement in a sequence gives "yes," and the probability of such an event rephrases how much the survived component was contained in the given initial state ϱ. The sequences are designed so as to reflect all of the matrix elements of ϱ, and the inversion of a linear relationship between the probabilities and the matrix elements reconstructs the given state ϱ.

IV. PARTIALLY POLARIZED SPIN CHANNEL

The realization of the polarized spin channel is one of the important issues to be tackled.[19] If the channel is only partially polarized, the fidelity of the spin-blockade measurement on X is degraded and the performance of the tomography deteriorates. Let us clarify the effect of the partially polarized spin channel on the tomographic scheme presented in Sec. III.

When the spin polarization is not perfect but r, the state of the electron in the channel would be effectively described by the density operator

TABLE II. Reconstruction of the two-qubit state ϱ from the probabilities $p_{\uparrow(\downarrow)}^{(n)}$ obtained by the sequences of operations listed in Table I. Here, $|\uparrow\downarrow\rangle = |\uparrow\rangle_X |\downarrow\rangle_A$, etc.

$$\langle\uparrow\uparrow|\varrho|\uparrow\uparrow\rangle = p_\uparrow^{(1)}, \quad \langle\downarrow\downarrow|\varrho|\downarrow\downarrow\rangle = p_\uparrow^{(3)}$$
$$\langle\uparrow\downarrow|\varrho|\uparrow\downarrow\rangle = p_\downarrow^{(1)}, \quad \langle\downarrow\uparrow|\varrho|\downarrow\uparrow\rangle = p_\downarrow^{(2)}$$
$$\langle\uparrow\uparrow|\varrho|\uparrow\downarrow\rangle = -\tfrac{1}{2}(p_\uparrow^{(4)}-p_\downarrow^{(4)}) - \tfrac{i}{2}(p_\uparrow^{(5)}-p_\downarrow^{(5)})$$
$$\langle\uparrow\downarrow|\varrho|\uparrow\uparrow\rangle = -\tfrac{1}{2}(p_\uparrow^{(4)}-p_\downarrow^{(4)}) + \tfrac{i}{2}(p_\uparrow^{(5)}-p_\downarrow^{(5)})$$
$$\langle\uparrow\uparrow|\varrho|\downarrow\uparrow\rangle = -\tfrac{1}{2}(p_\uparrow^{(6)}-p_\downarrow^{(6)}) - \tfrac{i}{2}(p_\uparrow^{(7)}-p_\downarrow^{(7)})$$
$$\langle\downarrow\uparrow|\varrho|\uparrow\uparrow\rangle = -\tfrac{1}{2}(p_\uparrow^{(6)}-p_\downarrow^{(6)}) + \tfrac{i}{2}(p_\uparrow^{(7)}-p_\downarrow^{(7)})$$
$$\langle\downarrow\downarrow|\varrho|\uparrow\downarrow\rangle = \tfrac{1}{2}(p_\uparrow^{(8)}-p_\downarrow^{(8)}) + \tfrac{i}{2}(p_\uparrow^{(9)}-p_\downarrow^{(9)})$$
$$\langle\uparrow\downarrow|\varrho|\downarrow\downarrow\rangle = \tfrac{1}{2}(p_\uparrow^{(8)}-p_\downarrow^{(8)}) - \tfrac{i}{2}(p_\uparrow^{(9)}-p_\downarrow^{(9)})$$
$$\langle\downarrow\downarrow|\varrho|\downarrow\uparrow\rangle = \tfrac{1}{2}(p_\uparrow^{(10)}-p_\downarrow^{(10)}) + \tfrac{i}{2}(p_\uparrow^{(11)}-p_\downarrow^{(11)})$$
$$\langle\downarrow\uparrow|\varrho|\downarrow\downarrow\rangle = \tfrac{1}{2}(p_\uparrow^{(10)}-p_\downarrow^{(10)}) - \tfrac{i}{2}(p_\uparrow^{(11)}-p_\downarrow^{(11)})$$
$$\langle\uparrow\uparrow|\varrho|\downarrow\downarrow\rangle = \tfrac{1}{4}(\langle\sigma_x^{(X)}\sigma_x^{(A)}\rangle - \langle\sigma_y^{(X)}\sigma_y^{(A)}\rangle - i\langle\sigma_x^{(X)}\sigma_y^{(A)}\rangle - i\langle\sigma_y^{(X)}\sigma_x^{(A)}\rangle)$$
$$\langle\downarrow\downarrow|\varrho|\uparrow\uparrow\rangle = \tfrac{1}{4}(\langle\sigma_x^{(X)}\sigma_x^{(A)}\rangle - \langle\sigma_y^{(X)}\sigma_y^{(A)}\rangle + i\langle\sigma_x^{(X)}\sigma_y^{(A)}\rangle + i\langle\sigma_y^{(X)}\sigma_x^{(A)}\rangle)$$
$$\langle\uparrow\downarrow|\varrho|\downarrow\uparrow\rangle = \tfrac{1}{4}(\langle\sigma_x^{(X)}\sigma_x^{(A)}\rangle + \langle\sigma_y^{(X)}\sigma_y^{(A)}\rangle + i\langle\sigma_x^{(X)}\sigma_y^{(A)}\rangle - i\langle\sigma_y^{(X)}\sigma_x^{(A)}\rangle)$$
$$\langle\downarrow\uparrow|\varrho|\uparrow\downarrow\rangle = \tfrac{1}{4}(\langle\sigma_x^{(X)}\sigma_x^{(A)}\rangle + \langle\sigma_y^{(X)}\sigma_y^{(A)}\rangle - i\langle\sigma_x^{(X)}\sigma_y^{(A)}\rangle + i\langle\sigma_y^{(X)}\sigma_x^{(A)}\rangle)$$
$$\langle\sigma_x^{(X)}\sigma_x^{(A)}\rangle = 2(p_\uparrow^{(12)}-p_\downarrow^{(12)}) + \langle\sigma_x^{(A)}\rangle$$
$$\langle\sigma_y^{(X)}\sigma_y^{(A)}\rangle = 2(p_\uparrow^{(13)}-p_\downarrow^{(13)}) - \langle\sigma_y^{(A)}\rangle$$
$$\langle\sigma_x^{(X)}\sigma_y^{(A)}\rangle = -2(p_\uparrow^{(14)}-p_\downarrow^{(14)}) + \langle\sigma_y^{(A)}\rangle$$
$$\langle\sigma_y^{(X)}\sigma_x^{(A)}\rangle = -2(p_\uparrow^{(15)}-p_\downarrow^{(15)}) - \langle\sigma_x^{(A)}\rangle$$
$$\langle\sigma_x^{(A)}\rangle = -(p_\uparrow^{(4)}-p_\downarrow^{(4)}) + (p_\uparrow^{(10)}-p_\downarrow^{(10)})$$
$$\langle\sigma_y^{(A)}\rangle = (p_\uparrow^{(5)}-p_\downarrow^{(5)}) - (p_\uparrow^{(11)}-p_\downarrow^{(11)})$$

FIG. 2. (Color online) Mechanism of the tomography for the sequences of operations for (a) $p_\uparrow^{(1)}$, (b) $p_\downarrow^{(1)}$, and (c) $p_\downarrow^{(2)}$. The curves describe how the components of a state evolve and entangle in time according to Hamiltonian (3.1), while the "walls" represent the projective measurements on qubit X. The survived curves which are not shut off by the walls correspond to the events where every measurement gives the desired result. The probabilities of such events are nothing but the probabilities $p_{\uparrow(\downarrow)}^{(n)}$ for the sequences of operations and are equivalent (in the simple cases shown here) to the occupations of the survived states in the given initial state ϱ, yielding its relevant matrix elements, (a) $\langle\uparrow\uparrow|\varrho|\uparrow\uparrow\rangle$, (b) $\langle\uparrow\downarrow|\varrho|\uparrow\downarrow\rangle$, and (c) $\langle\downarrow\uparrow|\varrho|\downarrow\uparrow\rangle$.

$$\varrho_{ch} = r|\uparrow\rangle\langle\uparrow| + \frac{1-r}{2}\mathbb{1} = \frac{1+r}{2}|\uparrow\rangle\langle\uparrow| + \frac{1-r}{2}|\downarrow\rangle\langle\downarrow|.$$

$$(4.1)$$

Due to the presence of the undesired ingredient, $|\downarrow\rangle\langle\downarrow|$ in Eq. (4.1), the confirmation of the increase in the channel current in response to the sweep of the gate voltage does not result in the pure projection $\varrho \to P_\uparrow\varrho P_\uparrow$ but would induce

$$\varrho \to \frac{1+r}{2}P_\uparrow\varrho P_\uparrow + \frac{1-r}{2}P_\downarrow\varrho P_\downarrow,$$

$$(4.2)$$

reflecting the classical mixture of the two states in Eq. (4.1) (with other possible nonideal features omitted).[21]

See Figs. 3 and 4, where the state reconstructions are simulated with the spin-blockade measurement with partially polarized spin channel, Eq. (4.2), in place of the ideal projective measurement $P_\uparrow$ in the recipe presented in Table I.

We have considered the imperfection of the spin-blockade measurement due to the partially polarized spin channel. The present formalism [Eq. (4.2)] would however be applicable to other physical origins of imperfections, including imperfect Pauli blocking.[22] The meaning of the parameter r is just to be reinterpreted.

V. TOWARD MULTIQUBIT SYSTEMS

Toward the tomography of multiple qubits (with $M \geq 3$), there exists a scheme applicable for an arbitrary number of qubits M. Here is the recipe; we consider four sequences of operations,

$$R_{\theta_0\varphi_0}^{(X)} \to P_\uparrow[\to U(\tau) \to R_{\theta\varphi}^{(X)} \to P_\uparrow]^{N-1}, \quad (5.1)$$

with $(\theta_0, \varphi_0) = (0,0)$, $(\pi, 0)$, $(\pi/2, 0)$, $(\pi/2, \pi/2)$, and $N \leq D^2/4$, where $D = 2^M$ is the dimension of the M-qubit system and $R_{\theta\varphi}^{(X)}$ represents a rotation of X defined by

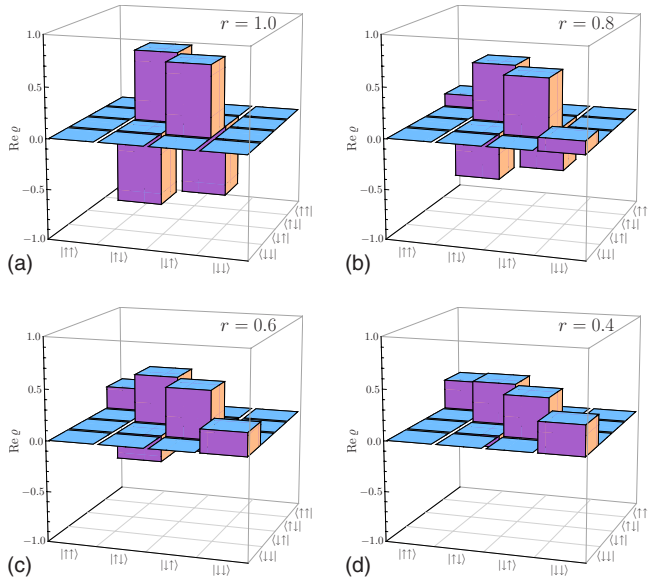

FIG. 3. (Color online) State tomography of $|\Psi^-\rangle = (|\uparrow\downarrow\rangle_{XA} - |\downarrow\uparrow\rangle_{XA})/\sqrt{2}$ with partially polarized spin channel. The polarization of the channel is defined by $r = (N_\uparrow - N_\downarrow)/(N_\uparrow + N_\downarrow)$ with $N_{\uparrow(\downarrow)}$ as the number of spins in the $|\uparrow(\downarrow)\rangle$ state in the channel.

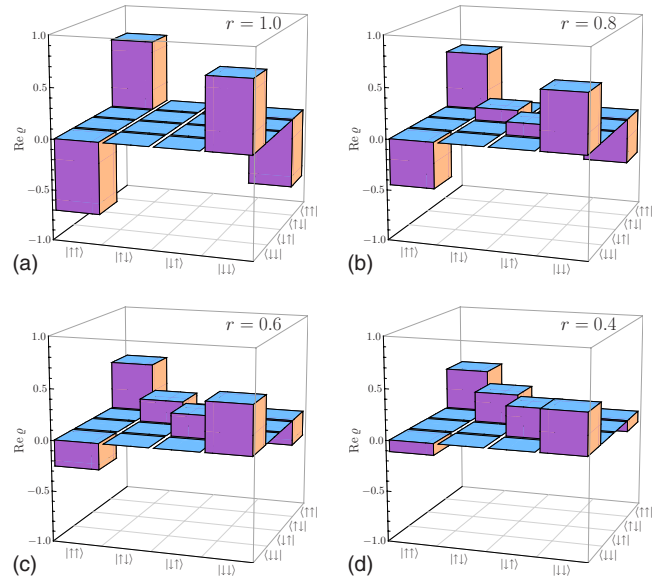

FIG. 4. (Color online) State tomography of $|\Phi^-\rangle = (|\uparrow\uparrow\rangle_{XA} - |\downarrow\downarrow\rangle_{XA})/\sqrt{2}$ with partially polarized spin channel.

$$R_{\theta\varphi}^{(X)\dagger}|\uparrow\rangle_X = e^{-i\varphi/2}\cos\frac{\theta}{2}|\uparrow\rangle_X + e^{i\varphi/2}\sin\frac{\theta}{2}|\downarrow\rangle_X. \quad (5.2)$$

Let $p_{\theta_0\varphi_0}(N)$ denote the probability of finding X in $|\uparrow\rangle_X$ successively N times up to the Nth measurement, which is given by

$$p_{\theta_0\varphi_0}(N) = \mathrm{Tr}\{[P_\uparrow R_{\theta\varphi}^{(X)}U(\tau)]^{N-1}P_\uparrow R_{\theta_0\varphi_0}^{(X)}$$

$$\times \varrho R_{\theta_0\varphi_0}^{(X)\dagger}P_\uparrow[U^\dagger(\tau)R_{\theta\varphi}^{(X)\dagger}P_\uparrow]^{N-1}\}$$

$$= \mathrm{Tr}_{AB...}\{[V_{\theta\varphi}(\tau)]^{N-1}\varrho_{\theta_0\varphi_0}[V_{\theta\varphi}^\dagger(\tau)]^{N-1}\} \quad (5.3)$$

with

$$V_{\theta\varphi}(\tau) = {}_X\langle\uparrow|R_{\theta\varphi}^{(X)}U(\tau)|\uparrow\rangle_X, \quad (5.4a)$$

$$\varrho_{\theta_0\varphi_0} = {}_X\langle\uparrow|R_{\theta_0\varphi_0}^{(X)}\varrho R_{\theta_0\varphi_0}^{(X)\dagger}|\uparrow\rangle_X. \quad (5.4b)$$

Then, such probabilities are related to the matrix elements of the given density operator ϱ of $X+A+B+\cdots$ through

$$\begin{pmatrix} p_{\theta_0\varphi_0}(1) \\ p_{\theta_0\varphi_0}(2) \\ \vdots \\ p_{\theta_0\varphi_0}(D^2/4) \end{pmatrix} = \mathcal{M} \begin{pmatrix} \langle u_1|u_1\rangle\langle v_1|\varrho_{\theta_0\varphi_0}|v_1\rangle \\ \langle u_2|u_1\rangle\langle v_1|\varrho_{\theta_0\varphi_0}|v_2\rangle \\ \vdots \\ \langle u_{D/2}|u_{D/2}\rangle\langle v_{D/2}|\varrho_{\theta_0\varphi_0}|v_{D/2}\rangle \end{pmatrix},$$

$$(5.5)$$

where

$$\mathcal{M} = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ \lambda_1\lambda_1^* & \lambda_1\lambda_2^* & \cdots & \lambda_{D/2}\lambda_{D/2}^* \\ (\lambda_1\lambda_1^*)^2 & (\lambda_1\lambda_2^*)^2 & \cdots & (\lambda_{D/2}\lambda_{D/2}^*)^2 \\ \vdots & \vdots & \ddots & \vdots \\ (\lambda_1\lambda_1^*)^{D^2/4-1} & (\lambda_1\lambda_2^*)^{D^2/4-1} & \cdots & (\lambda_{D/2}\lambda_{D/2}^*)^{D^2/4-1} \end{pmatrix}$$

$$(5.6)$$

and

$$V_{\theta\varphi}(\tau)|u_n\rangle = \lambda_n|u_n\rangle, \quad \langle v_n|V_{\theta\varphi}(\tau) = \lambda_n\langle v_n|. \quad (5.7)$$

The non-Hermitian operator $V_{\theta\varphi}(\tau)$ has been assumed to be diagonalizable.[7]

The matrix $\mathcal{M}$ in Eq. (5.6) is a Vandermonde matrix of order $D^2/4$, whose properties are well known.[23] In particular, its determinant is given by

$$\det \mathcal{M} = \prod_{(m,n)>(k,\ell)}(\lambda_m\lambda_n^* - \lambda_k\lambda_\ell^*) \quad (5.8)$$

and the formula for the inverse $\mathcal{M}^{-1}$ is available, where $(m,n)>(k,\ell)$ means $I_{mn}>I_{k\ell}$ with $I_{mn}=(D/2)(m-1)+n$. Determinant (5.8) is the product of all the differences that can be formed by any pairs taken from $\{\lambda_m\lambda_n^*\}$. It is therefore clear when it is possible to invert relation (5.5) to reconstruct the density operator $\varrho_{\theta_0\varphi_0}$ of $A+B+\cdots$; the parameters τ and (θ,φ) should be chosen so as to satisfy the conditions

$$\lambda_m\lambda_n^*\langle u_n|u_m\rangle \neq 0 \quad (m,n=1,\ldots,D/2),$$

$$\lambda_m\lambda_n^* \neq \lambda_k\lambda_\ell^* \quad \text{for } (m,n) \neq (k,\ell). \quad (5.9)$$

In this way, one gets a list of $\varrho_{\theta_0\varphi_0}$ for the four independent sets of (θ_0,φ_0), which completes the tomography of the state ϱ.

This scheme is quite simple and general: one simply repeats $P_\uparrow R_{\theta\varphi}^{(X)}$ necessary times, the scheme works for an arbitrary number of qubits M, and the conditions for the parameters are clear [Eq. (5.9)]. Only four independent sequences are required, irrespective of the number of qubits M.

VI. SUMMARY

In this paper, we have discussed the state tomography for a chain of qubits in the setup (Fig. 1) proposed as a possible physical realization of a quantum information processor. In this setup, only the state of the edge qubit of the chain is measurable via the spin-blockade measurement. However, the present analysis explicitly demonstrates that it is still possible to reconstruct the state of the whole chain of qubits. The idea is to make use of the entangling dynamics of the qubits, which enables one to gain information on the whole chain through the edge qubit.

Such an idea is not restricted to the current setup; there would be various physical systems in which only limited degrees of freedom are accessible in practice and similar strategies are required. The present idea would find many valuable applications.

In Sec. III, we have explicitly constructed a recipe for two qubits. We have also presented a general scheme based on repeated measurements that can be applied to an arbitrary number of qubits (Sec. V). There are, however, many other possibilities. For instance, the latter scheme requires $2^{2(M-1)}$ measurements for M qubits, i.e., four measurements for two qubits, while each sequence in Table I involves only two measurements. As mentioned in Sec. IV, the accuracy of the spin-blockade measurement relies on the polarization of the channel spins. For a partially polarized spin channel, it would be better to seek a scheme with fewer measurements. Shorter sequences of operations would be preferable also to minimize other possible errors, originating for instance from imperfect qubit rotations by ESR and decoherence during the processes.

There would exist recipes that involve only one measurement (and therefore with fewer rotations and a shorter execution time) for each sequence, but no general prescription for generating such sequences of operations is known (at least to the present authors). A possible strategy would be to generate sequences according to a certain rule anyway to select necessary number of sequences (since too many sequences might be generated for the reconstruction of a density operator with 4^M-1 independent matrix elements) and to check the invertibility of the relevant matrix, relating the matrix elements of the target density operator to the observable data. It is desirable to clarify how to generate the optimal sequences efficiently, which remains a future subject.

[21] Roughly speaking, the increase in the channel current with the $|{\uparrow}\rangle\langle{\uparrow}|$ component in Eq. (4.1) projects X onto $|{\uparrow}\rangle_X\langle{\uparrow}|$ while that with $|{\downarrow}\rangle\langle{\downarrow}|$ onto $|{\downarrow}\rangle_X\langle{\downarrow}|$, with these two cases summed up classically in accordance with the classical mixture in Eq. (4.1). A more rigorous derivation of Eq. (4.2) would be possible by formulating the spin-blockade measurement process as a projection on the state of the "current" degree of freedom and not on the spin degree of freedom of the channel electron. See, for instance, K. Koshino and A. Shimizu, Phys. Rep. **412**, 191 (2005).
