We study the phase diagram of a symmetric spin-1/2 Heisenberg diamond chain with additional cyclic four-spin exchange interactions. The presented analysis supplemented by numerical exact-diagonalization results for finite periodic clusters implies a rich phase diagram containing, apart from standard magnetic and spin-liquid phases, two different tetramer-dimer phases as well as an exotic fourfold degenerate dimerized phase. The characteristics of the established spin phases as well as the nature of quantum phase transitions are discussed as well.

I. INTRODUCTION

Spin systems with cyclic exchange interactions have been receiving an increasing amount of attention in the past few years. These interactions are known to be responsible for the properties of the triangular magnetic system composed of ³He atoms absorbed on graphite surfaces.¹ Recently, it was demonstrated that a certain amount of four-spin exchange could explain the neutron-scattering experiments concerning high- T_c compounds such as La₂CuO₄,² La₆Ca₈Cu₂4O₄₁,³ and La₄Sr₁₀Cu₂₄O₄₁.⁴ The latter two are spin-ladder compounds where charge fluctuations such as cyclic hopping processes modify the Heisenberg spin Hamiltonian by contributing a four-spin interaction term. In particular, it was found that these interactions substantially modify the spin triplon gaps and frustrate the formation of bound triplon states.⁴ On the theoretical side, in spite of the numerous numerical studies predicting rich phase diagrams,⁵ a number of important questions, concerning the type of spin orderings and quantum criticalities realized by the four-spin exchange, remains unsettled.6

In this paper we analyze the role of the cyclic four-spin exchange interactions in the symmetric diamond chain (SDC) which is one of the simplest spin models admitting multi-spin cyclic exchange interactions. The model is defined by the Hamiltonian (see Fig. 1)

$$\mathcal{H} = \sum_{n=1}^{L} h_{n,n+1},$$
 (1)

where *h*

$$h_{n,n+1} = J_1 \mathbf{s}_n \cdot (\boldsymbol{\sigma}_n + \boldsymbol{\sigma}_{n+1}) + J \boldsymbol{\sigma}_n \cdot \boldsymbol{\sigma}_{n+1} + J_{\perp} \mathbf{s}_{1n} \cdot \mathbf{s}_{2n} + K[(\mathbf{s}_{1n} \cdot \boldsymbol{\sigma}_n)(\mathbf{s}_{2n} \cdot \boldsymbol{\sigma}_{n+1}) + (\mathbf{s}_{1n} \cdot \boldsymbol{\sigma}_{n+1})(\mathbf{s}_{2n} \cdot \boldsymbol{\sigma}_n) - (\mathbf{s}_{1n} \cdot \mathbf{s}_{2n})(\boldsymbol{\sigma}_n \cdot \boldsymbol{\sigma}_{n+1})].$$

Here \mathbf{s}_{1n} , \mathbf{s}_{2n} , and $\boldsymbol{\sigma}_n$ are spin-1/2 operators defined on the sites of the *n*th elementary cell. In our model, the standard cyclic four-spin exchange interactions⁷ are slightly general-

ized by including its bilinear terms in the exchange parameters J, J_1 , and J_{\perp} . In what follows the action and the energy are measured in the units of \hbar and J_1 , respectively.

The frustrated diamond chain⁸ as well as its various modifications, such as the distorted diamond chain^{9,10} and the socalled AB_2 ferrimagnetic chain with Ising and Heisenberg spins,¹¹ have already been discussed in the literature in relation to some quasi-one-dimensional magnetic materials.¹² For the following analysis it is important to notice that the cyclic exchange interaction does not violate the local symmetry of the Hamiltonian under the exchange of the pair of spins ($\mathbf{s}_{1n}, \mathbf{s}_{2n}$) for each diamond in the SDC. Thus, in the important case of spin-1/2 operators \mathbf{s}_{1n} and \mathbf{s}_{2n} , the system is characterized by *L* local good quantum numbers $s_n=0,1$ (*n* =1,2,...,L) related to the composite spins $\mathbf{s}_n=\mathbf{s}_{1n}+\mathbf{s}_{2n}$: \mathbf{s}_n^2 $=s_n(s_n+1)$. Using this local symmetry and the standard commutation relations for spin operators, the local Hamiltonian $h_{n,n+1}$ can be represented in the compact form

$$h_{n,n+1} = \boldsymbol{\epsilon}_n + \mathbf{s}_n \cdot (\boldsymbol{\sigma}_n + \boldsymbol{\sigma}_{n+1}) + J_n \boldsymbol{\sigma}_n \cdot \boldsymbol{\sigma}_{n+1} + \frac{K}{2} \{ \mathbf{s}_n \cdot \boldsymbol{\sigma}_n, \mathbf{s}_n \cdot \boldsymbol{\sigma}_{n+1} \}.$$
(2)

Here $\epsilon_n/J_{\perp} = s_n(s_n+1)/2 - 3/4$ are fixed numbers (-3/4 or 1/4) for every sector defined as a sequence of the local quantum numbers $[s_1, s_2, \dots, s_L]$, $J_n = J + K/4 - s_n(s_n+1)K/2$, and $\{A, B\}$ is the anticommutator of two operators (*A* and *B*).

TABLE I. Eigenvalues and eigenstates of a single diamond composed of the spins $\mathbf{s}_1, \mathbf{s}_2, \boldsymbol{\sigma}_1$, and $\boldsymbol{\sigma}_2$. The eigenstates are classified according to the following good quantum numbers of the single-diamond cluster: the total diamond spin s_p , its z component s_p^z , and the diagonal spins s and $\boldsymbol{\sigma} [\mathbf{s}=\mathbf{s}_1+\mathbf{s}_2 \text{ and } \boldsymbol{\sigma}=\boldsymbol{\sigma}_1+\boldsymbol{\sigma}_2: \mathbf{s}^2 = s(s+1), \, \boldsymbol{\sigma}^2 = \boldsymbol{\sigma}(\boldsymbol{\sigma}+1)]$. The symbols $t^{\mu} (\mu=0,\pm)$ stand for the canonical basic states of the spin-1 operators, whereas t^s denotes the singlet state of two spin-1/2 operators. For brevity, only the $s_p^z=0$ components of the triplet (T_1^{μ}) and quintet (Q^{μ}) states are presented.

	s _p	S	σ	Eigenvalue	Eigenstate
<i>S</i> ₁	0	0	0	$-\frac{3}{4}(J_{\perp}+J)-\frac{3}{16}K$	$t_{\perp}^{s}t_{\parallel}^{s}$
S_2	0	1	1	$-2+\frac{1}{4}(J_{\perp}+J)+\frac{13}{16}K$	$\frac{1}{\sqrt{3}}(t_{\perp}^{+}t_{\parallel}^{-}+t_{\perp}^{-}t_{\parallel}^{+}-t_{\perp}^{0}t_{\parallel}^{0})$
T_{1}^{0}	1	1	1	$-1 + \frac{1}{4}(J_{\perp} + J) - \frac{7}{16}K$	$\frac{1}{\sqrt{2}}(t_{\perp}^{+}t_{\parallel}^{-}-t_{\perp}^{-}t_{\parallel}^{+})$
T_2^{μ}	1	0	1	$-\frac{3}{4}J_{\perp} + \frac{J}{4} + \frac{K}{16}$	$t_{\perp}^{\tilde{s}}t_{\parallel}^{\mu},\mu{=}0,\pm$
T_3^{μ}	1	1	0	$\frac{J_{\perp}}{4} - \frac{3}{4}J + \frac{K}{16}$	$t_{\perp}^{\mu}t_{\parallel}^{s},\ \mu=0,\pm$
Q^0	2	1	1	$1 + \frac{1}{4}(J_{\perp} + J) + \frac{K}{16}$	$\frac{1}{\sqrt{6}} \left(t_{\perp}^{+} t_{\parallel}^{-} + t_{\perp}^{-} t_{\parallel}^{+} + 2t_{\perp}^{0} t_{\parallel}^{0} \right)$

In the parameter space where the ground state is characterized by $s_n=0$ (n=1,2,...,L), the second and fourth terms in Eq. (2) vanish and the model is equivalent to the spin-1/2 Heisenberg chain with an exchange parameter J+K/4. On the other hand, if the ground state belongs to the sector s_n =1 (n=1,2,...,L), Eq. (2) defines the generic model of an alternating mixed-spin chain with the simplest three-spin exchange interaction. Finally, if the ground state is in the sector [1,0,1,0,...], the system is reduced to some modification of the well-known orthogonal dimer chain.¹³

II. PHASE DIAGRAM IN THE PARAMETER SPACE (K, J_{\perp})

It is instructive to begin with the phase diagram of a single diamond composed of the spins s_1 , s_2 , σ_1 , and σ_2 . The diamond eigenstates (see Table I) consist of two singlets $(S_1 \text{ and } S_2)$, three triplets $(T_1^{\mu}, T_2^{\mu}, \text{ and } T_3^{\mu}; \mu=0, \pm 1)$, and the quintet Q^{μ} ($\mu=0, \pm 1, \pm 2$). In Fig. 2, the phase boundaries between the single-diamond ground states $(S_1, S_2, T_1, \text{ and } T_2)$ are depicted by dashed lines. As discussed below, some of these lines coincide with the exact phase boundaries of the diamond chain [Eq. (1)].

A. Phases in the sector $[0,0,\cdots,0]$

For large enough values of the parameter J_{\perp} , the off-chain spins form local dimers $\mathbf{s}_{1n} \cdot \mathbf{s}_{2n} = -3/4$ so that the ground state of the model belongs to the sector $[0, 0, \dots, 0]$. Thus, Eq. (2) reduces to the form

$$h_{n,n+1} = -(3/4)J_{\perp} + (J + K/4)\boldsymbol{\sigma}_n \cdot \boldsymbol{\sigma}_{n+1}.$$
 (3)

This is the Hamiltonian of a spin-1/2 Heisenberg chain with the exchange constant J+K/4. The single-diamond line *AB* (defined by J+K/4=0) coincides with the exact boundary between the fully polarized ferromagnetic phase FM1 (J+K/4<0) and the critical spin-fluid phase SF (J+K/4>0).

Besides the well-documented collective modes, these phases exhibit additional single-particle modes (related to the off-diagonal spins) describing excited $(\mathbf{s}_{1n}, \mathbf{s}_{2n})$ dimers, $s_n = 1$. Being eigenstates of the Hamiltonian [Eq. (1)] these ex-

citations are completely localized. According to Eq. (2), an excited dimer (say at n=L) is described by the Hamiltonian

$$\mathcal{H}_{i} = C + \left(J + \frac{K}{4}\right) \sum_{n=1}^{L-1} \boldsymbol{\sigma}_{n} \cdot \boldsymbol{\sigma}_{n+1} + h_{i}, \qquad (4)$$

where $C = -\frac{3}{4}J_{\perp}(L-1)$ and h_i reads as

$$h_{i} = \frac{J_{\perp}}{4} + \left(J - \frac{3K}{4}\right)\boldsymbol{\sigma}_{L} \cdot \boldsymbol{\sigma}_{1} + J_{i}\mathbf{s}_{L} \cdot (\boldsymbol{\sigma}_{L} + \boldsymbol{\sigma}_{1}) + \frac{K}{2}\{\mathbf{s}_{L} \cdot \boldsymbol{\sigma}_{L}, \mathbf{s}_{L} \cdot \boldsymbol{\sigma}_{1}\}, J_{i} = 1.$$
(5)

Similar models, describing spin-S impurities in spin-1/2 an-

FIG. 2. (Color online) Phase diagram of the model [Eq. (1)] in the parameter space (K, J_{\perp}) for J=0 as obtained from the numerical diagonalization of periodic clusters containing up to L=12 unit cells. The dashed lines denote the boundaries of the single-diamond phase diagram containing the states S_1 , S_2 , T_1 , and T_2 (see Table I). The following abbreviations for the phases of Eq. (1) are used: critical spin-fluid state (SF), fully-polarized ferromagnetic state (FM1), ferrimagnetic state (FM2), tetramer-dimer states (TD1,TD2), dimerized singlet state (DM), and another ferrimagnetic state (FM3).

FIG. 3. (Color online) Short-range spin-spin correlations vs *K* in the tetramer-dimer phases TD1 and TD2 for periodic chains with L=8 cells $(J=0, J_{\perp}=1.15)$. $(1,2) \equiv \langle \boldsymbol{\sigma}_n \cdot \boldsymbol{s}_{1n} \rangle$, $(1,3) \equiv \langle \boldsymbol{\sigma}_n \cdot \boldsymbol{\sigma}_{n+1} \rangle$, $(3,4) \equiv \langle \boldsymbol{\sigma}_{n+1} \cdot \boldsymbol{\sigma}_{n+2} \rangle$, and $(2,5) \equiv \langle \boldsymbol{s}_{1n} \cdot \boldsymbol{s}_{1n+2} \rangle$.

tiferromagnetic Heisenberg chains, have been discussed in the literature.¹⁴ In particular, the above model may be considered as a special class of open chains with symmetric couplings of the end spins (σ_1 and σ_L) to the external spin s_L ($s_L=1$).

Turning to the region occupied by the SF phase, renormalization-group arguments predict that symmetric perturbations to the open chain are, at most, marginal. Thus, the marginally relevant perturbation $J_i \mathbf{s}_L \cdot (\boldsymbol{\sigma}_L + \boldsymbol{\sigma}_1)$ ($J_i > 0$) is expected to renormalize to ∞ in the SF phase. This corresponds to a fixed point where the end spins $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_L$ are effectively removed from the chain to screen the external spin \mathbf{s}_L . In terms of the original model [Eq. (1)] the spins $\boldsymbol{\sigma}_1, \boldsymbol{\sigma}_L, \mathbf{s}_{1L}$, and \mathbf{s}_{2L} form a decoupled single-diamond state (S_2) in the low-energy sector of the spectrum. Such local excitations are relevant relatively close to the phase boundary AB, where the coupling $J_i \mathbf{s}_L \cdot (\boldsymbol{\sigma}_L + \boldsymbol{\sigma}_1)$ dominates the biquadratic term in Eq. (5).

For larger values of the parameter *K*, the biquadratic exchange in h_i becomes important. Since the energy of the quintet state *Q* grows up with *K* (see Table I), we concentrate on the triplet state T_1 whose energy decreases with *K* and crosses the energy level of S_2 at K=4/5. As discussed in Ref. 14, such a local triplet state does not correspond to a stable fixed point since the antiferromagnetic interaction of the effective spin-1 impurity with the rest of the chain is marginally relevant. Thus, one expects that the couplings to the next

FIG. 4. (Color online) Spin-wave spectrum of the $(s_1, s_2) = (1, 1/2)$ chain with three-spin exchange interactions [Eq. (6)] in (a) the ferrimagnetic and (b) the canted ground states at $\kappa = 0.8$ and 1.5, respectively. $J=J_{\perp}=0$ and $\kappa \equiv K/2$.

FIG. 5. (Color online) Lowest-energy excited states in a periodic chain with L=12 diamonds in the sectors with magnetic moments M_0-1 (triangles) and M_0+1 (circles). $M_0=L(S_1-S_2)=6$ is the magnetic moment of the ferrimagnetic ground state. K=1 and $J=J_{\perp}=0$.

two spins in the chain, σ_{L-1} and σ_2 , grow up to ∞ . There appears another fixed point where the latter two spins also decouple from the chain in order to screen the spin of the triplet state T_1 . Note that in sectors containing more spin-1 dimers, other types of screening are possible as well. For example, the spins of neighboring T_1 diamonds in Fig. 3 may be screened by forming a singlet state. As before, the number of decoupled chain spins is four. We suggest that such decoupled singlet states, composed of longer S_2 or T_1 diamond chains, control the observed instability of the SF phase upon decreasing the parameter J_{\perp} . Note that similar complexes of S_1 diamonds cannot produce the instability since the energy of the resulting product state $[\sigma_1, \sigma_2][\sigma_3, \sigma_4] \cdots [\sigma_{L-1}, \sigma_L]$ exceeds the energy of the critical phase for arbitrary J_{\perp}, K >0.

B. Tetramer-dimer phases

A detailed numerical study of periodic clusters containing up to L=12 cells close to the lines FA, AC, and CD in Fig. 2 suggests that for smaller values of J_{\perp} the ground state belongs to the sector $[1,0,\cdots,1,0]$. In the special case K=0, our numerical results reproduce the phase diagram of the frustrated SDC,⁸ where the so-called tetramer-dimer phase (denoted as TD1 in Fig. 2) appears in the interval 0.909 $< J_{\perp} < 2$. This doubly degenerate singlet state may be roughly represented as a product of single-diamond S_2 states on every second diamond, as depicted in Fig. 3. The shortrange correlations shown in Fig. 3 imply that the simple product state is a good variational wave function over the entire region occupied by the TD1 phase, excluding a narrow region near the line AE. The product state is an exact ground state at $(K,J_{\perp})=(0,2)$. An extrapolation of the exactdiagonalization (ED) data suggests that the phase boundary between the TD1 and SF phases lies extremely close to the AC line separating the single-diamond states S_1 and S_2 . On the other hand, the phase boundary between the TD1 and FM1 phases clearly deviates from the single-diamond boundary AF. The deviation from the line AF is related to weak but finite interactions between neighboring S_2 diamonds appearing in the second-order perturbation theory in the parameter J + K/4.

On increasing the cyclic exchange parameter K at fixed J_{\perp} one finds another tetramer-dimer type state (TD2). The picture of the spin-spin correlations [Fig. 3] suggests that every second diamond is approximately in the T_1 state. Nevertheless, the numerical analysis shows relatively strong antiferromagnetic correlations between neighboring T_1 diamonds as opposed to the TD1 state where the S_2 diamonds are weakly correlated. Clearly, both tetramer-dimer phases are gapped and doubly degenerated. According to the general rules,¹⁵ one may expect a discontinuous quantum phase transition between the quantum gapped phases TD1 and TD2. Numerically, the transition point is indistinguishable from the exact single-diamond phase boundary CE (K=4/5) separating the single-diamond states S_2 and T_1 .

C. Phases in the sector $[1, 1, \dots, 1]$

A numerical inspection of the short-range correlators $\langle \mathbf{s}_{1n} \cdot \mathbf{s}_{2n} \rangle$ in finite periodic chains implies that for moderate values of the parameter J_{\perp} the established ground states belong to the sector $[1, 1, \dots, 1]$. Thus, in the low-energy region the diamond model [Eqs. (1) and (2)] is equivalent to the following mixed-spin Heisenberg model ($|\mathbf{s}_n| \equiv s_1 = 1$ and $|\boldsymbol{\sigma}_n| \equiv s_2 = 1/2$) with three-spin exchange interactions,

$$\mathcal{H}_{1} = \sum_{n=1}^{L} \left[\mathbf{s}_{n} \cdot (\boldsymbol{\sigma}_{n} + \boldsymbol{\sigma}_{n+1}) - J' \, \boldsymbol{\sigma}_{n} \cdot \boldsymbol{\sigma}_{n+1} + \frac{K}{2} \{ \mathbf{s}_{n} \cdot \boldsymbol{\sigma}_{n}, \mathbf{s}_{n} \cdot \boldsymbol{\sigma}_{n+1} \} \right], \tag{6}$$

where J' = 3K/4 - J. To the best of our knowledge, generic mixed-spin quantum Heisenberg models with multiple-spin exchange interactions have not been discussed in the literature although these interactions may play an important role in some recently synthesized mixed-spin magnetic materials.^{16,17} Here we restrict ourselves to a general overview of the spin phases in the specific case (s_1, s_2) =(1,1/2) and to ferromagnetic exchange interactions between the σ_n spins (J' > 0). The first two terms in Eq. (6) define a standard mixed-spin Heisenberg model containing additional nonfrustrated J' exchange bonds. The Lieb-Mattis theorem¹⁸ predicts a ferrimagnetic ground state for this bipartite model which coincides with the classical ferrimagnetic two-sublattice Néel state (the FM2 phase in Fig. 2). To study the role of the competing three-spin interactions, we use a qualitative spin-wave analysis supplemented by numerical ED calculations for finite periodic chains.

Let us start with a discussion of the semiclassical limit of model (6). Since the three-spin interaction contains an additional overall factor of s_1s_2 , it is convenient to redefine the coupling constant *K* and measure the strength of these interactions in terms of $\kappa = s_1s_2K$. The classical Néel configuration defined by $\mathbf{s}_n = s_1(0,0,1)$ and $\boldsymbol{\sigma}_n = s_2(0,0,-1)$ survives up to $\kappa = 1$. For $\kappa > 1$, the ferromagnetic arrangement of the smaller s_2 spins remains unchanged whereas the orientation of the s_1 spins deviates from the *z* axis: $\mathbf{s}_n = s_1(\sin \theta \cos \phi_n, \sin \theta \sin \phi_n, \cos \theta)$. Here $\cos \theta = 1/\kappa$ and the azimuthal angle ϕ_n takes arbitrary values from the interval $0 \le \phi_n < 2\pi$ $(n=1,\ldots,L)$. As a rule, quantum fluctua-

FIG. 6. (Color online) Short-range spin-spin correlations vs *K* for periodic chains with L=12 cells $(J=J_{\perp}=0)$.

tions favor the planar spin configurations ($\phi_n = 0, \pi$, with n = 1, 2, ..., L) so that one may expect a reduction in the degeneracy to 2^L . Such high degeneracy of the ground state is typical for a number of spin models on corner-sharing lattices. As seen in Fig. 4(b), in a spin-wave approximation the degeneracy produces a full line of zero modes $\omega_F = 0$ in the Brillouin zone. Note that the presence of the gapless antiferromagnetic mode $\omega_{AF} \propto k$ ($k \ll 1$) for $\kappa > 1$ is related to the finite transverse magnetization of the classical canted state. The explicit expression for ω_{AF} reads as

$$\omega_{\rm AF} = 2J' s_2 \left| \sin\left(\frac{k}{2}\right) \right| \sqrt{\sin^2\left(\frac{k}{2}\right) + \frac{s_1}{s_2}\alpha \cos k}, \qquad (7)$$

where $\alpha = (\kappa^2 - 1)/(2\kappa J')$. It is clear that the antiferromagnetic mode ω_{AF} is stabilized by the ferromagnetic couplings between the σ_n spins. The above picture of low-lying excitations in the ferrimagnetic phase close to the phase-transition point is confirmed by the numerical results at K = 1, Fig. 5. The numerical estimate for the phase-transition point is $K_c \approx 1.2$.

Additional information about the phase diagram of Eq. (6) may be obtained from the behavior of the short-range correlations [Fig. 6] and the singlet-triplet excitation gap [Fig. 7] with the parameter *K*. For larger K > 1.2, the ED results indicate at least two additional phases denoted by DM and FM3 in Fig. 2: DM is a nonmagnetic gapped singlet state stabilized approximately in the region $1.5 \le K \le 2.3$ (see Fig. 7), and FM3 is a magnetic phase similar to the FM2 phase.

FIG. 7. (Color online) The excitation gap in the DM phase as a function of the parameter K.

FIG. 8. (Color online) Caricature of the dimerized singlet phase DM as obtained from an extrapolation of the numerical ED results for periodic chains with L=8, 10, and 12. The open circles (thick lines) denote the symmetric (antisymmetric) eigenstates of two spin-1/2 operators. K=2, $J_{\perp}=J=0$, and $(s_1,s_2)=(1,1/2)$.

Since the unit cell consists of three spin-1/2 variables, the Lieb-Schultz-Mattis theorem¹⁹ suggests that the spin gap must be accompanied with at least doubly-degenerate ground states.

Further information about the DM phase can be extracted from the dimerization operator $D_n = \mathbf{S}_n \cdot \mathbf{S}_{n+1} - \mathbf{S}_n \cdot \mathbf{S}_{n-1}$, where S_n is the spin operator at site *n*. The lattice sites n-1 and n+1 are supposed to be symmetric under the reflection from the central site n. It is convenient to use the symmetric (antisymmetric) combinations $|s,a\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2}$, where $|0\rangle$ is the translationally invariant singlet ground state of the finite periodic chain and $|1\rangle$ is the singlet excited state which is almost degenerate with $|0\rangle$. The states $|s,a\rangle$ are not translationally invariant and may be expected to produce finite values of the dimer order-parameter $\langle s, a | D_n | s, a \rangle$ in a dimerized system.²⁰ The caricature of the DM state presented in Fig. 8 is obtained from the extrapolation of the ED results for $\langle s, a | D_n | s, a \rangle$ (L=8, 10, and 12). A pronounced enhancement of the dimer order parameter with L is indicated only for two types of bonds in the dimer model (the thick lines in Fig. 8). Clearly, the suggested ground state exhibits a fourfold degeneracy.

Finally, the numerical results point toward the existence of another partially polarized magnetic phase in the narrow interval 1.2 < K < 1.5 between the ferrimagnetic (FM2) and the dimerized (DM) phases (the hatched area in Fig. 2). Recently, similar exotic magnetic states have been predicted in a number of one-dimensional spin systems with magnetic frustrations.²¹ Typically, discussed spin states exhibit a partially polarized magnetization in the *z* direction ($M < M_0$ $= s_1 - s_2$), a quasi-long-range transverse magnetic order, and a gapless linear mode related to the destroyed classical canted state. Unfortunately, the methods used in the present study do not suggest a clear statement indicating the existence of such an exotic phase in the discussed system.

III. SUMMARY

In conclusion, we have examined the impact of the cyclic four-spin exchange interactions on the ground-state phase diagram of the symmetric spin-1/2 diamond chain. Using the local symmetries of the model, the spin phases were classified by the set of good quantum numbers $s_n=0,1$ (n = 1,2,...,L) related to the composite spins $s_n=s_{1n}+s_{2n}$. The presented study demonstrates a rich phase diagram in the parameter space (K,J_{\perp}). Apart from the standard magnetic and paramagnetic phases, the system exhibits two different tetramer-dimer phases in the sector [1,0,1,0,...,1,0] as well as an exotic fourfold-degenerate dimerized ground state in the sector [1,1,...,1].
