(Received 9 December 2010; revised manuscript received 5 January 2011; published 28 February 2011)

The optical conductivity of graphite in quantizing magnetic fields is analytically evaluated for frequencies in the range of 10–300 meV, where the electron relaxation processes can be neglected and the low-energy excitations at the “Dirac lines” are more essential. The conductivity peaks are explained in terms of the electron transitions in graphite. Conductivity calculated per one graphite layer tends, on average, to the universal conductivity of graphene. The (semi)metal-insulator transformation is possible under doping in high magnetic fields.

Graphite is usually considered as a layered semimetal composed of the graphene monolayers. Within this assumption, the graphite electron spectrum was evaluated many years ago within the Slonczewski-Weiss-McClure (SWM) theory.¹ The so-called “Dirac cone” turns into four bands with the twofold degenerate zero mode where electrons and holes are located.² The zero-mode dispersion is very small, of the order of 20 meV, in the main-axis direction because the interlayer interaction is weak. Unusual properties of graphite have attracted much attention for more than 50 years. The most accurate method to study the band structure of graphite is a study of the Landau levels (LLs) through experiments such as magneto-optics^{3–9} and magnetotransport.^{10–14} However, the interpretation of the experimental results involves a significant degree of uncertainty since, as noticed by Doezema *et al.*⁴ and Chuang *et al.*¹⁵ “it is not clear where the resonances are to be marked.”

The SWM theory requires the use of many tight-binding parameters and provides the simple description of observed phenomena either in the semiclassical limit of weak magnetic fields or for high frequencies when the largest tight-binding parameter $\gamma_1 = 0.4$ eV plays the leading role.¹⁶ At the relatively strong magnetic fields $B \sim 1\text{--}30$ T and frequencies $\omega \sim 10\text{--}350$ meV, the smaller tight-binding parameters γ_2, γ_5 , and Δ of the order of 20 meV are essential. In this case, any physical property for graphite in a magnetic field is represented by an integral over the momentum projection k_z . The SWM model can be simplified assuming that only the integration limits produce the main contributions.^{7,15,17} Such an approximation is similar to the theory of magneto-optical effects in topological insulators¹⁸ and graphene.¹⁹ However, in the three-dimensional systems, the other features such as the band extrema or the integration limits at the Fermi level can contribute as well. Therefore, the analytical expression for the dynamic conductivity in the presence of magnetic fields is needed for an interpretation of magneto-optics experiments. The theoretical study of magneto-optical properties in multi-layer graphene is realized in Ref. 20.

In this Rapid Communication, we evaluate a formula for the optical conductivity of graphite in the presence of quantizing magnetic fields and the results are compared with experiments. We remind that the notation for the LLs in graphite using the Hamiltonian is in the form of Refs. 21 and 22. The expression for both the longitudinal and Hall dynamical conductivities is

given. The (semi)metal-insulator transition is discussed in the conclusion.

Neglecting the trigonal warping γ_3 , the effective Hamiltonian near the KH line of the Brillouin zone can be written in the form

$$H(\mathbf{k}) = \begin{pmatrix} \tilde{\gamma}_5 & vk_+ & \tilde{\gamma}_1 & 0 \\ vk_- & \tilde{\gamma}_2 & 0 & 0 \\ \tilde{\gamma}_1 & 0 & \tilde{\gamma}_5 & vk_- \\ 0 & 0 & vk_+ & \tilde{\gamma}_2 \end{pmatrix}, \quad (1)$$

where $k_{\pm} = \mp ik_x - k_y$, $v = 1.02 \times 10^8$ cm/s is the intralayer velocity, and $\tilde{\gamma}_j$ are the functions of k_z

$$\tilde{\gamma}_1 = 2\gamma_1 \cos(k_z c_0), \quad \tilde{\gamma}_2 = 2\gamma_2 \cos(2k_z c_0), \\ \tilde{\gamma}_5 = 2\gamma_5 \cos(2k_z c_0) + \Delta,$$

with the distance $c_0 = 3.35$ Å between the layers in graphite.

At the magnetic field B , the momentum projections $k_{x,y}$ become the operators with the commutation rule $\{k_+, k_-\} = -2e\hbar B/c$, and we can use the relations

$$k_+ = \sqrt{2|e|\hbar B/c} a, \quad k_- = \sqrt{2|e|\hbar B/c} a^\dagger,$$

involving the creation and annihilation operators. We seek the eigenfunction of the Hamiltonian in the form

$$\psi_{sn}^\alpha(x) = \begin{cases} C_{sn}^1 \varphi_{n-1}(x) \\ C_{sn}^2 \varphi_n(x) \\ C_{sn}^3 \varphi_{n-1}(x) \\ C_{sn}^4 \varphi_{n-2}(x) \end{cases}, \quad (2)$$

where the Landau numbers $n \geq 2$ and $\varphi_n(x)$ are orthonormal Hermitian functions with $n \geq 0$. Then every row in the Hamiltonian (1) becomes proportional to the Hermitian function with the definite n , and we obtain a system of the linear equations for the eigenvector \mathbf{C}_{sn}

$$\begin{pmatrix} \tilde{\gamma}_5 - \varepsilon & \omega_c \sqrt{n} & \tilde{\gamma}_1 & 0 \\ \omega_c \sqrt{n} & \tilde{\gamma}_2 - \varepsilon & 0 & 0 \\ \tilde{\gamma}_1 & 0 & \tilde{\gamma}_5 - \varepsilon & \omega_c \sqrt{n-1} \\ 0 & 0 & \omega_c \sqrt{n-1} & \tilde{\gamma}_2 - \varepsilon \end{pmatrix} \times \begin{pmatrix} C_{sn}^1 \\ C_{sn}^2 \\ C_{sn}^3 \\ C_{sn}^4 \end{pmatrix} = 0, \quad (3)$$

where $\omega_c = v\sqrt{2|e|\hbar B/c}$.

FIG. 1. (Color online) LLs ε_{sn} for $n = 0$ to 6 in four bands s as functions of momentum k_z along the KH line in the Brillouin zone ($K = 0$, $H = \pi/2c_0$) at the magnetic field $B = 20$ T using the SWM model with the TB parameters taken from Refs. 21 and 22 and neglecting trigonal warping; the Fermi energy $\varepsilon_F = 0$ eV is shown in the dash-dotted line. Electron transitions are possible between the levels $\varepsilon_{sn} < 0$ and $\varepsilon_{s'n'} > 0$ with the selection rule $\Delta n = \pm 1$.

At each Landau number n , the eigenvalues ε_{sn} of the Hamiltonian are marked by the index of the band $s = 1, 2, 3, 4$ numerating the levels from the bottom. We will use the notation $|sn\rangle$ for levels. LLs with $n \geq 2$ are in every four bands, shown in Fig. 1 as functions of k_z along the KH line of the Brillouin zone. The eigenvalues are determined by the equation

$$\begin{aligned} & [(\tilde{\gamma}_5 - \varepsilon)(\tilde{\gamma}_2 - \varepsilon) - \omega_c^2(n-1)] \\ & \times [(\tilde{\gamma}_5 - \varepsilon)(\tilde{\gamma}_2 - \varepsilon) - \omega_c^2 n] - \tilde{\gamma}_1^2(\tilde{\gamma}_2 - \varepsilon)^2 = 0. \end{aligned}$$

In addition, there are four levels. One of them, $\varepsilon_0 = \tilde{\gamma}_2$, with $n = 0$ and the eigenvector $\mathbf{C}_0 = (0, 1, 0, 0)$.

This level intersects the Fermi level and belongs to the electron (hole) band near the K (H) point. The other three levels, $s = 1, 2, 3$, are indicated by $n = 1$ with $C_{s1}^4 = 0$. One level, $|21\rangle$, is very close to the level with $n = 0$. This pattern is consistent with Ref. 6. The level structure at the $K'H'$ line is similar therefore each level is fourfold degenerate, twice in spin and twice in pseudospin of the KH and $K'H'$ valleys.

In the region where $\tilde{\gamma}_1 \gg \tilde{\gamma}_2, \tilde{\gamma}_5$, the two closest bands are written as

$$\varepsilon_{3,2}(n) = \tilde{\gamma}_2 \pm \omega_c^2 \sqrt{n(n-1)} / \tilde{\gamma}_1.$$

The Fermi energy at zero temperature $T = 0$ is determined by the equality of the electron and hole concentrations given by the sum of integrals

$$n_{h,e} = \frac{\hbar \omega_c^2}{\pi^2 v^2 c_0} \sum_{sn} \int dz, \quad (4)$$

over the region in the Brillouin half-zone $z = c_0 k_z$ where electrons and holes are located. As known, the Fermi energy oscillates in the quantum Hall regime. We will consider the relatively strong magnetic fields where the oscillations

do not exceed 2 meV according to the electroneutrality condition (4).

At finite temperatures the conductivity is expressed in terms of the correlation function²³ (for details see Ref. 24)

$$\mathcal{P}(\omega) = T \sum_{\omega_m} \int dx dx' Tr \{ v^i \mathcal{G}(\omega_+, x, x') v^j \mathcal{G}(\omega_-, x', x) \}, \quad (5)$$

where $\mathcal{G}(\omega_\pm, x, x')$ is the temperature Green's function $\omega_\pm = \omega \pm \omega_m$, Tr is taken over the $|sn\rangle$ eigenstates, and the x, x' integration is over the coordinate involved explicitly in the Hamiltonian while the Landau gauge is used. Then the Fourier transform of the eigenstates with respect to the y coordinate is assumed. Using the eigenfunctions (2), we write the Green's function of the Hamiltonian (1)

$$\mathcal{G}^{\alpha\beta}(\omega, x, x') = \sum_{sn} \frac{\psi_{sn}^\alpha(x) \psi_{sn}^{*\beta}(x')}{i\omega - \varepsilon_{sn}}.$$

The intralayer-velocity matrix v^i is given by the derivative of the Hamiltonian (1)

$$\mathbf{v} = \frac{\partial H(\mathbf{k})}{\partial \mathbf{k}}. \quad (6)$$

The straightforward calculation of the dynamical conductivity gives

$$\begin{aligned} \left. \begin{aligned} \sigma_{xx}(\omega) \\ \sigma_{xy}(\omega) \end{aligned} \right\} &= i\sigma_0 \frac{4\omega_c^2}{\pi^2} \sum_{n,s,s'} \int_0^{\pi/2} dz \frac{dz}{\Delta_{ss'n}} [f(\varepsilon_{s'n+1}) - f(\varepsilon_{s,n})] \\ &\times [(\omega + i\Gamma + \Delta_{ss'n})^{-1} \pm (\omega + i\Gamma - \Delta_{ss'n})^{-1}] \\ &\times |C_{sn}^2 C_{s'n+1}^* + C_{sn}^3 C_{s'n+1}^{4*}|^2, \quad (7) \end{aligned}$$

where $\Delta_{ss'n} = \varepsilon_{sn} - \varepsilon_{s'n+1}$ is the level spacing, $\omega_c = v\sqrt{2|e|\hbar B}/c$ is the cyclotron frequency, and $f(\varepsilon) = [\exp(\frac{\varepsilon - \mu}{T}) + 1]^{-1}$ is the Fermi-Dirac function. The integration over the Brillouin half-zone $0 < z < \pi/2$ and the summation

FIG. 2. (Color online) Real and imaginary parts of the longitudinal dynamical conductivity at $B = 20$ T (thick line); the partial contributions of various electron transition are shown in the thin lines. Temperature $T = 0.1$ meV is less than the level broadening $\Gamma = 5$ meV.

FIG. 3. (Color online) Real and imaginary parts of the dynamical Hall conductivity at $B = 20$ T (thick line) with the partial contributions of the various electron transitions shown in the thin lines.

over the Landau number n as well as the bands s, s' should be done in Eq. (7).

The selection rule $\Delta n = \pm 1$ appears as a result of the integration over x and x' in Eq. (5). If the trigonal warping is taken into account, the selection rule is changed^{25,26}. Let us notice that the choice of the selection rule can be done examining the intensities of the cyclotron resonance lines. Our choice corresponds with the observations in Refs. 7 and 15. The results for the longitudinal conductivity $\sigma_{xx}(\omega)$ are shown in Figs. 2 and 4 for two values of the magnetic field to compare the effect of the field. The dynamical Hall conductivity $\sigma_{xy}(\omega)$ shown in Figs. 3 and 5 describes the Faraday rotation.⁹ The formula (7) is valid in the collisionless limit, when the relaxation rate is much less than the frequency $\Gamma \ll \omega$.

In the calculations, we use the values $\gamma_1 = 400$ meV, $\gamma_2 = -10$ meV, $\gamma_3 = 5$ meV, and $\Delta = 45$ meV of Refs. 21 and 22, and $\Gamma = 5$ meV, $E_F = 3$ meV.

FIG. 4. (Color online) The same as in Fig. 2 but at $B = 7$ T.

The conductivity units of

$$\sigma_0 = \frac{e^2}{4\hbar c_0},$$

have the simple meaning, being the graphene dynamic conductivity $e^2/4\hbar$ ²⁷ multiplied by the number $1/c_0$ of layers within the distance unit in the z direction. One can see in Figs. 2 and 4 that the value of the conductivity calculated per one graphite layer tends, on average, to the graphene universal conductance.

Let us analyze the spectroscopy of the cyclotron resonances at $B = 20$ T. The line at 292 meV is a doublet resulted from the electron transitions $|25\rangle \rightarrow |36\rangle$ and $|26\rangle \rightarrow |35\rangle$ near the K point of the Brillouin zone (see Fig. 1). In a similar way, the 240-meV line includes the $|24\rangle \rightarrow |35\rangle$ and $|25\rangle \rightarrow |34\rangle$ doublet splitted due to the electron-hole asymmetry. However, the broad line at 165 meV involves other transitions besides the similar $|23\rangle \rightarrow |34\rangle$, $|24\rangle \rightarrow |33\rangle$ doublet at 184 meV. First is the transition $|11\rangle \rightarrow |10\rangle$ (161 meV) near the H point.

Then the transitions $|22\rangle \rightarrow |21\rangle$ produce the broad band. The high-frequency side of the band (170 meV at H) and the low-frequency side (70 meV, at the intersection of the $|21\rangle$ -level with the Fermi level) contribute into the 165-meV and 50-meV lines, correspondingly. The position of the broad band is very sensitive to the variation of the tight-binding parameters and to the magnetic field. The comparison of Fig. 4 to Fig. 2 shows that the $|23\rangle \rightarrow |34\rangle$ line does not interfere with other transitions at the weaker field. The main contribution into the sharp 50-meV line is resulted from $|21\rangle \rightarrow |32\rangle$ transitions near the K point. The positions of the lines for the fields in the range of 20–30 T agree very well with the observations of Refs. 7 and 15. We do not correct the positions by a variation of the tight-binding parameters. Let us emphasize that the imaginary part of the dynamical conductivity is of the order of the real part.

The optical Hall conductivity $\sigma_{xy}(\omega)$ in the ac regime is shown in Figs. 3 and 5. It is evident that the interpretation of the Faraday rotation governed by the conductivity $\sigma_{xy}(\omega)$ is

FIG. 5. (Color online) Real and imaginary parts of the dynamical Hall conductivity at $B = 7$ T (thick line) with the partial contributions of various electron transitions are shown in the thin lines.

much more complicated in comparison with the longitudinal conductivity. The conductivities $\sigma_{xx}(\omega)$ and $\sigma_{xy}(\omega)$ allow us to calculate the reflectivity and the Faraday rotation as functions of frequency.

Notice that the band structure shown in Fig. 1 constrains to consider the (semi)metal-insulator transition while varying the carrier concentration and applying the magnetic field. The phase transition induced by the electron-hole interaction has been discussed in Refs. 10, 28, and 29. As one can see in Fig. 1, the hole doping can decrease the Fermi energy. While the Fermi level appears between the $|22\rangle$ and $|10\rangle$ levels, the

insulator arises with a gap of 34 meV. This phase transition does not involve the electron-electron interaction and it results from the layered graphite structure with the small electron dispersion of the zero mode in the k_z direction.

The author is thankful to A. Kuzmenko for discussions and corrections.
