(Received 2 December 2011; revised manuscript received 11 June 2012; published 24 July 2012)

Anomalous anisotropy of work function values in ternary alkali metal transition metal acetylides is reported. Work function values of some characteristic surfaces in these emerging semiconducting materials may differ by more than 2 eV as predicted by density functional theory calculations. This large anisotropy is a consequence of the relative orientation of rodlike  $[\text{MC}_2]_\infty$  negatively charged polymeric subunits and the surfaces, with M being a transition metal or metalloid element and  $\text{C}_2$  refers to the acetylide ion  $\text{C}_2^{2-}$ , with the rods embedded into an alkali cation matrix. It is shown that the conversion of the seasoned  $\text{Cs}_2\text{Te}$  photoemissive material to ternary acetylide  $\text{Cs}_2\text{TeC}_2$  results in substantial reduction of its  $\approx 3$  eV work function down to 1.71–2.44 eV on the  $\text{Cs}_2\text{TeC}_2(010)$  surface, while its high quantum yield is preserved. Similar low work function values are predicted for other ternary acetylides as well, allowing for a broad range of applications from improved electron and light sources to solar cells, field emission displays, detectors, and scanners.

### I. INTRODUCTION

For many photophysical applications photoemissive materials are sought after that can turn a high fraction of the incident photons into emitted electrons, that is, materials that have a high quantum yield. Often, the quantum yield of these materials depends heavily on the wavelength of incident photons. For many applications, ranging from electron guns for synchrotrons and free-electron lasers to night vision devices, high quantum-yield photoemission using visible or infrared irradiation is desirable. In electron guns of synchrotrons and free-electron lasers, emission in the visible range is advantageous for the improved control of the shape of the emitted electron bunch that is critical for time-resolved applications. In night-vision devices a very low flux of infrared photons has to be turned into emitted electrons with a high yield in order to obtain an image as sharp as possible. Therefore there is a quest for new and improved materials with optimized quantum yield and low-work function.<sup>1</sup>

$\text{Cs}_2\text{Te}$  has been known since the 1950s for its high quantum yield<sup>2</sup> using ultraviolet illumination with photon energies above  $\approx 3.0$  eV and has been used for many decades as a primary high-yield photocathode. Besides not being photoemissive in the visible region, its other main drawback is that its surface gets oxidized in practical vacuum, whereby its quantum efficiency substantially reduces.<sup>3</sup> Despite this disadvantage,  $\text{Cs}_2\text{Te}$  still has 20–30 times longer operational lifetime than competing multialkali antimonide photocathodes, such as  $\text{K}_2\text{CsSb}$  and  $(\text{Cs})\text{Na}_3\text{KSb}$ , especially when operated in radio-frequency accelerating cavities.<sup>3</sup>

In the process of attempting to design modifications of  $\text{Cs}_2\text{Te}$  with lowered work function and preserved high quantum yield, we have considered the effects of small gas molecules on  $\text{Cs}_2\text{Te}$  surfaces. Such effects have been studied by di Bona *et al.*<sup>3</sup> using small gas molecules occurring in vacuum, such as  $\text{O}_2$ ,  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{CO}$ , and  $\text{CH}_4$ . It occurred to us that the effect of another small gas molecule, acetylene ( $\text{C}_2\text{H}_2$ ), has not been considered yet, despite the potentially interesting reactions between  $\text{C}_2\text{H}_2$  and  $\text{Cs}_2\text{Te}$ .  $\text{C}_2\text{H}_2$  is widely used for welding

(not in accelerators though) and it might occur in accelerator vacuums as well, in trace amounts. It is an acidic compound and prefers to decompose to acetylide anion  $\text{C}_2^{2-}$  and to  $2\text{H}^+$  in the presence of a base. Based on the acidic character of  $\text{C}_2\text{H}_2$ , one might investigate the working hypothesis that the reaction of

would produce a ternary acetylide  $\text{Cs}_2\text{TeC}_2$ , whereby the oxidation number of Te would change from  $-2$  to  $0$  and that of H from  $+1$  to  $0$ , with (cr) denoting crystal and (g) gas phase. Interestingly, the class of ternary (i.e., three-component) acetylides indeed exists, involving already synthesized members with the general formula of  $\text{A}_2\text{MC}_2$  with  $\text{A} \in [\text{Na}, \text{K}, \text{Rb}, \text{Cs}]$  and  $\text{M} \in [\text{Pd}, \text{Pt}]$ , and the oxidation number of the metal M in them is zero.<sup>4,5</sup> All existing compounds of the  $\text{A}_2\text{MC}_2$  formula have a hexagonal unit cell with rodlike  $[\text{MC}_2]_\infty$  substructures running parallel with the main crystallographic axis, and very similar distribution of alkali atoms around the  $[\text{MC}_2]_\infty$  rods, just as indicated in Figs. 1 and 2. All known  $\text{A}_2\text{MC}_2$  materials are colored semiconductors with 2.1–2.8 eV direct band gaps.<sup>5</sup> The other class of ternary acetylides with synthesized members contains only a single alkali atom and has the formula of  $\text{AMC}_2$ <sup>6</sup> with the  $[\text{MC}_2]_\infty$  rods adopting three different kinds of rod packings.<sup>7</sup>

### II. METHODOLOGY

Adopting the structure of the unit cell of  $\text{Na}_2\text{PdC}_2$  and substituting Na with Cs and Pd with Te we have carried out a full crystal structure (lattice parameters and atomic fractional coordinates) optimization using density functional theory (DFT), without any symmetry and point group constraints on the translational unit cell. We have used the PWSCF code,<sup>8</sup> plane-wave representation of wave functions with 80 Rydbergs wave function cutoff, the PBE exchange-correlation functional<sup>9</sup> in conjunction with norm-conserving pseudopotentials for Cs, Na, and Te and ultrasoft ones for the other elements as available in the PWSCF distribution. The

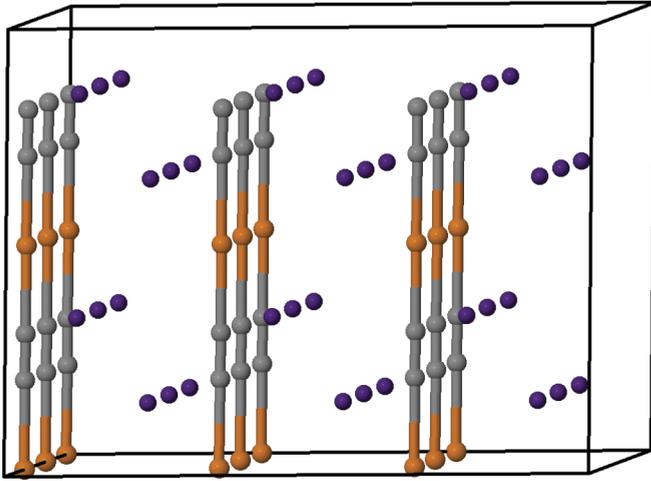

FIG. 1. (Color online) A side view of the  $3 \times 3 \times 2$  supercell of the hexagonal unit cell of  $\text{Cs}_2\text{TeC}_2$ . Bronze spheres denote Te, gray ones C, and dark-purple ones Cs. Notice the  $[\text{TeC}_2]_\infty$  rods.

$k$ -space grids were at least  $6 \times 6 \times 6$  large for optimizations, the residual forces on fractional coordinates were less than  $4 \times 10^{-4}$  Ry/a.u., and residual pressure on the unit cell less than 1 kbar. For validation of the DFT-based methodology, we have calculated known structural parameters and work functions of compounds with similar composition, achieving good agreement between computed and experimental values as indicated in Tables I, II, and III. Note that in some cases, like  $\text{Na}_2\text{PdC}_2$  and  $\text{Cs}_2\text{PdC}_2$ , the difference between calculated and experimental  $a$  and  $b$  lattice parameters (rod distances) was about 3%–3.5%, significantly larger than that for the  $c$  lattice parameter ( $<1\%$ ), which we have accepted on the basis that the interrod interactions are more difficult to accurately predict, similar to general intermolecular interactions. The work function calculations were based on slabs of at least 30 Å width separated by vacuum layers up to 120 Å following the methodology of Ref. 10. For additional validation of the

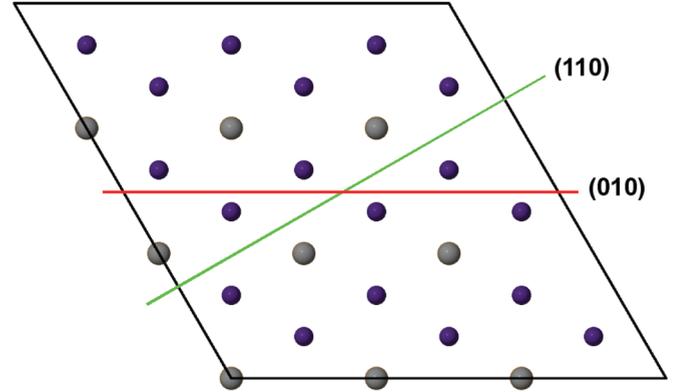

FIG. 2. (Color online) A top-down view of a  $3 \times 3 \times 2$  supercell of the hexagonal unit cell of  $\text{Cs}_2\text{TeC}_2$ . Color codes are identical with those in Fig. 1. The  $[\text{TeC}_2]_\infty$  rodlike substructures are running perpendicularly to the plane viewed. The red line indicates the energetically preferred cleavage plane for the (010) surface running between two layers of Cs atoms, parallel with the rods, while the green line refers to the preferred cleavage plane for the (110) surface that involves  $[\text{TeC}_2]_\infty$  rods directly exposed on the surface. Note that the (010) and (100) planes are identical.

use of the PBE functional here, we have compared the direct band gaps of  $\text{Na}_2\text{PdC}_2$  and  $\text{Cs}_2\text{PdC}_2$  to experimental data. Experimental direct band gaps of  $\text{Na}_2\text{PdC}_2$ ,  $\text{K}_2\text{PdC}_2$ , and  $\text{Rb}_2\text{PdC}_2$  are at 2.09, 2.55, and 2.77 eV, that of  $\text{Cs}_2\text{PdC}_2$  is estimated to be slightly greater than that of  $\text{Rb}_2\text{PdC}_2$ .<sup>5</sup> Our PBE calculations predict the lowest energy direct transitions between 1.2 and 1.8 eV for  $\text{Na}_2\text{PdC}_2$  (near the H point) and 1.7 and 2.6 eV for  $\text{Cs}_2\text{PdC}_2$  (near the H and K points), as shown in Fig. 3. The overall characteristics of these bands is similar to those calculated previously for ternary acetylides, for example, in Refs. 5, 7, and 11. Band gaps of bulk  $\text{Cs}_2\text{Te}$ ,  $\text{Cs}_2\text{TeC}_2$ , and  $\text{Na}_2\text{TeC}_2$  have been predicted to be between 1.8 and 2.0 eV, using the PBE functional (Fig. 4).

TABLE I. Validation of the  $a$ ,  $b$ , and  $c$  lattice parameters on several test systems using the PBE density functional, as described in the discussion. Orthorhombic and hexagonal  $\text{Cs}_2\text{C}_2$  are denoted as o- $\text{Cs}_2\text{C}_2$  and h- $\text{Cs}_2\text{C}_2$ , respectively, with structural parameters not very accurately determined due to the coexistence of the two phases at any temperature.

We have also calculated the optical absorption spectra of some ternary acetylides and Cs<sub>2</sub>Te (Figs. 5 and 6) in the random phase approximation (RPA) using the YAMBO code.<sup>12</sup> All optical absorption calculations have been performed with a resolution of  $\Delta k < 0.1 \text{ \AA}^{-1}$ , and a Gaussian broadening of 0.03 Ry. Note that for maximum absorption the polarization of the light was parallel with rods in the ternary acetylides and parallel with the crystallographic  $c$  axis in Cs<sub>2</sub>Te (see Fig. 7). Due to the lack of norm-conserving pseudopotential for Pd, optical absorption spectra of Na<sub>2</sub>PdC<sub>2</sub> and Cs<sub>2</sub>PdC<sub>2</sub> could not be calculated. In order to associate these gaps with transition probabilities, a crude approximation of these spectra using only plane waves with  $G = 0$  wave vectors was attempted. It indicates absorption maxima at 1.8 and 2.6 eV for Na<sub>2</sub>PdC<sub>2</sub> and Cs<sub>2</sub>PdC<sub>2</sub>, respectively (Fig. 5). Unexpectedly, PBE0<sup>13</sup> calculations at the same geometries result in about 1.0 eV larger gaps than the experimental ones.

### III. RESULTS AND DISCUSSION

The optimization reveals that Cs<sub>2</sub>TeC<sub>2</sub> has a very similar structure to other compounds of the A<sub>2</sub>MC<sub>2</sub> class. Our DFT calculations predict that the electronic energy change in Eq. (1) is  $\Delta E = +1.1$  eV per Cs<sub>2</sub>TeC<sub>2</sub> unit, while that in the alternative reaction of

is  $\Delta E = -0.95$  eV, indicating the stability of the Cs<sub>2</sub>TeC<sub>2</sub> crystal and an alternative synthesis route. In fact the synthesis

TABLE III. Experimental and calculated (DFT) properties of photoemissive surfaces of validation materials: Work functions ( $\Phi$ ), band gaps at the  $\Gamma$ -point  $E_g(\Gamma)$ , and surface energies ( $\sigma$ ).

K <sub>2</sub> CsSb	1.9–2.1 <sup>24,25</sup>	–	–	–

in Eq. (2) is analogous to that of already existing A<sub>2</sub>MC<sub>2</sub> compounds.<sup>5</sup> The predicted stability of a ternary acetylide with a metalloid element (Te) instead of a transition metal for M in the A<sub>2</sub>MC<sub>2</sub> formula is indicative of potential extension of this class of materials with metalloids, while preserving the peculiar rodlike [MC<sub>2</sub>]<sub>∞</sub> substructures. Our analysis at this point cannot exclude the existence of other structures for Cs<sub>2</sub>TeC<sub>2</sub>. We have attempted to start the optimization of a five atomic unit cell of Cs<sub>2</sub>TeC<sub>2</sub> from several randomly chosen initial lattice parameters and atomic positions. In all cases the formation of [TeC<sub>2</sub>]<sub>∞</sub> rods was evident after a few hundred steps. Here we have relied on the fact that A<sub>2</sub>MC<sub>2</sub> compounds have been found only with hexagonal rod packing so far. Also, the structure of h-Cs<sub>2</sub>C<sub>2</sub> already contains the hexagonal rod packing of the C<sub>2</sub> units leaving a place for intercalatable atoms, such as Te, or transition metals, between neighboring C<sub>2</sub> along a rod.

One should also note that the linear chains of carbon atoms, [C<sub>2</sub>]<sub>∞</sub> with alternating C-C and C≡C bonds (polycarbyne) or with uniform C=C bonds (cumulenes, polyallenes), have long been a subject of theoretical and materials science interest.<sup>26,27</sup> However, unlike their hydrogenated analog [C<sub>2</sub>H<sub>2</sub>]<sub>∞</sub> polyacetylene, containing alternating C-C and C=C bonds, famous for high electrical conductivity on the order of that of silver when doped,<sup>28,29</sup> [C<sub>2</sub>]<sub>∞</sub> could not have been synthesized until a decade ago, proving the existence of [C<sub>2</sub>]<sub>n</sub> with  $n \approx [200,300]$ .<sup>30</sup> Interestingly, the efficient synthesis of [C<sub>2</sub>]<sub>n</sub> involves copper acetylides.<sup>30</sup> Furthermore, copper acetylides can also be used as the starting material for their synthesis,<sup>31</sup> pointing to the intimate relationship of the rodlike [MC<sub>2</sub>]<sub>∞</sub> substructures in ternary acetylides A<sub>2</sub>MC<sub>2</sub> and AMC<sub>2</sub> to linear carbon chains. Copper-acetylide molecules are also studied for their self-assembly into extremely thin nanowires.<sup>32</sup> It is also important to note that while transition-metal acetylides are known explosives, their alkalinated versions AMC<sub>2</sub> and A<sub>2</sub>MC<sub>2</sub> are not explosive at all and can survive heating up to  $\approx 500$ – $600$  °C and grinding.<sup>5,33</sup>

As it is indicated in Table IV, the work functions of different surfaces of Cs<sub>2</sub>TeC<sub>2</sub> have largely different values. Concerning the three most important surfaces (Fig. 2), there is a  $\approx 1$  eV decrease as one goes from (001) through (110) to (010) in each step, with work functions of 3.71, 2.77, and 1.71 eV, and surface energies of 0.022, 0.020, and 0.013 eV/Å<sup>2</sup>, respectively, for the unrelaxed surfaces. Relaxed surfaces have somewhat greater work function values, but still allowing for emission in the visible spectrum. Relaxation of the surface layers greatly influences the unoccupied bands, while the occupied ones change significantly less, as indicated in Fig. 8. Also note that the total energy differences between relaxed and unrelaxed surfaces are small, for example, they are only 0.3 eV for a whole Cs<sub>2</sub>TeC<sub>2</sub>(010) slab, that is, about 0.01 eV/atom in the top surface layers, which allows for thermal population of a great variety of surface structures at room temperature. In Cs<sub>2</sub>TeC<sub>2</sub>(010) and Na<sub>2</sub>TeC<sub>2</sub>(010) surface relaxations may break the [TeC<sub>2</sub>]<sub>∞</sub> rods, while the rods stay intact in Pd (or other transition metal) based ternary acetylides. In Cs<sub>2</sub>PdC<sub>2</sub>(010) and Na<sub>2</sub>PdC<sub>2</sub>(010) the rods provide quasirails along which Cs and Na can easily move due to thermal motion. This is also in accordance with the anomalous broadening of peaks in the x-ray powder spectra

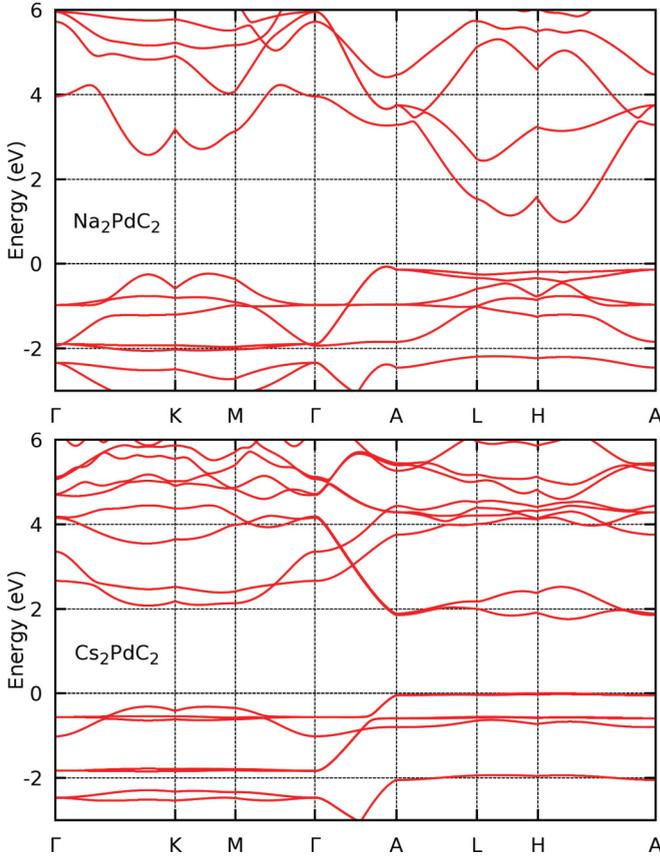

FIG. 3. (Color online) Band structures of  $\text{Na}_2\text{PdC}_2$  and  $\text{Cs}_2\text{PdC}_2$  using the PBE<sup>9</sup> exchange-correlation functional. The  $k$  space was  $14 \times 14 \times 14$  large. The Fermi energy is at 0 eV. Flat bands are characteristic for ternary acetylides.

TABLE IV. Calculated (DFT) properties of photoemissive surfaces of acetylide compounds: Work functions ( $\Phi$ ), band gaps at the  $\Gamma$ -point  $E_g(\Gamma)$ , and surface energies ( $\sigma$ ). Relaxed slabs refer to the relaxation of unrelaxed ones with the central two layers fixed. For h- $\text{Cs}_2\text{C}_2(001)$  and  $\text{Na}_2\text{TeC}_2(010)$ ,  $E_g(\Gamma) \approx 0.05$  eV has been found for a single band above  $E_F$  as well.

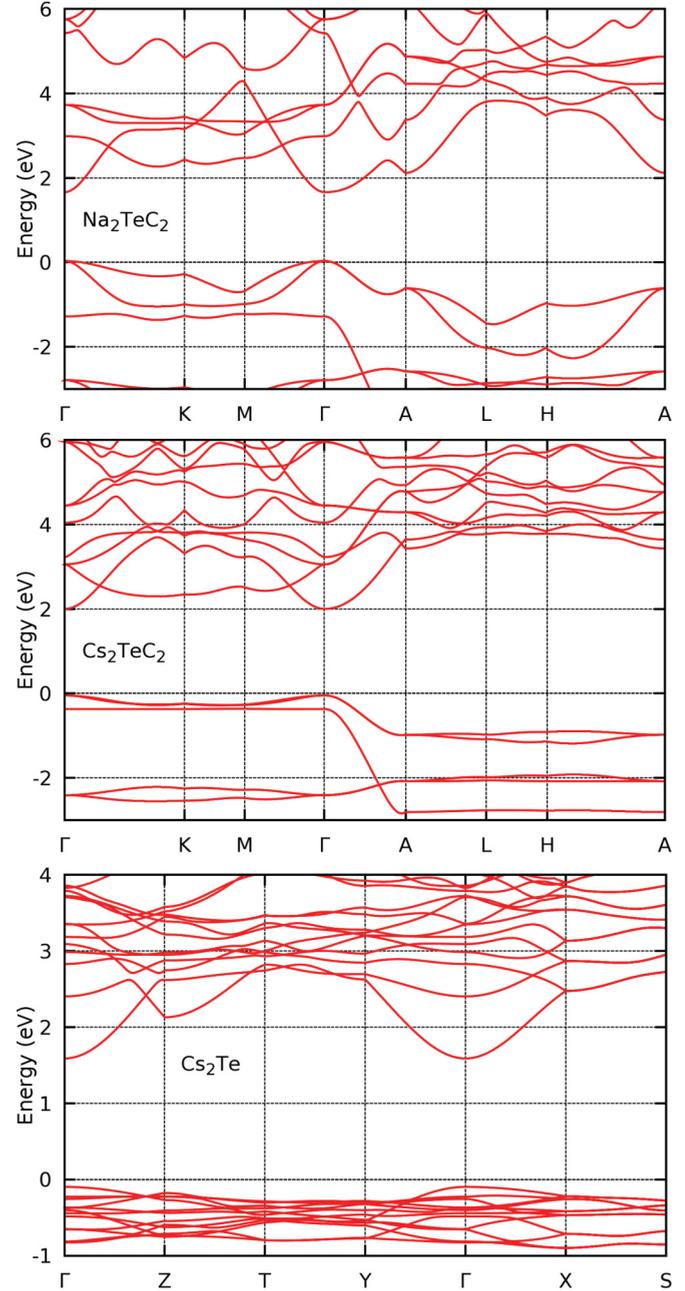

FIG. 4. (Color online) Band structures of  $\text{Na}_2\text{TeC}_2$ ,  $\text{Cs}_2\text{TeC}_2$ , and  $\text{Cs}_2\text{Te}$  using the PBE<sup>9</sup> exchange-correlation functional. The  $k$  space was  $14 \times 14 \times 14$  large. The Fermi energy is at 0 eV.

of ternary acetylides.<sup>7</sup> Such an anomalous anisotropy of work function values is highly unusual and represents a broad range of work function choice within a single material, allowing for emission in ultraviolet, visible, and near infrared radiation. The lowest surface cleavage energy  $\text{Cs}_2\text{TeC}_2$  surface, (010), has a similar surface energy as those of  $\text{Cs}_2\text{Te}$  surfaces; it is, however, associated with a much lower (by  $\approx 1.3$  eV) work function. The highly anisotropic properties of  $\text{Cs}_2\text{TeC}_2$  are due to the relative orientation of the rodlike  $[\text{TeC}_2]_\infty$  substructures and the surfaces. Surface energies reveal that cutting the rods by cleaving the M-C bonds [(001) surface] is energetically disadvantageous, and it is also disadvantageous to allow for

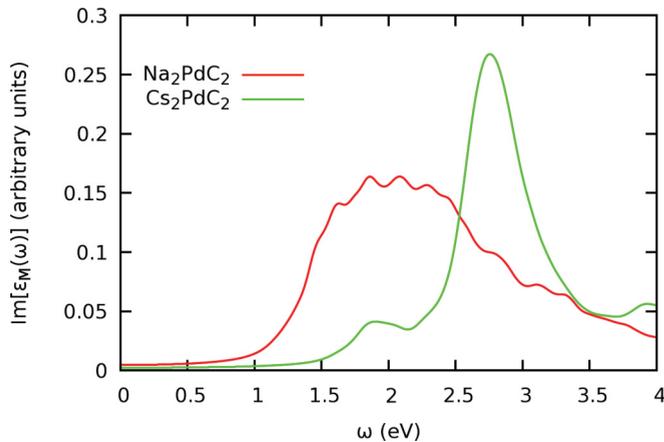

FIG. 5. (Color online) Optical absorption spectra of bulk  $\text{Na}_2\text{PdC}_2$  and  $\text{Cs}_2\text{PdC}_2$  from the imaginary part of the macroscopic dielectric function  $\epsilon_M(\omega)$ . Only the  $G = 0$  plane waves were used to calculate intensities in the RPA approximation. The polarization vector of the light is along the main crystallographic axis (along the  $[\text{PdC}_2]_\infty$  chains).

rods to be directly exposed on the surface [(110) surface], while cleavage between Cs atoms with rods embedded under the surface is the most energetically favorable construct [(010) surface]. While numerous variants of surface coverages may exist at different temperatures that expose or cover rods by Cs on the surface, here we do not go beyond a single surface unit to study the energetics of surfaces. The sticking of Cs to these surfaces may be a similarly important issue here as in the case of cesiated III/V semiconductor surfaces (e.g., GaAs).<sup>34</sup> As the rods are twice negatively charged per  $\text{MC}_2$  unit, we expect that the sticking of Cs cations would be relatively strong.

High anisotropy can be observed in  $\text{Na}_2\text{PdC}_2$ ,  $\text{Na}_2\text{TeC}_2$ , and  $\text{Cs}_2\text{PdC}_2$  as well, with somewhat smaller, 1.1–1.6 eV difference between the extremal surfaces. The type of the alkali atom very sensitively influences the work functions: Substituting Na with Cs results in more than 1 eV reduction of the work function on the (110) and (010) surfaces independently from the type of the  $[\text{MC}_2]_\infty$  chain, even though the M-C bonding in these chains is very different. One has to note that the Pd-C distance is significantly shorter than the Te-C in these compounds, 2.01 vs 2.45 Å, respectively, while Te and Pd have very similar covalent radii of  $\approx 1.4$  Å.<sup>35</sup> The (001) surface energies also indicate a much stronger Pd-C bond than the Te-C one. While there is a  $\sigma$  bond in both Pd-C and Te-C links between the  $2sp^1$  hybrid orbital of the C atom and the  $5sp^1$  hybrids of Pd and Te (all oriented along the M-C-C line) the Pd-C link is further strengthened by strong backdonation of Pd  $4d$  shell electrons to the antibonding  $\pi$  orbitals of the  $\text{C}_2^{2-}$  ions, also associated with lengthening of the C-C bond.<sup>5</sup> Also note that  $\text{Cs}_2\text{Te}$  (and also  $\text{Cs}_2\text{TeC}_2$ ) has the advantage over the formerly mentioned multialkali antimonides that Cs is better bound in them allowing for a longer operational lifetime.<sup>1</sup> Another interesting comparison can be made to amorphous cesiated carbon films obtained from the co-deposition of high-energy negatively charged carbon ions and Cs on silicon substrates, as the low,  $\approx 1.1$  eV work function in them might be associated with increased acetylide ion concentration. However, there is no available data of how well Cs is bound in these systems.<sup>36</sup>

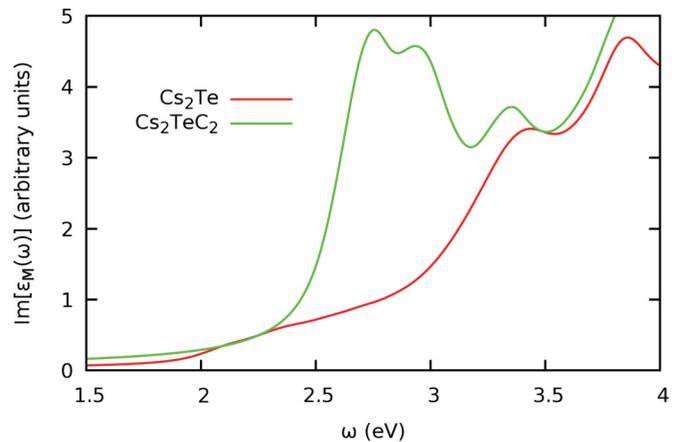

FIG. 6. (Color online) Optical absorption spectra of bulk  $\text{Cs}_2\text{Te}$  and  $\text{Cs}_2\text{TeC}_2$  from the imaginary part of the macroscopic dielectric function  $\epsilon_M(\omega)$ . The 4000 lowest energy plane waves were used to calculate intensities in the RPA approximation. The polarization vector of the light is along the main crystallographic axis (along the  $[\text{TeC}_2]_\infty$  chains and the  $c$  axis of  $\text{Cs}_2\text{Te}$ ).

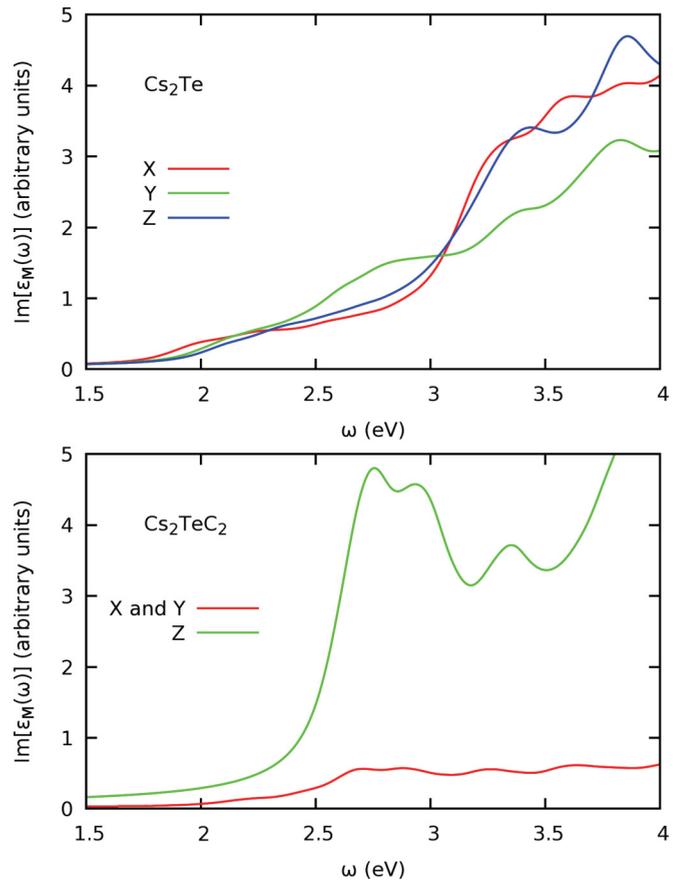

FIG. 7. (Color online) Dependence of the optical absorption spectra of bulk  $\text{Cs}_2\text{Te}$  and  $\text{Cs}_2\text{TeC}_2$  on the polarization of the incident light. The  $z$  direction is along the main crystallographic axis ( $c$  axis), which is parallel with the  $[\text{TeC}_2]_\infty$  chains in  $\text{Cs}_2\text{TeC}_2$ . While absorption in  $\text{Cs}_2\text{TeC}_2$  is highly anisotropic, with  $\approx 9$  times higher values for the  $z$  direction than for the  $x$  and  $y$  ones, there is no significant anisotropy of absorption in  $\text{Cs}_2\text{Te}$ . Similar anisotropy can be seen in  $\text{Na}_2\text{TeC}_2$  as well, and likely in all ternary acetylides, due to the electric dipoles along the  $[\text{MC}_2]_\infty$  chains.

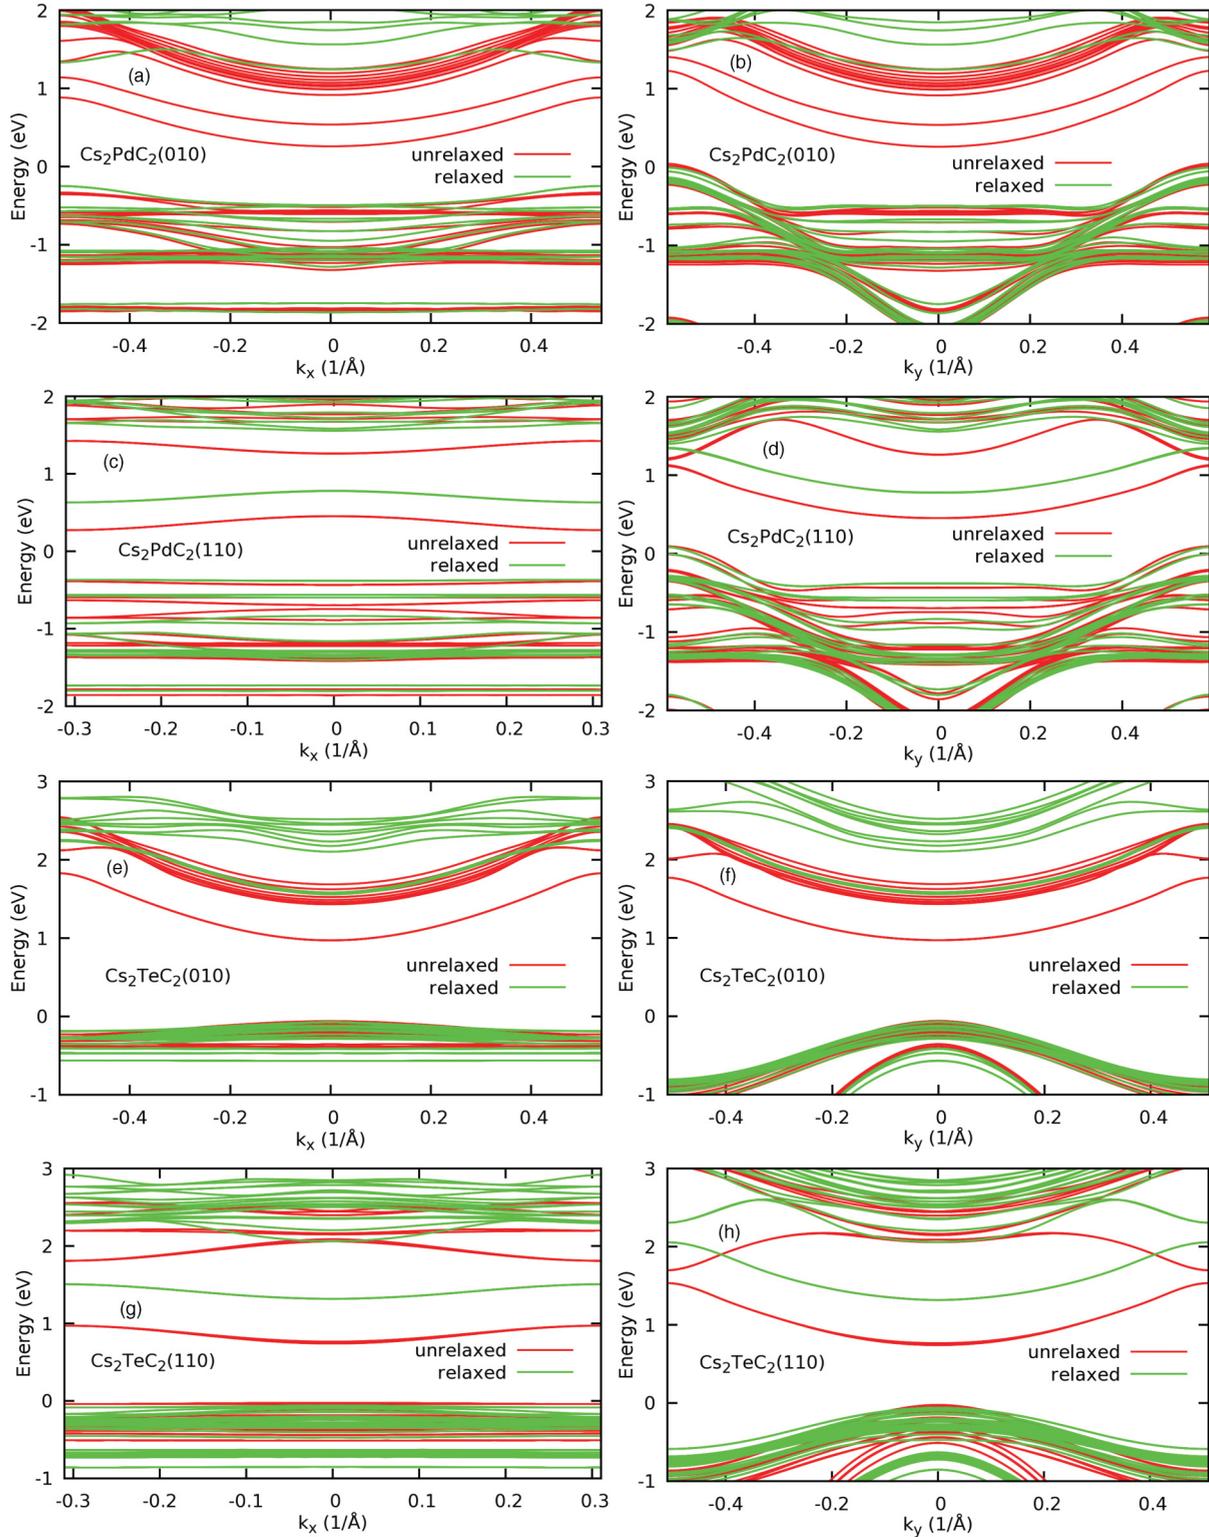

FIG. 8. (Color online) Electronic bands of the slabs of the (010) and (110) surfaces of  $\text{Cs}_2\text{PdC}_2$  and  $\text{Cs}_2\text{TeC}_2$  along the two orthogonal reciprocal surface lattice vectors  $k_x$  (panels A, C, E, and G) and  $k_y$  (panels B, D, F, and H). The  $[\text{MC}_2]_\infty$  rods are parallel with the  $y$  direction for all (010) and (110) surface slabs. Bands at both relaxed (green) and unrelaxed (red) slabs are shown. The Fermi energy is at 0 eV.

In order to estimate the quantum yield of  $\text{Cs}_2\text{TeC}_2$  relative to  $\text{Cs}_2\text{Te}$ , we have calculated their optical absorption spectra (Fig. 6) using the lowest energy 4000 plane waves at which the spectrum becomes saturated against further increase of the

number of plane waves. The spectra indicate that acetylation of  $\text{Cs}_2\text{Te}$  shifts its first absorption peak in the visible region to 2.7 eV, while preserving the same absorption intensity. This comparison suggests that  $\text{Cs}_2\text{TeC}_2$  may have similarly

high quantum efficiency as that of  $\text{Cs}_2\text{Te}$ , however, even for visible and potentially also for near infrared photons. The band gaps at the  $\Gamma$  point of  $\text{Cs}_2\text{TeC}_2$  surfaces (see Table IV) also support that photon energies near the work function are sufficient to induce emission in this material. An interesting characteristic of ternary acetylides is the extensive presence of flat bands (see Figs. 3 and 4). While there are some flat band parts in  $\text{Cs}_2\text{Te}$  as well, such a feature is much more characteristic for ternary acetylides. Flat bands greatly increase the density of states for some spectral regions, thus they contribute to increased absorption of light. Interestingly, not only the work functions of these materials show high anisotropy, but also their optical absorption (see Fig. 7). The optical absorption is almost a magnitude greater when the light's polarization vector is parallel with the  $[\text{MC}_2]_\infty$  rods. This property can allow, for example, for the generation of pulsed electron beams when these surfaces are illuminated by circularly polarized light. Several other optical applications can be envisioned based on the anisotropy of optical absorption in ternary acetylides, such as polar filters and optical switching elements.

It is also important to call attention to the rest of the ternary acetylides as valuable photoemissive materials. For example, the already synthesized  $\text{Cs}_2\text{PdC}_2(010)$ <sup>4</sup> material is predicted here to have a very low 1.33–2.03 eV work function, even smaller than that of  $\text{Cs}_2\text{TeC}_2(010)$  and a similar density of states.

While it may be difficult to lower the work function into the infrared spectral domain (below 1.5 eV), multiphoton absorption of infrared light may still provide a way to photoemission in this domain as well. Strong multiphoton absorption of organic and inorganic compounds with acetylide units is well known,<sup>37</sup> for example, in platinum acetylides,<sup>38</sup> the analogy suggests that multiphoton absorption may be

strong in ternary acetylides as well. Multiphoton absorption happens via simultaneous absorption of multiple photons without the need of real intermediate states as opposed to cascaded multiple step one-photon absorptions.<sup>37</sup> These latter ones are also possible in ternary acetylides as there are surface states 1–1.5 eV above the Fermi level as indicated in Fig. 8.

Emission from  $\text{A}_2\text{MC}_2(001)$  surfaces (rods perpendicular to surface) may especially be suitable for generating low transverse emittance electron beams<sup>39</sup> as excited electrons are expected to be guided along the  $[\text{MC}_2]_\infty$  rods while traveling from inside the bulk of the cathode toward the surface, whereby not being scattered sideways, analogously to needle-array cathodes of field emission.<sup>40</sup>

#### IV. CONCLUSIONS

In the present work we have demonstrated unique photoemissive properties of ternary acetylides, such as low work functions, high anisotropy of the work functions and optical absorptions and high quantum yield. We have also demonstrated how the acetylation of the seasoned  $\text{Cs}_2\text{Te}$  photocathode material leads to significantly lowered work function while preserving its high quantum yield.
