(Received 11 April 2012; revised manuscript received 16 July 2012; published 1 August 2012)

We report detailed magnetic, transport, and thermodynamic properties of metastable $Rh₃Bi₁₄$ single crystals in a superconducting and normal state. We show that Rh_3Bi_{14} is a nearly isotropic, weakly to intermediately coupled BCS superconductor, whereas the electronic resistivity above superconducting $T_c = 2.94$ K is dominated by the phonon scattering in the large unit cell with pores filled by Bi atoms. Superconductivity is strongly influenced by the nature of atoms that fill the voids in the crystal structure.

I. INTRODUCTION

Complex crystal structures with atomic subunits often show significant electronic and magnetic tunability through incorporation of various elements in the (sub)structure. Examples include covalently bonded IV group thermoelectric clathrates that are under the influence of anharmonic lattice vibrations with electron-phonon coupling strength comparable to MgB₂, alkali doped fullerenes, and magnetic molecules. $1-8$ Cluster units may substantially define physical properties, whereas their size may considerably deviate from the length scales defined by the lattice parameters, even in intermetallic systems where delocalized metallic bonds are present.^{[9](#page-4-0)}

A binary Rh-Bi intermetallic phase diagram has been studied for more than eight decades. Yet, a structurally complex metastable Rh_3Bi_{14} with 136 atoms per unit cell has been discovered only in recent years[.10–12](#page-4-0) The bismuth-rich side of this phase diagram also includes α -RhBi₂, β -RhBi₂, $RhBi₃$, and $RhBi₄$ phases.^{13,14} According to the Rh-Bi phase diagram, Rh₃Bi₁₄ is a metastable phase hidden in the RhBi₄-Bi solid phase region. Since the kinetic of peritectic reaction forming RhBi4 is extremely slow, it can be easily suppressed by undercooling due to nucleation problems.^{[11](#page-4-0)} Hence, Rh_3Bi_{14} single crystals can be decanted from the Bi liquid, whereas the RhBi4 single crystals are difficult to obtain.

Rh3Bi14 has orthorhombic symmetry (*Fddd* space group) with $a = 0.69041(4)$ [0.68959(15)] nm, $b = 1.73816(9)$ [1.7379(3)] nm, and $c = 3.1752(2)$ [3.1758(6)] nm.^{11,12} In a $Rh₃Bi₁₄$ unit cell there are 24 Rh and 112 Bi atoms.¹² Each Rh atom is surrounded by eight Bi atoms, however there are two inequivalent Rh positions in the unit cell. Rh1 is cubically coordinated, whereas Rh2 exhibits a square antiprismatic coordination as shown in Fig. [1\(a\).](#page-1-0) Each [RhBi8*/*2] polyhedra shares a common edge with four other polyhedra, and thus creates a porous three-dimensional (3D) framework with channels along the [100] direction. In these channels there are chiral inner surfaces filled with bismuth ions [Fig. [1\(b\)\]](#page-1-0). Partial oxidation of RhBi₄ using bromine results in $Rh₃Bi₁₂Br₂$, isostructural with Rh_3Bi_{14} .^{[12](#page-4-0)} The difference between Rh_3Bi_{14} and $Rh_3Bi_{12}Br_2$ is in the atoms in the channels. In Rh_3Bi_{14} , Bi atoms fill the channels, whereas they are filled by Br atoms in $Rh₃Bi₁₂Br₂$. The theoretical calculation indicates that the 3D polyhedral frameworks in Rh_3Bi_{14} and $Rh_3Bi_{12}Br_2$ are formed by covalently bonded rhodium and bismuth atoms, consistent with the results of high-pressure studies.¹² On the other hand, there are no direct bonds between this 3D polycation framework and anions $(Bi^{-1}$ or Br^{-1} in the channels), which leads to the higher compressibility along the *a* axis when compared to those along the *b* and *c* axes mainly controlled by the covalently bonded polycation.¹²

Magnetization measurement indicates that $Rh₃Bi₁₄$ is a superconductor with $T_c = 2.82(5)$ K.^{[11](#page-4-0)} Although the crystal structure and chemical bonding have been studied, $11,12,15$ the studies on physical properties, especially in connection with superconductivity, are still lacking.^{[11](#page-4-0)} In this work we report on detailed analysis of $Rh₃Bi₁₄$ physical properties in the superconducting and normal states. We show that electronic scattering in the normal state is dominated by phonons, whereas in its superconducting state $Rh₃Bi₁₄$ is an isotropic, weakly to intermediately coupled BCS superconductor.

II. EXPERIMENT

Single crystals of $Rh₃Bi₁₄$ were grown by the flux-growth method with a Rh:Bi = $5:95$ molar ratio. Rh pieces (99.9%) and Bi shot (99.9%) were weighed, combined into an alumina crucible, covered with quartz wool, and sealed into the quartz tube with a partial pressure of argon. The quartz tube was heated to $1000\,^{\circ}$ C, held constant for 2 h, and then cooled at a rate of −3.5 ◦C*/*h to 300 ◦C, where crystals were decanted. Single crystals with a typical size $0.5 \times 0.2 \times 0.2$ mm³ were obtained. Crystal structure and phase purity were examined by powder and single crystal x-ray diffraction pattern (XRD) with Cu K_{α} radiation ($\lambda = 0.15418$ nm) using a Rigaku Miniflex x-ray machine. The structure parameters are extracted by fitting the XRD spectra using the Rietica software.¹⁶ The crystal was oriented using a Bruker SMART APEX II single crystal x-ray diffractometer. The composition of the $Rh₃Bi₁₄$ single crystal was determined by examination of multiple points on the crystals using energy dispersive x-ray spectroscopy (EDX) in an JEOL JSM-6500 scanning electron microscope. Electrical transport, heat capacity, and magnetization measurements were performed in a Quantum Design PPMS-9 and MPMS XL 5.

III. RESULTS AND DISCUSSION

All powder x-ray reflections [Fig. $1(c)$] can be indexed in the *Fddd* space group. The refined lattice parameters are $a =$ 0.6891(1) nm, $b = 1.7388(1)$ nm, and $c = 3.1718(2)$ nm with $R_p = 5.220$, $R_{wp} = 6.720$, and $\chi^2 = 0.919$, consistent with the values reported in literature.^{[11,12](#page-4-0)} On the other hand, we also

FIG. 1. (Color online) (a) Crystal structure of Rh₃Bi₁₄. Three-dimensional framework is built of [RhBi_{8/2}] cubes and square antiprisms which share common edges. Bi4 atoms fill the channels of the framework. (b) Edge-sharing [RhBi_{8/2}] cubes and square antiprisms enclosing bismuth ions form the zigzag channel in Rh_3Bi_{14} . (c) Powder XRD pattern of a Rh_3Bi_{14} single crystal. (d) The EDX spectrum of a single crystal.

refined the lattice parameters using single crystal XRD. The lattice parameters are $a = 0.707(3)$ nm, $b = 1.755(5)$ nm, and $c = 3.154(8)$ nm, which are also close to the result obtained from powder XRD and previous results. EDX spectrum of a single crystal [Fig. $1(d)$] confirms the presence of only Rh and Bi with the average atomic ratios $Rh:Bi = 3.0(4):13.8(4)$.

The temperature-dependent electrical resistivity $\rho(T)$ of $Rh₃Bi₁₄$ is shown in Fig. [2\(a\).](#page-2-0) The sharp resistivity drop with $T_{c, \text{onset}} = 3.04 \text{ K}$ is caused by a superconducting transition [inset of Fig. $2(a)$]. The residual resistivity ratio (RRR), defined as ρ (295 K)/ ρ (3.04 K), is about 9.3. The curve ρ (*T*) is convex above 50 K, with a tendency to saturate at high temperature. The saturation of $\rho(T)$ could be related to the Ioffe-Regel limit, 17 when the charge carrier mean free path is comparable to the interatomic spacing and/or to the two-band conductivity.^{[18](#page-4-0)} According to the phenomenological model^{[19](#page-4-0)}

$$
\frac{1}{\rho(T)} = \frac{1}{\rho_{\text{ideal}}} + \frac{1}{\rho_{\text{sat}}}, \quad \text{with} \quad \rho_{\text{sat}} \approx \frac{\nu_F}{\varepsilon_0 \Omega_p^2 a}, \qquad (1)
$$

where v_F is the Fermi velocity, Ω_p is the plasma frequency, *a* is interatomic spacing, and $\rho_{\text{ideal}} = \rho_r + \rho_i(T)$. The $\rho_i(T)$ is the inelastic resistivity due to the phonon contribution, whereas ρ_{sat} is the saturation resistivity. Phonon contribution can be explained by the Bloch-Grüneisen formula:

$$
\rho_i(T) = \left(\frac{c}{\Theta_D}\right) \left(\frac{T}{\Theta_D}\right)^5 \int_0^{\Theta_D/T} \frac{x^5}{(e^x - 1)(1 - e^{-x})} dx, \quad (2)
$$

where Θ_D is the Debye temperature and *c* is a constant which depends on the electronic structure of the metal through the Fermi velocity v_F and the density of states at the Fermi energy.^{[20](#page-4-0)} The fitting result over the full temperature range of ρ_T is shown in Fig. [2\(a\)](#page-2-0) as a solid line, revealing excellent agreement between the model and data for $\rho_r = 60.0(4)$ *μ*Ωcm, $ρ_{\text{sat}} = 640(2)$ *μ*Ωcm, $Θ_D = 95.0(8)$ K, and $c =$ $27.7(6) \times 10^4 \mu \Omega$ cm.

To confirm the presence of bulk superconductivity in $Rh₃Bi₁₄$ single crystals, the magnetization is measured using the dc susceptibility method. Figure $2(b)$ shows the temperature dependence of the dc susceptibility for a crystal with dimension of $0.2 \times 0.4 \times 0.2$ mm³ for *H* || *a*, *H* || *b*, and $H \parallel c$ with zero-field cooling (ZFC) and field cooling (FC) under an applied magnetic field of 10 Oe. The steep transition shows that the Rh_3Bi_{14} single crystal has a superconducting transition temperature for all field directions of 2.91 K $(T_{c,onset})$ with a transition width $\Delta T_c = 0.30$ K, consistent with the result of resistivity measurement. At 2 K, the ZFC dc susceptibility approaches a value of −1 for all directions after demagnetization correction, indicating bulk superconductivity. The FC signal shows a flux exclusion of 61%, 70%, and 81% for $H \parallel a$, $H \parallel b$, and $H \parallel c$, respectively. The big superconducting volume fraction for FC indicates the rather weak flux pinning effects.

The shape of the $M(H)$ curve at 1.8 K [Fig. [3\(a\)\]](#page-2-0) confirms weak pinning, in agreement with Fig. $2(b)$. In order to obtain the lower critical fields of $Rh₃Bi₁₄$, we measured the initial $M(H)$ curves at various temperatures with the field directions

FIG. 2. (Color online) (a) Temperature dependence of the resistivity $\rho_a(T)$ of Rh₃Bi₁₄. Inset: resistivity near T_c . (b) Temperature dependence of dc magnetic susceptibility of $Rh₃ Bi₁₄$ with ZFC and FC at 10 Oe for $H \parallel a$, $H \parallel b$, and $H \parallel c$. The superconducting transition temperature $T_{c, \text{onset}}$ is marked by an arrow.

along the *a*, *b*, and *c* axis. For each field direction, all curves clearly fall on the same line and deviate from linearity for different temperatures. Linear fits for the initial parts of the magnetization curves describe the Meissner shielding effects ("Meissner line").

The value of H_{c1}^* at which the field starts to penetrate into the sample can be determined by examining the point of deviation from the Meissner line on the initial slope of the magnetization curve. The first penetration field H_{c1}^* is not the same as the real lower critical field H_{c1} , due to the geometric effect. The H_{c1} can be deduced from the H_{c1}^* , assuming that the magnetization $M = -H_c$ when the first vortex enters into the sample. Thus *H* has been rescaled to $H = H_a - NM$ and $H_{c1} = H_{c1}^*/(1 - N)$, where *N* is the demagnetization factor and H_a is the external field.^{[21](#page-4-0)} We estimate demagnetization factors 0.47, 0.23, and 0.59 for *H a*, *H* \parallel *b*, and *H* \parallel *c* by using $H_{c1} = H_{c1}^{*}/\tanh(\sqrt{0.36b/a})$, where *a* and *b* are the width and thickness of a platelike superconductor.^{[22](#page-4-0)} The corrected data are plotted in Figs. $3(b)$, $3(c)$, and $3(d)$. Considering the demagnetization factors, the obtained slopes of the linear fitting at the lowest temperature of our measurements $T = 1.8$ K are $-0.972(2)$, $-0.988(2)$, and $-0.987(2)$, very close to -1 ($4\pi M = -H$) for all field directions. Thus the full Meissner shielding effect in our

(b)–(d) Low field parts of $M(H)$ at various temperatures for $H||a, H||b$, and $H \| c$ with correct demagnetization, respectively. The solid blue lines are the "Meissner line" as discussed in the text. (e) Temperature dependence of H_{c1} for $H||a, H||b$, and $H||c$. The dashed lines are the fitted lines using $H_{c1} = H_{c1}(0)[1 - (T/T_C)^2]$. (f) The temperature dependence of anisotropy of H_{c1} , $\gamma_{H_{c1}} = H_{c1,a}(T)/H_{c1,b}(T)$, $\gamma_{H_{c1}} =$ $H_{c1,c}(T)/H_{c1,b}(T)$, and $\gamma_{H_{c1}} = H_{c1,c}(T)/H_{c1,a}(T)$.

measurement provides a reliable way to determine the value of H_{c1} .

 H_{c1} is determined as the point deviating from linearity based on the criterion $\Delta M = (M_m - M_{th}) = 2 \times 10^{-6}$ emu, M_m is the measured moment value and M_{th} is the fitted moment value at the same external field. From Figs. $3(b)$, $3(c)$ and $3(d)$, H_{c1}^a , H_{c1}^b , and H_{c1}^c values at the different temperatures can be obtained as shown in Fig. $3(e)$. The $H_{c1}(T)$ can be fitted according to $H_{c1}(T) = H_{c1}(0)[1 - (T/T_c)^2]$. Fitting lines are shown in Fig. 3(e). The obtained $H_{c1}^{a}(0)$, $H_{c1}^{b}(0)$, and $H_{c1}^{c}(0)$ are 90(1), 63(1) and 93(1) Oe, respectively. The anisotropy of H_{c1} along each axis can be determined as shown in Fig. $3(f)$. It can be seen that the anisotropy of $H_{c1}(T)$ is very close to 1, especially for *H* \parallel *c* and *H* \parallel *a*, indicating that Rh₃Bi₁₄ is a nearly isotropic superconductor.

With increasing magnetic fields [Figs. $4(a)$ and $4(b)$] the superconducting transition width broadens and the onset of transition shifts gradually to lower temperatures for both $H \parallel b$ and *H* \parallel *c*. When *H* = 6 kOe, the superconducting transition cannot be observed above 1.9 K for both field directions. It is interesting to observe kinks in the $R(T)$ curves below T_c under fields for both field directions. The kinks are becoming more pronounced with the increasing field. The origin of these kinks implies rich vortex physics, similar to $NbSe₂$.^{[23](#page-4-0)} The upper critical field H_{c2} is determined by the criterion of 90% of the normal state resistivity at various fields for both field directions [Fig. [4\(c\)\]](#page-3-0). The slopes dH_{c2}/dT for $H \parallel b$ and $H \parallel c$ are

FIG. 4. (Color online) (a) Temperature dependence of the resistivity in a set of magnetic fields from 0 to 6 kOe for (a) $H \parallel b$ and (b) $H \parallel c$. (c) Temperature dependence of the upper critical field H_{c2} for $H \parallel b$ and (b) $H \parallel c$.

equal to $-6.47(5)$ and $-6.01(11)$ kOe/K, respectively. For dirty limit superconductors, $H_{c2}(0)$ can be obtained from the Werthammer-Helfand-Hohenberg formula²⁴:

$$
H_{c2}(0) = -0.693 \frac{dH_{c2}}{dT} \big|_{T_c} T_c,
$$
\n(3)

yielding $H_{c2}^{b}(0) = 13.4(1)$ kOe and $H_{c2}^{c}(0) = 12.4(2)$ kOe. Since the Pauli limiting field $H_p(0) = 18.4T_c \sim 52 \text{ kOe}^{25}$ $H_p(0) = 18.4T_c \sim 52 \text{ kOe}^{25}$ $H_p(0) = 18.4T_c \sim 52 \text{ kOe}^{25}$ the orbital effect should be the dominant pair-breaking mechanism. The small difference in the H_{c2} values for both field directions indicates that $Rh₃Bi₁₄$ shows almost isotropic $H_{c2}(T)$ as seen in Fig. 4(c).

Since $H_{c1}^a \approx H_{c1}^c$, according to the anisotropic Ginzburg-Landau (GL) theory, we assume $\xi_a \sim \xi_c$ and coherence length $\xi(0)$ can be estimated from the $H_{c2}(0)$ with $H_{c2}^{b}(0)$ =

FIG. 5. (Color online) (a) Low temperature specific heat C_p/T vs T^2 from 1.95 to 300 K at $H = 0$ kOe. The solid line shows the fit (see text). (b) Temperature dependence of the electronic specific heat of Rh_3Bi_{14} plotted as C_{es}/T vs T at $H = 0$ kOe.

 $\Phi_0/[2\pi \xi_a(0)\xi_c(0)]$ and $H_{c2}^c(0) = \Phi_0/[2\pi \xi_a(0)\xi_b(0)]$, where $\Phi_0 = 2.07 \times 10^{-15}$ Wb. Based on the values of $H_{c1}(0)$ and $H_{c2}(0)$, GL parameters $\kappa_i(0)$ are obtained from the equation $H_{c2}^{i}(0)/H_{c1}^{i}(0) = 2\kappa_i^2(0)/\ln \kappa_i(0)$, where *i* denotes the field applied along the *i* direction. The thermodynamic critical field $H_c(0)$ can be obtained from $H_c(0) =$ *H*_{*i*}₂(0)/[$\sqrt{2}$ *k_i*(0)]. The GL penetration lengths are evaluated by the equations $\kappa_b(0) = \lambda_a(0)/\xi_c(0)$ and $\kappa_a(0) \approx \kappa_c(0) =$ *λ_a*(0)/ξ_b(0) = [$λ_a(0)λ_b(0)/ξ_c(0)ξ_b(0)$]^{1/2}. The anisotropy is $\gamma_{\text{anis}} = H_{c2}^b(0)/H_{c2}^c(0) = \xi_b(0)/\xi_c(0).^{26}$ All of the obtained parameters are listed in Table I.

Specific heat divided by temperature [Fig. $5(a)$] shows a jump at 2.94 K, indicating the bulk superconducting transition. Specific heat includes both the electron and lattice parts $C(T) = C_e(T) + C_{ph}(T)$. In the normal state, the specific heat of the lattice part is expressed by the βT^3 term at temperatures far below the Debye temperature Θ_D and electronic specific heat is assumed to be $\sim \gamma T$. Using $C_p/T = \gamma + \beta T^2$ we obtain [Fig. 5(a)] $\gamma = 8(1)$ mJ mol⁻¹ K⁻² and $\Theta_D \sim 113.9(7)$ K using $\Theta_D = (12\pi^4 N R/5\beta)^{1/3}$, where $N = 17$ is the number of atoms per formula unit and *R* is the gas constant. Θ_D is similar to the value obtained from $\rho(T)$. The electronphonon coupling constant *λ*e-ph is obtained from the McMillan equation:

$$
\lambda_{e-ph} = \frac{\mu^* \ln(1.45T_c/\Theta_D) - 1.04}{1.04 + \ln(1.45T_c/\Theta_D)(1 - 0.62\mu^*)},\tag{4}
$$

and assuming the common value for the Coulomb pseudopotential $\mu^* \approx 0.13$. The value of λ_{e-ph} is determined to be 0.74(1) by using $T_c = 2.94$ K and $\Theta_D = 113.9(7)$ K. The

value of *λ*e-ph implies intermediately or weakly coupled BCS superconductivity. The electronic specific heat C_{es} in the superconducting state [Fig. $5(b)$] is obtained by subtracting the lattice contribution estimated from the total specific heat. The extracted specific heat jump at T_c [$\Delta C/\gamma T_c = 1.8(2)$] is somewhat larger than the weak coupling value 1.43, and also points to intermediate coupling strength.²⁷

 $Rh₃Bi₁₂Br₂$ has a similar structure to $Rh₃Bi₁₄$, but the two Bi atoms at Bi4 position are replaced by the Br atoms. $Rh_3Bi_{12}Br_2$ is a metal above 2 K without superconducting transition.¹⁵ From theoretical calculation,¹² the density of state (DOS) at Fermi energy is similar for both compounds, however the contributions of atoms (*s* and *p* states of Bi) at Bi4 position to DOS are nearly removed when voids in the crystal structure are filled with Br atoms. Therefore, the superconductivity in $Rh₃Bi₁₄$ might be related to the *s* and *p* states of the Bi atom in the interstitial Bi4 position of $Rh₃Bi₁₄$.

IV. CONCLUSION

In summary, we present a comprehensive study of the normal and superconducting state properties of metastable intermetallic superconductor $Rh₃Bi₁₄$. The temperature dependence of resistivity $\rho(T)$ above the superconducting transition can be explained by the phonon scattering. $Rh₃Bi₁₄$ is an isotropic, weakly to intermediately coupled BCS superconductor. Presence (absence) of superconductivity in $Rh₃Bi₁₄$ $(Rh_3Bi_{12}Br_2)$ suggests that the nature of atoms that fill the pores in the structure is rather important.
