(Received 15 November 2013; revised manuscript received 3 December 2013; published 31 December 2013)

We report a detailed Raman scattering study of the lattice dynamics in detwinned single crystals of the underdoped high-temperature superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ ($x = 0.75, 0.6, 0.55$, and 0.45). Whereas at room temperature the phonon spectra of these compounds are similar to that of optimally doped $\text{YBa}_2\text{Cu}_3\text{O}_{6.99}$, additional Raman-active modes appear upon cooling below ~ 170 – 200 K in underdoped crystals. The temperature dependence of these new features indicates that they are associated with the incommensurate charge density wave state recently discovered using synchrotron x-ray scattering techniques on the same single crystals. Raman scattering thus has the potential to explore the evolution of this state under extreme conditions.

I. INTRODUCTION

When charges are injected into the Mott-insulating, antiferromagnetically ordered CuO_2 planes of layered copper oxides, antiferromagnetic long-range order is rapidly suppressed and is eventually replaced by high-temperature superconductivity.^{1–3} At low doping levels, diffraction methods have revealed spatially periodic modulations of the charge density in the CuO_2 planes. Two such patterns have been identified: the “striped” state in which antiferromagnetically ordered regions are separated by charged domain walls, which has been extensively studied in the “214” family $[\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ and $\text{La}_{2-x-y}\text{Sr}_x(\text{Nd},\text{Eu})_y\text{CuO}_4]$,^{4–12} and the biaxial charge density wave (CDW) state recently discovered in “123” compounds of composition $(\text{Y},\text{Nd})\text{Ba}_2\text{Cu}_3\text{O}_{6+x}$ ^{13–20} and in Bi-based superconductors.^{21,22} Whereas the data show clear evidence of competition between static stripe and CDW order and superconductivity, the influence of correlated charge fluctuations on d -wave Cooper pairing in the cuprates remains one of the central research questions in this field.

The spectroscopic determination of the dispersions and linewidths of lattice vibrations is a promising avenue to explore this issue, because they are expected to couple to charge fluctuations via the electron-phonon interaction.²³ Inelastic neutron scattering (INS) and inelastic x-ray scattering (IXS) studies have indeed revealed anomalous dispersions of the Cu-O-Cu bond-stretching and bond-bending vibrations of doped cuprates.^{24–31} In the 214 system, the wave vector of the bond-stretching phonon anomalies detected by INS is compatible with stripe order. However, in order to provide a firm basis for the quantitative interpretation of these effects, it is desirable to identify clear manifestations of static stripe order in the electronic band dispersions and/or the phonon dispersions. In particular, one generally expects a Fermi surface reconstruction as well as new phonon modes at the Brillouin zone (BZ) center due to folding of the crystallographic BZ in the stripe-ordered state. However, to the best

of our knowledge, neither of these effects has been clearly identified in stripe-ordered 214 materials.

Recent work on the 123 system has provided new perspectives on electronic ordering phenomena in the copper oxides. At low doping levels [$0.3 < x < 0.45$ in $(\text{Y},\text{Nd})\text{Ba}_2\text{Cu}_3\text{O}_{6+x}$],³² a unidirectional, static, incommensurate magnetic structure is observed, whereas at higher doping levels ($0.5 < x < 0.75$), a large gap opens in the spin excitations and low-energy fluctuations of the charge density appear.¹⁵ The latter are found to be biaxial and incommensurate, and centered at a wave vector not directly related to that of the magnetic fluctuations. Substitution of nonmagnetic Zn for planar Cu revealed that static spin and charge modulated phases are actually competing in the 123 system.¹⁷ The CDW correlation length increases strongly upon cooling and reaches ~ 20 lattice spacings at $T = T_c$, but the superconducting transition preempts the transition to CDW long-range order. Magnetic fields degrade superconductivity and enhance the CDW correlations, and recent evidence points towards the formation of a long-range ordered CDW state in high magnetic fields.^{14,19,33} The small Fermi surface pockets revealed by recent quantum oscillation measurements^{34,35} have been attributed to electronic band-folding effects associated with CDW order. Very recent high-resolution IXS experiments have demonstrated static (albeit short-range) CDW order even in zero magnetic fields, presumably as a consequence of pinning of CDW fluctuations by defects.^{33,36}

In analogy to the 214 system, anomalies in the Cu-O-Cu bond-stretching and bond-bending vibrations have been observed at wave vectors compatible with those of the CDW fluctuations in 123 compounds. Pronounced anomalies were observed in acoustic and low-energy optical phonons at the CDW wave vector,^{33,36} thus providing a direct link between both phenomena. The situation regarding BZ-center phonons remains less clear, however, because numerous modes related to the CuO chains are present in both Raman and infrared spectra of underdoped 123 materials. In particular, a set of phonon modes detected by infrared spectroscopy at

low temperatures had been tentatively attributed to charge correlations on the CuO chains.³⁷ Since the newly discovered CDW can be unambiguously assigned to the CuO₂ planes^{15–17} and appears to be generic to the superconducting cuprates, a reinvestigation of this situation is in order.

In this paper, we present a systematic Raman scattering study of the lattice dynamics in the 123 family as a function of doping, temperature, and incident photon wavelength using Raman scattering. This technique has proven to be a powerful probe of electronic and lattice vibrational excitations in strongly correlated systems.³⁸ In particular, the resulting data on 214 compounds at low frequencies have been interpreted in terms of phasons and amplitudons of charge stripes.³⁹ In the same family, the symmetry-dependent Raman intensity has been attributed to collective electronic excitations arising from fluctuations of a charge-ordered state.^{40–43} Their absence in the 123 family has been discussed as a consequence of short correlation lengths.⁴⁴ Here, we checked five twin-free YBa₂Cu₃O_{6+x} single crystals, with doping levels p ranging from the optimal to the strongly underdoped, which have previously been investigated using resonant x-ray scattering.^{15–17} We show that despite the complexity of the Raman spectra of the underdoped, nonstoichiometric samples, which contain numerous features associated with chain oxygen ordering^{45,46} and/or local defects, vibrational modes associated with the CDW can be unambiguously identified under specific resonant conditions. Raman scattering can thus be used as a sensitive and versatile tool to investigate CDW correlations in these compounds. In agreement with a previous study,¹⁵ we observe that they disappear rapidly below $p \sim 0.09$, where the incommensurate spin fluctuations become static and where the quantum oscillations disappear. We further found that dynamical signatures of the CDW can be detected up to temperatures significantly higher than those at which signatures of static CDW order can no longer be discerned by x rays. However, they disappear at temperatures below the pseudogap temperature T^* , as seen with various experimental techniques.⁴⁷

II. EXPERIMENTAL DETAILS

A. Samples

The Raman experiments were performed on high-quality detwinned YBa₂Cu₃O_{6+x} single crystals grown as described in Refs. 48 and 49. We present here measurements performed on five single crystals of compositions YBa₂Cu₃O_{6.99} ($p \sim 0.16$ and $T_c = 90$ K), YBa₂Cu₃O_{6.75} ($p \sim 0.135$ and $T_c = 75$ K), YBa₂Cu₃O_{6.6} ($p \sim 0.12$ and $T_c = 61$ K), YBa₂Cu₃O_{6.55} ($p \sim 0.10$ and $T_c = 61$ K), and YBa₂Cu₃O_{6.45} ($p \sim 0.08$ and $T_c = 35$ K). The crystals were cut into uniform rectangular shapes of typical size $3 \times 3 \times 1$ mm³, and detwinned individually under a uniaxial pressure as described in Refs. 50 and 51. In order to keep these oxygen concentrations unchanged, the samples were detwinned at 400°C under Ar flow. During detwinning, the samples were examined using a polarized light microscope. Measurements of the superconducting transitions using a superconducting quantum interference device (SQUID) showed transition widths $\Delta T_c < 2$ K, indicating good homogeneity of our samples. The hole doping level p was determined from the known dependence of the out-of-plane lattice parameter c

and of T_c on p .⁴⁹ Polarized light microscopy and Laue x-ray diffraction show that the a , b , and c axes were always parallel to the edges of our rectangular-shaped single-domain crystals. The Raman spectra are reproducible at different spots of the ab surface of each sample, further attesting to the homogeneity of the single crystals. The in-plane orientation of the crystal was determined using Laue diffraction and further checked with the strong anisotropy of the Raman signal. [Chain-related features appear indeed only when light is polarized along the b axis^{52,53} (see also Fig. 5).]

B. Raman measurements

The Raman scattering experiments were performed in backscattering geometry on a Labram (Horiba Jobin-Yvon) single-grating Raman spectrometer equipped with a razor-edge filter. As incident photon wavelengths we used the $\lambda = 632.8$ nm line of a He⁺/Ne⁺ mixed gas laser (red line), the $\lambda = 532$ nm line of a Nd:YAG laser (green), the 514.52 nm of an Ar⁺ laser (green), and the $\lambda = 488$ nm of a diode-pumped solid-state laser. The incident laser power was ~ 1 mW, and the beam focused through a $\times 50$ long-working distance objective. The samples were cooled in a He-flow cryostat. Laser-induced heating is always an issue in these kinds of measurements, and its amplitude can be hard to estimate at low temperatures where the anti-Stokes signal is very low. We could check that the heating was not larger than 5 K by looking at the well-known superconductivity-induced renormalization of the 340-cm⁻¹ phonon mode.^{54–64} In all samples, the effect was observed at T_c , as expected (see also Fig. 9). The spectral resolution of the spectrometer was about 2 cm⁻¹.

To describe the scattering geometries, we use the Porto notation A(BC)A', where A(B) and A'(C) stand for the propagation (polarization) directions of the incident and scattered light relative to the crystalline axes. All of the data presented in this paper were taken with the light propagation direction along the crystalline c axis; hence only the polarization orientations will be specified. In the literature,^{55–61} the small orthorhombic distortion of YBa₂Cu₃O_{6+x} is often neglected, and one refers to the phonons using the tetragonal (D_{4h} point group) notation. Using the XX and YY polarizations for incident and scattered photons propagating along the crystallographic c axis, we couple to A_{1g} and B_{1g} symmetry phonons. In the more accurate orthorhombic notation (D_{2h} point group), which will be used here,^{54,65} the modes have the A_g symmetry.

C. X-ray characterization of chain ordering

X-ray diffuse scattering measurements were conducted at the high energy wiggler beamline BW5 at the Synchrotronstrahlungslabor (HASYLAB) at the Deutsches Elektronen-Synchrotron (DESY), with x-ray beam energy of 100 keV. Following Ref. 66, hard x-ray diffuse scattering measurements on the YBa₂Cu₃O_{6.6} crystal reveal broad structures centered at the (4.39, 0, 2.5) and (4.61, 0, 2.5) positions of reciprocal space (Fig. 1). They correspond to an ortho-VIII type of oxygen superstructure with a correlation length of ~ 16 Å, as expected for this oxygen content.⁴⁶ A detailed mapping of the reciprocal space structure of the chains

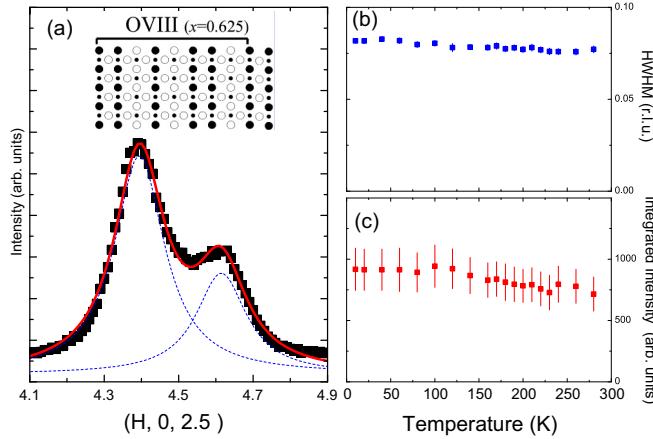

FIG. 1. (Color online) (a) X-ray diffuse scattering intensity around the (4.5 0 2.5) reciprocal space point. A schematic of the ortho-VIII ordering is shown in the inset (from Ref. 45). (b) Temperature dependence of the half-width at half maximum (HWHM) of the O-superstructure peaks. (c) Temperature dependence of the integrated intensity of the O-superstructure peaks.

can be found in the supplementary information of Ref. 33. The integrated intensities and widths are essentially temperature independent, in agreement with Ref. 66. The $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ and $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ single crystals were prepared with ortho-III and ortho-II order, respectively. The corresponding superstructure peaks were measured using soft x-ray resonant scattering,^{16,17} and correlation lengths of $\sim 37 \text{ \AA}$ for the ortho-III and $\sim 100 \text{ \AA}$ for the ortho-II samples were found.

III. EXPERIMENTAL RESULTS

We have performed temperature-dependent Raman scattering measurements on all the samples. Room-temperature Raman spectra for the five single crystals are shown on the left panel of Fig. 2. They consist of a broad, featureless electronic continuum on top of which are superimposed sharp optical phonons. The five Raman-active modes associated with the ortho-I unit cell (full CuO chains) are visible at room temperature in all samples. These modes have been widely studied in the literature.^{52–65,67,68} The corresponding atomic displacement as well as the typical energies corresponding to these modes are given in Table I. Note that these values are strongly doping dependent.^{54,57} In particular, the mode close to the 500 cm^{-1} mode softens a lot with diminishing oxygen content.

The main result of this work is clearly visible in the raw Raman data at temperature $T = T_c$ (right panel of Fig. 2). At optimal doping, no dramatic changes in the spectra are seen upon cooling, other than the expected sharpening of the aforementioned modes. In all underdoped compounds, on the other hand, the low-temperature spectra appear quite different from the room-temperature spectra. In addition to many weak features, which are sample dependent and related to superstructures induced by O dopants, we observe a very large scattering intensity at around 205, 465, 560, and 610 cm^{-1} . In $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ and $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$, the peak close to 465 cm^{-1} overlaps with the in-phase vibration of the planar oxygen atoms (labeled “O(2) + O(3)” in Table I) and the apical O(4) mode.

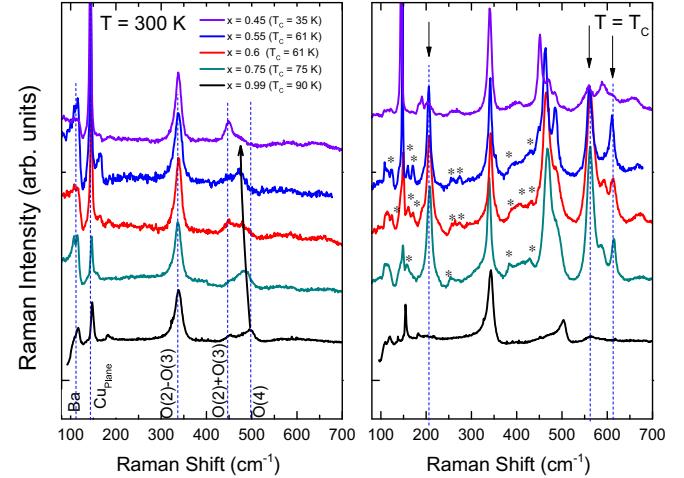

FIG. 2. (Color online) Room-temperature Raman spectra of detwinned optimally doped $\text{YBa}_2\text{Cu}_3\text{O}_{6.99}$ and underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$, $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$, $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$, and $\text{YBa}_2\text{Cu}_3\text{O}_{6.45}$ single crystals in the XX channel taken with a Neon laser line ($\lambda = 632.8 \text{ nm}$) at room temperature and $T = T_c$. The mode assignment corresponds to Ref. 58. For clarity, the absolute intensity of the spectra was normalized and a vertical offset was added.

A detailed look at the data of $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ (Fig. 3), which is more ordered than the other underdoped compounds, and therefore has sharper phonons, demonstrates that the 465-cm^{-1} feature is distinct from the two surrounding phonons.

A. Raman selection rules

In Fig. 4, we have plotted the Raman intensity measured in various scattering geometries at $T = T_c$ for the $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ sample. The new modes are visible only in the XX and $X'X'$ scattering geometries, which select respectively the A_g and $A_g + B_{1g}$ modes (in the orthorhombic notation). This shows that these features have the A_g symmetry.

B. Role of the chains

In the 123 family, the doping level is controlled by the occupation of O positions in the CuO chains, which can lead to the formation of superstructures with different periodicity along the a axis, depending on the heat treatment and on the oxygen content.^{45,46} As explained in the Experimental Details section, these superstructures have been characterized and can give rise to a large number of new Raman-active modes (different for each type of unit cell). In the ortho-II

TABLE I. Typical phonon (approximate) energies (in cm^{-1}) for the Raman-allowed modes of the ortho-I structure.

Displacement	Approx. Energy (cm^{-1})
Ba(z)	115
Mixed Ba/Cu(2)(z)	150
O(2) – O(3)(z)	340
O(2) + O(3)(z)	435
O(4)(z)	500

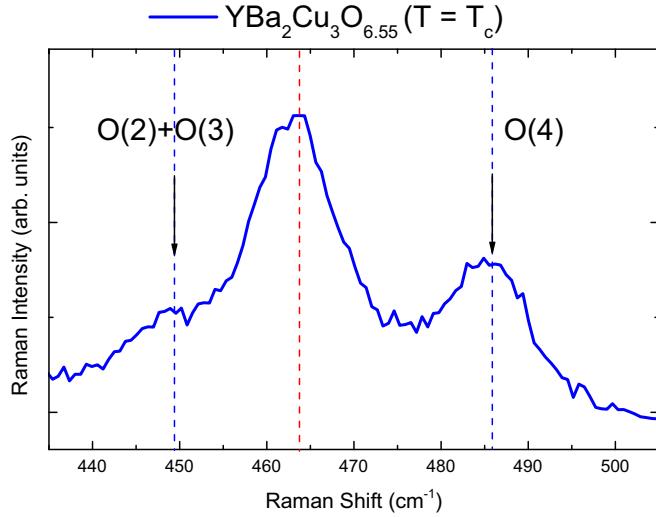

FIG. 3. (Color online) Detailed view of the XX Raman spectrum of $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ at $T = T_c$.

structure observed for oxygen contents close to $x \sim 0.5$, where empty and full chains alternate with correlation lengths larger than 100 \AA , the superlattice-induced modes (six new Raman-active phonons with the A_g symmetry) are visible but remain considerably weaker than those of the ortho-I allowed modes at all temperatures.^{62,64,69} In view of the decreasing correlation length of the superstructures (37 \AA for ortho-III and only 16 \AA for ortho-VIII), it is reasonable to expect the related phonons to be weak and sample dependent, such as those marked with “*” in Fig. 2(b).

The strong features at around 205 , 465 , 560 , and 610 cm^{-1} observed in these three samples do not meet this expectation. Further, at variance with the weaker modes mentioned above, their energies are essentially doping independent, suggesting a common physical origin. In the most underdoped sample investigated here, $\text{YBa}_2\text{Cu}_3\text{O}_{6.45}$, these modes are also observed but remain extremely weak.

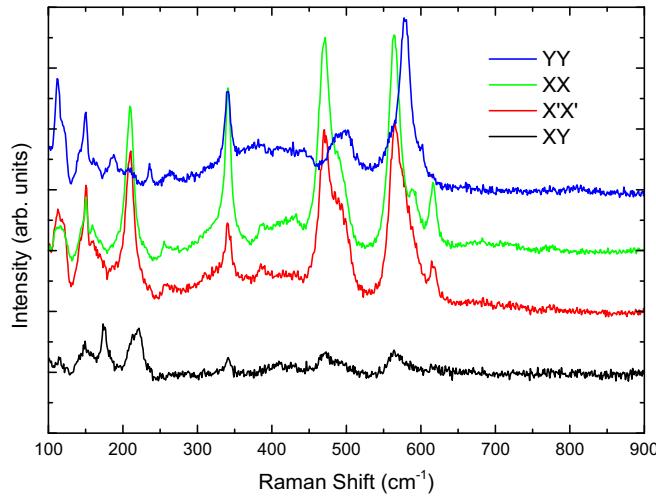

FIG. 4. (Color online) Raman spectra of $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ obtained in various scattering geometries at $T = T_c$. The intensities have been normalized at 900 cm^{-1} and shifted vertically for clarity.

A look at the data taken in the YY geometry (which also selects the A_g symmetry) provides further evidence against an O-structure-related origin for these modes. In this geometry, the new modes are hardly visible. The observation of the 560 - and 610-cm^{-1} features is prohibited by the presence of additional phonons arising from the broken CuO chains,^{63,65,67,70} in particular, the one at 590 cm^{-1} , which is very intense for the 632.8-nm incident wavelength and strongly temperature dependent at all doping levels (i.e., also at optimal doping where the new modes are not seen). At 205 cm^{-1} , where

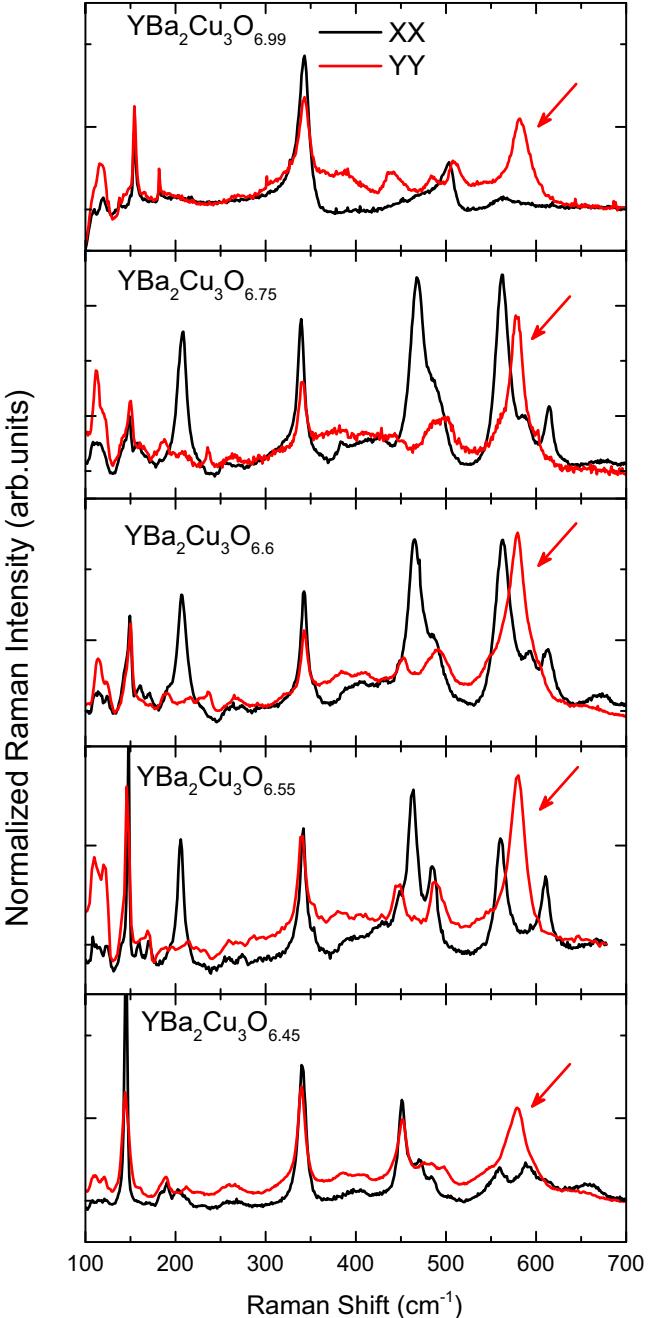

FIG. 5. (Color online) Comparison of the Raman spectra obtained at $T = T_c$ in XX and YY scattering geometries. The arrows indicate the strongly temperature dependent mode at 590 cm^{-1} , associated with the O vibration within broken CuO chains.

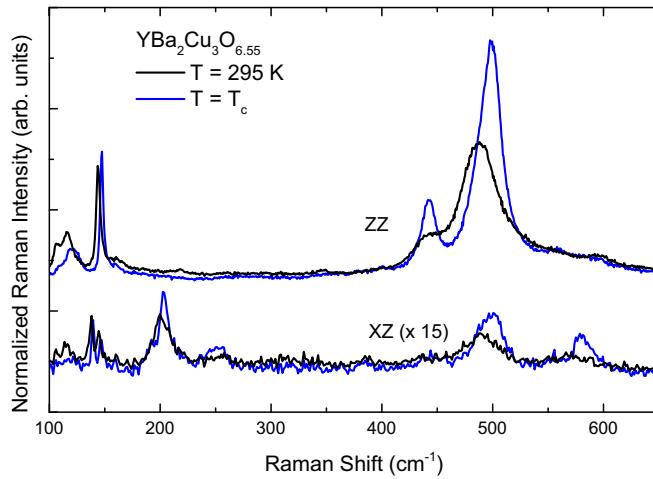

FIG. 6. (Color online) Comparison of the Raman spectra obtained at $T = T_c$ and room temperature in XZ and ZZ scattering geometries on $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$. For clarity, the XZ spectra has been magnified 15 times, and a vertical offset has been applied between the two sets of data.

chain-related features are not present, we do not observe any peak.

It is important to emphasize that in our detwinned single crystals, the chain-related structures are visible *only* in the YY geometry and are seen at all doping levels (Fig. 5). Other effects such as laser-induced local disorder of the oxygen structures^{62,71} are also expected to occur only in the YY channel, albeit for much higher power densities than the one used here. Those would furthermore also occur in the optimally doped compound where no effect is seen here. This allows us to rule out already at this stage any chain-related origin for the 205-, 465-, 560-, and 610-cm⁻¹ modes. This conclusion

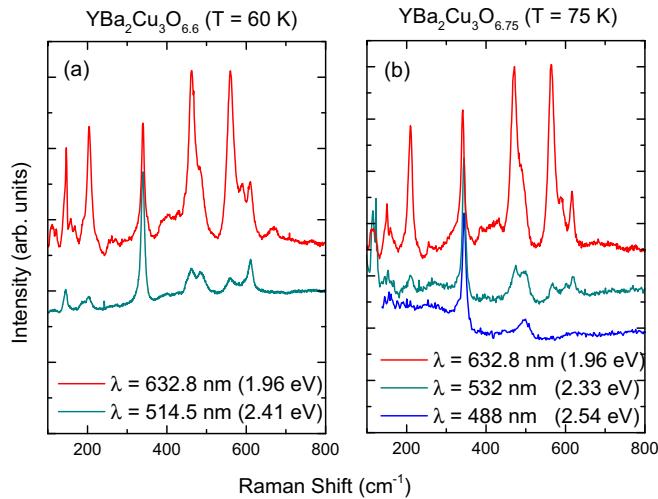

FIG. 7. (Color online) (a) XX Raman spectra of $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ measured at $T = 60$ K with red ($\lambda = 632.8$ nm) and green ($\lambda = 514.5$ nm) incident laser lights. (b) XX Raman spectra of $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ measured at $T = 75$ K with red ($\lambda = 632.8$ nm), green ($\lambda = 532$ nm), and blue ($\lambda = 488$ nm) incident laser lights. For clarity, the intensities of the spectra have been normalized to that of the 340-cm⁻¹ phonon.

will be reinforced by looking at resonance effects (Sec. III D) and at the detailed temperature dependence of these modes (Sec. III E).

C. ZZ and XZ geometries

Before addressing these points, we present data taken with the light polarized in the ac plane on the ortho-II sample YBa₂Cu₃O_{6.55}. In Fig. 6 we show spectra measured in XZ and ZZ geometries that respectively probe the B_{2g} and A_g geometries at room temperature and $T = T_c$, and that agree well with previous reports.^{57,68,69} At variance with the data obtained using in-plane scattering geometries, no extra features were observed at low temperature in these spectra. We note that in the B_{2g} spectra, a Raman-active phonon is seen at 203 cm⁻¹ that was previously attributed to planar vibrations of the apical O(4).⁶⁸ The energy of this mode is very close to that of the feature we observe at low temperature around 205 cm⁻¹. Unlike this feature, however, the weak B_{2g} peak is already seen at room temperature and appears to have a conventional temperature dependence. Furthermore, since none of the other new modes seen in the XX geometry at 465, 560, and 610 cm⁻¹ appear in these spectra, we are led to conclude that the energy proximity between the 205-cm⁻¹ feature and the B_{2g} mode is very likely coincidental. Note, finally, that the absence of a strongly temperature-dependent feature at 600 cm⁻¹ in the ZZ data allows us to rule out laser-induced damage of the chains during the measurement, as reported in Ref. 67. Together with our previous observations, this indicates that the A_g Raman tensor associated with the new modes is highly anisotropic ($\alpha_{XX} \gg \alpha_{YY}, \alpha_{ZZ}$).

D. Resonance effects

From now on, we will focus on the spectra obtained in the XX scattering geometry where the chain-related complications are absent. Having determined the Raman selection rules for the new modes, we now turn to their resonance properties, that is, the evolution of their intensity as a function of the incident laser light energy. The resonance profile of an excitation can bring useful information, as it can be directly related to the intermediate state involved in the scattering process and has been widely used to study selectively electronic, phononic, and magnetic excitations in cuprates.^{55,63,72-78} Interestingly, when using green incident laser light, the new modes are still clearly visible, but their relative intensity is strongly reduced compared to, e.g., the 340-cm⁻¹ phonon (Fig. 7). Using the blue line, the modes disappear completely. This trend differs from previous reports concerning the other Raman-active modes,⁵⁵ and from the behavior of the chain-defect-induced features,^{62,63,67,70} whose intensities are maximized for green and yellow incident lights, respectively.

Since most of the phonon studies carried out on underdoped YBa₂Cu₃O_{6+x} have used green light,^{54,57,59,62,64} this might explain why this effect has not been reported by previous Raman studies. We note, however, that the 205-, 560-, and 610-cm⁻¹ features were in fact seen in the XX channel in the data presented in Ref. 69 in an ortho-II crystal with $T_c = 57.5$ K. (The effect at 80 K is weaker than the one reported

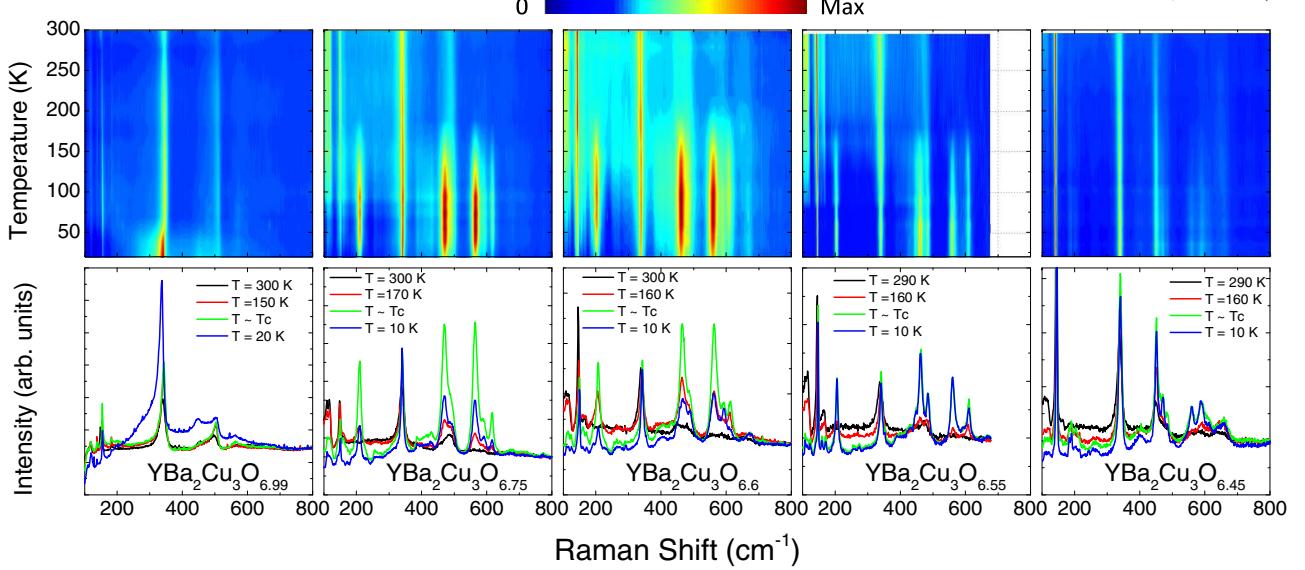

FIG. 8. (Color online) Upper panel: Color map representation of the temperature dependence of the Raman intensity measured with $\lambda = 632.8$ nm in the XX channel for optimally doped $\text{YBa}_2\text{Cu}_3\text{O}_{6.99}$, and underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$, $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$, $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$, and $\text{YBa}_2\text{Cu}_3\text{O}_{6.45}$. Lower panel: Raman spectra of the same compounds for selected temperatures.

here, likely due to a lower doping level, but still clearly visible), as well as in a sample with $T_c = 70$ K measured with the 647.1-nm Kr^+ line at 15 K in Ref. 63, where they are referred to as “weak” (which is indeed the case at low temperature) and were not studied further.

E. Detailed temperature dependence

We now take a closer look at the temperature dependence of the Raman spectra shown in Fig. 8. At optimal doping, a redistribution of the electronic continuum as well as a renormalization of the line shape of those phonons that couple strongly to the electrons (including the 340-cm^{-1} buckling mode and the low-frequency c -axis polarized Ba and Cu modes) are seen upon cooling below T_c (see Fig. 9). This is a direct consequence of the opening of the superconducting gap in the electronic density of states, an effect widely studied and quantitatively well understood.^{56–59,61,79} In the underdoped compounds, the amplitude of the superconductivity-induced renormalization is strongly reduced, in agreement with previous studies.^{57,59} This doping evolution is understood as a consequence of the increase of the maximal gap amplitude as doping is reduced, and of the opening of the normal-state pseudogap that suppresses the electronic density of states (and consequently, the electron-phonon coupling) at the Fermi level.

The intensity maps of Fig. 8 show clearly that the new modes in the underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$, $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$, and $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ samples appear in the normal state, far above their respective superconducting transition temperatures. The integrated intensities of the 205 , 560 , and 610-cm^{-1} modes are displayed as a function of temperature in Fig. 10. We leave the feature around 465 cm^{-1} aside, because as mentioned earlier, we cannot rule out that part of its intensity originates from the O(2) + O(3) and/or the O(4) Raman-active modes (though it is clearly distinct from them, as evidenced in the ortho-II samples where all three features can be resolved, as seen in Fig. 3). In a given sample, the three modes behave

in a very similar manner, their intensity being maximized around T_c . A significant decrease of the intensity in the superconducting state is seen especially in $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ and $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$. The sensitivity of the measurement further

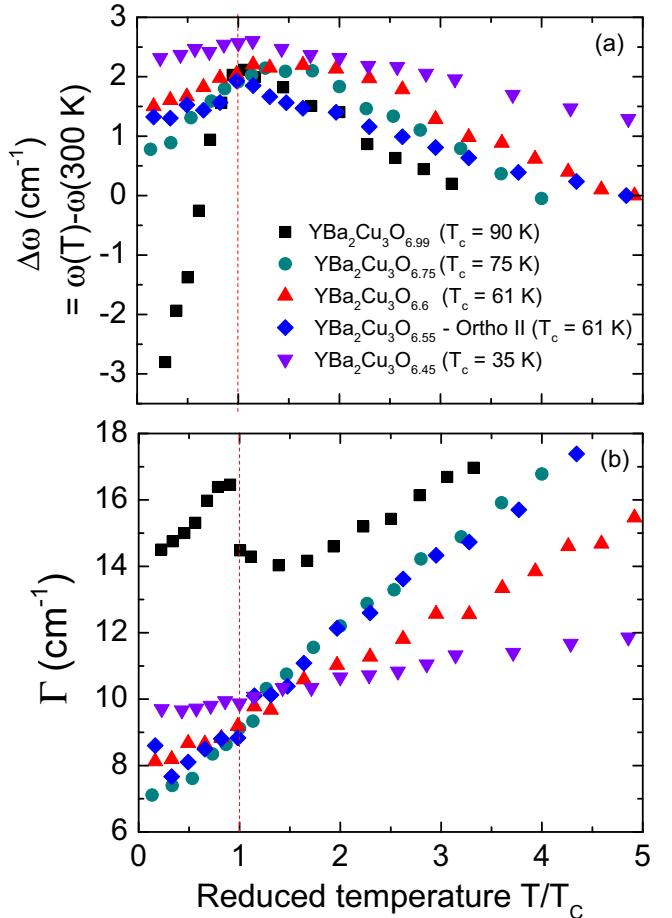

FIG. 9. (Color online) Renormalization of the 340-cm^{-1} “buckling” mode through T_c for the different doping levels.

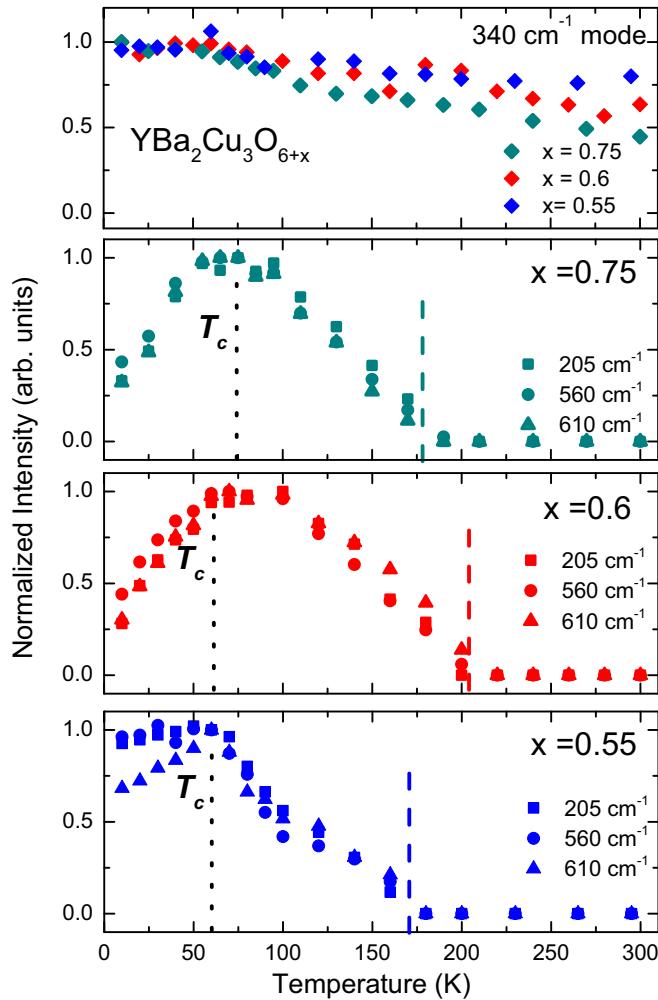

FIG. 10. (Color online) Temperature dependence of the integrated intensity of the modes at 340 cm^{-1} (upper panel) and 205 , 560 , and 610 cm^{-1} (lower panel) in $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ samples (green symbols), $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ (red symbols), and $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ samples (blue symbols).

allows us to study the doping dependence of the onset temperature, which appears nonmonotonic and reaches its maximum value in $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ at around 200 K. In both $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ and $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ the onset temperatures are around 175 K. The frequencies and linewidths of the new modes (not shown here) do not display any remarkable behavior. The modes harden and narrow slightly upon cooling, as expected from anharmonicity.

IV. DISCUSSION

We start our discussion with a brief summary of our main experimental findings. We have shown that new, intense phonon features appear below ~ 200 K in the polarized Raman spectra of three moderately underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ single crystals ($x = 0.55$, 0.6 , and 0.75). They could not be detected at optimal doping ($x = 0.95$) and become extremely weak at lower doping ($x = 0.45$). These new features are best seen with red incident laser light, in contrast to regular Raman-

active phonons (which are best seen with green light⁵⁵) and chain-induced defect modes (which are best seen with yellow light^{63,70}). The intensity of these new features is maximal at the superconducting transition temperature and decreases upon cooling below T_c . The polarization selection rules, the resonance conditions, and the doping and temperature dependencies of these modes allow us to rule out a chain-related origin.

The number of phonon branches is determined by the lattice symmetry. It cannot change with temperature in the absence of a structural phase transition that (i) lifts the degeneracy of some of the modes, (ii) breaks the IR/Raman selection rules (when suppressing the inversion symmetry of the crystal or driving an atom out of an inversion-symmetric site), or (iii) backfolds the phonon dispersion and thus give rises to new optical modes at the Γ point (when increasing the size of the original unit cell). The first two cases can easily be ruled out in our case. Clearly, the new features we observe do not originate from splitting of the Raman-active phonons of the $\text{YBa}_2\text{Cu}_3\text{O}_7$ structure; the modes that we are probing in the XX geometry are actually nondegenerate A_g modes. The breakdown of inversion symmetry also seems unlikely, as the new feature energies do not match those of known IR active modes.^{37,80} This therefore indicates that we are in the third situation.

The temperature and doping dependencies of the new modes, and particularly the fact that their intensity is maximized at T_c , is strongly reminiscent of the recently discovered CDW correlations in underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$,^{15,16,19} which compete with superconductivity. Studies carried out on the same single crystals using resonant x-ray scattering unveiled a biaxial CDW in $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ (Ref. 15) and $\text{YBa}_2\text{Cu}_3\text{O}_{6.75}$ (Ref. 16) single crystals, and a more anisotropic (but still biaxial) signal in ortho-II $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$.^{17,20} Qualitatively, it is natural to associate the appearance of new optical modes to the folding of the phonon dispersion in the new BZ as the CDW appears. The CDW incommensurability is only slightly doping dependent, decreasing from $\delta \sim 0.32$ to 0.3 (along the b^* direction) when going from $x = 0.55$ (Ref. 20) to $x = 0.75$ (Refs. 16 and 20). This is consistent with the doping independence of the mode frequencies. The appearance of new phonons in an electronically driven charge ordered state has been reported for other materials such as transition metal dichalcogenides (see, e.g., Ref. 81 and references therein), manganites,⁸² but also in stripe-ordered nickelates.^{83,84} When the CDW is commensurate with the lattice, these effects are strong and can be quantitatively understood based on group symmetry analysis; the new zone center modes are simply the zone-boundary phonons of the high-temperature phase. In the case of incommensurate structures, or in the fluctuating regime above the phase transition, these effects are usually much weaker.

In the 123 system, the CDW-induced atomic displacements are incommensurate with the underlying lattice, and the intensity ratio of the CDW satellite reflections and neighboring Bragg reflections yields an estimate of $\sim 10^{-3}a$ for their amplitude.¹⁹ Moreover, the CDW state always remains short-range ordered, at least in the absence of a high magnetic field.^{85–87} In this sense, the amplitude of the effect reported here appears rather strong. One should, however, keep in mind

the strongly resonant character of the new modes, i.e., the strong dependence of their Raman intensity on the incident photon frequency. Among the wavelengths investigated here, we observed maximal intensity for red photons with energy 1.96 eV, which indicates that the intermediate states for Raman scattering in this photon energy range [close to the charge-transfer gap energy between the O(2p) and Cu(3d) levels⁷³] are extremely sensitive to the CDW fluctuations.

It would be interesting to assign the new modes to atomic displacement patterns. While this is relatively straightforward for commensurate CDWs, the task is far more complex here owing to the incommensurate nature of the modulation. In addition, our recent x-ray diffuse scattering reciprocal space mapping revealed a complicated structure factor,³³ and a clear real-space picture of the atomic displacements associated with this modulated state has not yet emerged. Finally, we recall that in the presence of oxygen superstructures in the underdoped compound, the original phonon dispersion is still poorly known to date. The only reasonable starting point is the phonon spectrum of fully oxygenated $\text{YBa}_2\text{Cu}_3\text{O}_7$ that has been widely studied using INS and IXS.^{27–31,80} The best candidates for the 560- and 610- cm^{-1} features are the branches associated with in-plane vibrations of the oxygen atoms in CuO_2 planes. These branches comprise bond-stretching modes previously argued to couple dynamically with charge inhomogeneities in the CuO_2 planes.^{27–29} The assignment of the 205- cm^{-1} feature is more subtle since it is located in a denser region of the phonon spectrum. The energetically closest mode experimentally measured so far is associated with in-plane motion of Y and planar Cu atoms (IR-active at the zone center).⁸⁰ Finally, the 465- cm^{-1} peak might originate from the backfolding of the branch dispersing from the O(2) + O(3) Raman-active mode.⁸⁰

We now turn to the temperature dependence of the new Raman features, and more specifically, to their onset temperature. The three samples in which the Raman phonons are the strongest are those in which a superstructure peak has been clearly identified using soft x-ray scattering.^{15–17} As shown in Fig. 11, the onset temperature of the Raman signal is always observed at a temperature significantly higher than the onset of the incommensurate signal seen with x rays in the same samples.^{15–17} This offset has to be related to the frequency of the probe. Recent hard x-ray experiments performed with high energy resolution^{33,36} have demonstrated that the x-ray intensity is dominated by a quasielastic “central peak” with energy width lower than ~ 0.1 meV, (corresponding to fairly slow (~ 13 ps), quasistatic fluctuations of the charge density in the system) which appears in the 150–170 K range for doping levels close to $p = 0.11$. Phonons, on the other hand, can be seen as probes of the charge dynamics at higher frequency, i.e., on a much faster time scale (~ 0.1 ps). The appearance of the new modes around 220 K in $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ is hence a natural consequence of the survival of fast CDW fluctuations up to this temperature.

In Fig. 11 we have plotted the onset temperature of the new phonons as a function of doping, along with other phase transitions or crossover lines reported in the literature. The onset temperatures reported for the pseudogap differ substantially, possibly caused by the variety of criteria used to identify this phenomenon in different experimental techniques.

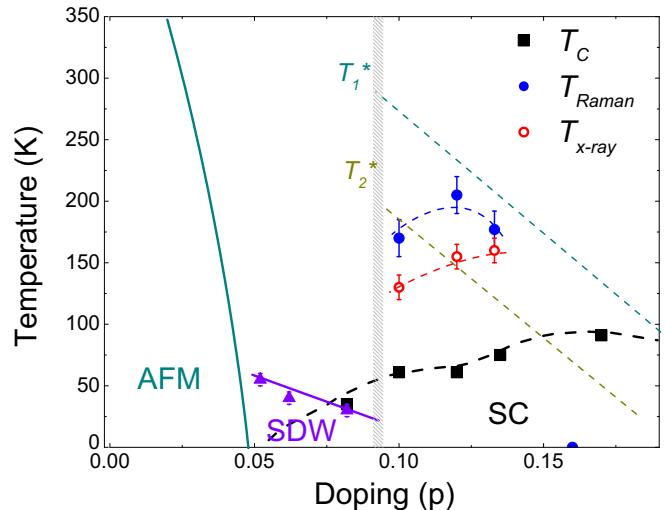

FIG. 11. (Color online) Schematic phase diagram for the Y123 family. T_{Raman} corresponds to the appearance temperature of the new modes at 205, 560, and 610 cm^{-1} , while $T_{\text{x-ray}}$ stands for the onset of the CDW peak seen in soft x-ray scattering experiments (Refs. 15–17) in the same samples. Other lines are discussed in the text.

Nonetheless, these temperatures can be roughly grouped into two categories.^{19,85,88,89} The first one (labeled T_1^* in Fig. 11) corresponds to the reported doping dependence of the anomalous polar Kerr effect⁹⁰ in $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ single crystals, and also coincides approximately with the sign change of the Hall coefficient⁹¹ and the decrease of the drop of the dynamical magnetic susceptibility seen in NMR relaxation measurements.^{92–94} The other line, labeled T_2^* , at higher temperature refers, among others, to the drop of the static spin susceptibility seen in NMR Knight shift measurements,⁹⁵ the onset of the $Q = 0$ polarized neutron diffraction signal,^{96–98} the signature of a broken rotational symmetry in the Nernst effect,⁹⁹ the decrease of spectral weight in the c -axis optical conductivity,^{100,101} and the more recently observed anomalies in resonant ultrasound spectroscopy.⁸⁵ These two lines differ by ~ 100 K at around 10% doping. The onset temperatures of the Raman phonons and of the quasistatic CDW fluctuations generally fall in between T_1^* and T_2^* , but neither of them matches the doping dependence of these lines. In any event, the CDW fluctuations appear below T_1^* , indicating that the CDW might be an instability within the pseudogapped state. Further work is required to elucidate the relationship between the CDW and the pseudogap determined by other spectroscopic probes.

At optimal doping, no evidence for the CDW-related Raman phonons is discernible in our data down to 10 K. Looking carefully at the data obtained on the most underdoped $\text{YBa}_2\text{Cu}_3\text{O}_{6.45}$ sample, it appears that at least the 205- and 560- cm^{-1} features are visible. However, the ratio of their intensities to that of the 340- cm^{-1} phonon is an order of magnitude weaker than in the $\text{YBa}_2\text{Cu}_3\text{O}_{6.55}$ and $\text{YBa}_2\text{Cu}_3\text{O}_{6.6}$ compounds. At the same time, quasistatic incommensurate magnetism is observed using INS^{102,103} and NMR^{94,104} at low temperature in the same compound. This confirms that the two types of modulations (spin and charge) compete with each other in the 123 family.¹⁷ Clearly, the charge modulation replaces the spin modulation precisely in the doping region

where, at high magnetic fields, the metal-insulator transition and quantum oscillations have been observed.¹⁰⁵

V. CONCLUSIONS

In conclusion, using Raman scattering we have observed clear signatures of the CDW state recently discovered by x-ray scattering in underdoped single crystals of $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$. This observation allowed us to study the doping dependence of this new phenomenon in detail. The results highlight the subtle interplay between the various phases competing with superconductivity in the underdoped cuprates. Owing to the versatility of Raman scattering, the identification of

Raman signatures of CDW formation will facilitate further investigations of the CDW under extreme conditions such as high magnetic fields and high pressure.
