# **Unconventional sign-changing superconductivity near quantum criticality in YFe<sub>2</sub>Ge<sub>2</sub>**

Alaska Subedi

*Centre de Physique Theorique, ´ Ecole Polytechnique, CNRS, 91128 Palaiseau Cedex, France ´* (Received 12 November 2013; revised manuscript received 26 December 2013; published 14 January 2014)

I present the results of first principles calculations of the electronic structure and magnetic interactions for the recently discovered superconductor YFe<sub>2</sub>Ge<sub>2</sub> and use them to identify the possible nature of superconductivity and quantum criticality in this compound. I find that the Fe 3*d* derived states near the Fermi level show a rich structure with the presence of both linearly dispersive and heavy bands. The Fermi surface exhibits nesting between hole and electron sheets that manifests as a peak in the susceptibility at (1*/*2*,*1*/*2). The antiferromagnetic spin fluctuations associated with this peak may be responsible for mediating the superconductivity in this compound resulting in a  $s_{\pm}$  state similar to that of the previously discovered iron-based superconductors. I also find that various magnetic orderings are almost degenerate in energy, which indicates that the proximity to quantum criticality is due to competing magnetic interactions.

#### **I. INTRODUCTION**

Unconventional superconductivity and quantum criticality are two of the most intriguing phenomena observed in physics. However, the underlying mechanisms and the properties exhibited by the systems in which these two phenomena occur has not been fully elucidated because unconventional superconductors and materials at quantum critical point are so rare. The dearth of realizable examples has also held back the study of the relationship and interplay between unconventional superconductivity and quantum criticality, if there are any.

Therefore, the recent report of non-Fermi liquid behavior and superconductivity in YFe<sub>2</sub>Ge<sub>2</sub> by Zou *et al.* is of great interest despite a low superconducting  $T_c$  of ~ 1.8 K [\[1\]](#page-4-0). This material is also interesting because it shares some important features with the previously discovered iron-based high-temperature superconductors. Like the other iron-based superconductors, its structural motif is a square plane of Fe that is tetrahedrally coordinated, in this case, by Ge. This  $Fe<sub>2</sub>Ge<sub>2</sub>$ layer is stacked along the *z* axis with an alternating layer of Y ions. The resulting body-centered tetragonal structure (*I*4*/mmm*) of this compound is the same as that of the "122" family of the iron-based superconductors.

The nearest neighbor Fe-Ge and Fe-Fe distances of 2.393 and 2.801 Å, respectively, in this compound  $[2]$  $[2]$  are similar to the Fe-As and Fe-Fe distances of  $2.403$  and  $2.802$  Å, respectively, found in BaFe<sub>2</sub>As<sub>2</sub> [\[3\]](#page-4-0). This raises the possibility that the direct Fe-Fe hopping is important to the physics of this material, which is the case for the previously discovered iron-based superconductors [\[4\]](#page-4-0).

Furthermore, Zou *et al.* report that the superconductivity in this compound exists in the vicinity of a quantum critical point that is possibly associated with antiferromagnetic spin fluctuations [\[1\]](#page-4-0). A related isoelectronic compound  $LuFe<sub>2</sub>Ge<sub>2</sub>$ that occurs in the same crystal structure exhibits antiferromagnetic spin density wave order below 9 K [\[5,6\]](#page-4-0), and the magnetic transition is continuously suppressed in  $\text{Lu}_{1-x}Y_x\text{Fe}_2\text{Ge}_2$  series as Y content is increased, with the quantum critical point lying near the composition  $Lu_{0.81}Y_{0.19}Fe_2Ge_2$  [\[7\]](#page-4-0). The proximity of  $YFe<sub>2</sub>Ge<sub>2</sub>$  to quantum criticality is observed in the non-Fermi liquid behavior of the specific-heat capacity and resistivity. Zou *et al.* find that the unusually high Sommerfeld coefficient

with a value of  $C/T \simeq 90 \text{ mJ/mol K}^2$  at 2 K further increases to a value of  $\sim$ 100 mJ/mol K<sup>2</sup> as the temperature is lowered, although the experimental data is not detailed enough to distinguish between a logarithmic and a square root increase. They also find that the resistivity shows a behavior  $\rho \propto T^{3/2}$ up to a temperature of 10 K.

In this paper, I use the results of first principles calculations to discuss the interplay between superconductivity and quantum criticality in  $YFe<sub>2</sub>Ge<sub>2</sub>$  in terms of its electronic structure and competing magnetic interactions. I find that the fermiology in this compound is dominated by Fe 3*d* states with the presence of both heavy and linearly dispersive bands near the Fermi level. The Fermi surface consists of five sheets. There is an open tetragonal electron cylinder around  $X = (1/2, 1/2, 0)$ . A large three dimensional disk shaped sheet is situated around  $Z = (0,0,1/2) = (1,0,0)$ . This sheet encloses a cylindrical and two almost spherical hole sheets. The tetragonal cylinder sheet around *X* nests with the spherical and the cylindrical sheets around *Z*, which manifests as a peak at (1*/*2*,*1*/*2) in the bare susceptibility. The superconductivity in this compound may arise from the antiferromagnetic spin fluctuations associated with this peak, and the resulting superconductivity will have a sign-changing *s*<sup>±</sup> symmetry with opposite signs on the nested sheets around *X* and *Z*. This superconductivity is similar to the one proposed for the previously discovered iron-based superconductors [\[8,9\]](#page-4-0). Furthermore, I find that there are competing magnetic interactions in this compound, and the quantum criticality is due to the fluctuations associated with these magnetic interactions.

### **II. COMPUTATIONAL DETAILS**

The results presented here were obtained within the local density approximation (LDA) using the general full-potential linearized augmented plane wave method as implemented in the WIEN2K software package [\[10\]](#page-4-0). Muffin-tin radii of 2.4, 2.2, and 2.1 a.u. for Y, Fe, and Ge, respectively, were used. A  $24 \times 24 \times 24$  *k*-point grid was used to perform the Brillouin zone integration in the self-consistent calculations. An equivalently sized or larger grid was used for supercell calculations. Some magnetic calculations were also checked with the ELK software package [\[11\]](#page-4-0). I used the experimental

parameters ( $a = 3.9617$  and  $c = 10.421$  Å) [[2\]](#page-4-0), but employed the internal coordinate for Ge  $z_{\text{Ge}} = 0.3661$  obtained via non-spin-polarized energy minimization. The calculated value for  $z_{\text{Ge}}$  is different from the experimentally determined value of  $z_{\text{Ge}} = 0.3789$ . The difference in the Ge height between the calculated and experimental structures is  $0.13 \text{ Å}$ , which is larger than the typical LDA error in predicting the crystal structure. Such a discrepancy is also found in the other iron-based superconductors [\[4\]](#page-4-0). This may suggest that  $YFe<sub>2</sub>Ge<sub>2</sub>$ shares some of the underlying physics with the previously discovered iron-based superconductors.

#### **III. RESULTS AND DISCUSSION**

The non-spin-polarized LDA band structure and density of states (DOS) are shown in Figs. 1 and 2, respectively. The lowest band that starts out from  $\Gamma$  at  $-5.2$  eV relative to the Fermi energy has Ge  $4p<sub>z</sub>$  character. There is only one band with Ge  $4p<sub>z</sub>$  character below the Fermi level, and there is another band with this character above the Fermi level. This indicates that the Ge ions make covalent bonds along the *c* axis, which is not surprising given the short Ge-Ge distance in that direction. The four bands between  $-1.2$  and  $-4.8$  eV that start out from at −1.5 and −2.6 eV have Ge 4*px* and 4*py* character. The rest of the bands below the Fermi level have mostly Fe 3*d* character. Similar to the other iron-based superconductors [\[4\]](#page-4-0), there is no gaplike structure among the Fe 3*d* bands splitting them into lower lying  $e_g$  and higher lying  $t_{2g}$  states. This shows that Fe-Ge covalency is minimal and direct Fe-Fe interactions dominate. Almost all of the Fe 4*s* and Y 4*d* and 5*s* characters

FIG. 1. Top: LDA non-spin-polarized band structure of  $YFe<sub>2</sub>Ge<sub>2</sub>$ . Bottom: A blowup of the band structure around the Fermi level. The long  $\Gamma$ -*Z* direction is from  $(0,0,0)$  to  $(1,0,0)$  and the short one is from (0*,*0*,*0) to (0*,*0*,*1*/*2). The *X* point is (1*/*2*,*1*/*2*,*0). The stacking of the Brillouin zone is such that  $(1,0,0) = (0,0,1/2)$ . See Fig. 1 of Ref. [\[13\]](#page-4-0) for a particularly illuminating illustration of the reciprocalspace structure.

FIG. 2. (Color online) Electronic density of states of non-spinpolarized  $YFe<sub>2</sub>Ge<sub>2</sub>$  and projections onto the LAPW spheres per formula unit for both spin basis.

lie above the Fermi level. This indicates a nominal occupation of Fe  $3d^{6.5}$ , although the actual occupancy will be different because there is some covalency of Fe 3*d* states with Y 4*d* and Ge 4*p* states.

The electronic states near the Fermi level come from Fe 3*d* derived bands and show a rich structure. The electronic DOS at the Fermi level is  $N(E_F) = 4.50 \text{ eV}^{-1}$  on a per formula unit both spin basis corresponding to a calculated Sommerfeld coefficient of 10.63 mJ/mol  $K^2$ . The Fermi level lies at the bottom of a valley with a large peak due to bands of mostly  $d_{xz}$ and *dyz* characters on the left and a small peak due to a band of mostly  $d_{xy}$  character on the right. (The local coordinate system of the Fe site is rotated by 45◦ in the *xy* plane with respect to the global Cartesian axes such that the Fe *dx*<sup>2</sup>−*y*<sup>2</sup> orbital points away from the Ge  $p_x$  and  $p_y$  orbitals.) There is a pair of linearly dispersive band with mostly  $d_{xz}$  and  $d_{yz}$  as well as noticeable Ge  $p<sub>z</sub>$  characters on either side of *Z*. If they are not gapped in the superconducting state, they will provide the system with a massless excitation. In addition to this pair of linearly dispersive bands, there is also a very flat band near the Fermi level along  $X - \Gamma$ . This band has an electronlike nature around *X* and crosses the Fermi level close to it. Along the *X* direction, it reaches a maximum at 0.08 eV above the Fermi level, turns back down coming within 0.01 eV of touching the Fermi level, and again moves away from the Fermi level. It may be possible to access these band critical points that have vanishing quasiparticle velocities via small perturbations due to impurities, doping, or changes in structural parameters. The role of such band critical points in quantum criticality has been emphasized recently [\[12\]](#page-4-0), and similar physics may be relevant in this system.

The Fermi surface of this compound is shown in Fig. [3.](#page-2-0) There is an open very two dimensional tetragonal electron cylinder around *X*. This has mostly  $d_{xz}$  and  $d_{yz}$  character. There are four closed sheets around *Z*. One of them is a large three dimensional disk shaped sheet with  $d_{xz}$ ,  $d_{yz}$ ,  $d_{xy}$ , and  $d_{z^2}$ characters. There are two almost spherical hole sheets. These have mostly  $d_{xz}$  and  $d_{yz}$  characters, with the smaller one also

<span id="page-2-0"></span>

FIG. 3. (Color online) Top: LDA Fermi surface of  $YFe<sub>2</sub>Ge<sub>2</sub>$ . Bottom: The Fermi surface without the large sheet. The shading is by velocity.

containing noticeable Ge  $p<sub>z</sub>$  character. These two spherical sheets are enclosed by a closed cylindrical hole sheet that has mostly *dxy* character.

The cylindrical and larger spherical sheets centered around *Z* touch at isolated points. Otherwise, the Fermi surface is comprised of disconnected sheets. If one considers the  $\Gamma$ -*Z*- $\Gamma$ path along the  $k_z$  direction, there is a series of box-shaped cylindrical hole sheets that encloses the two spherical sheets. Although there are no sections around  $\Gamma$ , these sheets around  $\Gamma$ enclose almost two-thirds of the  $\Gamma$ - $Z$ - $\Gamma$  path. Therefore, there is likely to be substantial nesting between the sheets around *Z* and *X* that will lead to a peak in the susceptibility at the wave vector (1*/*2*,*1*/*2).

I have calculated the Lindhard susceptibility

$$
\chi_0(q,\omega) = \sum_{k,m,n} |M_{k,k+q}^{m,n}|^2 \frac{f(\epsilon_k^m) - f(\epsilon_{k+q}^n)}{\epsilon_k^m - \epsilon_{k+q}^n - \omega - i\delta}
$$

at  $\omega \to 0$  and  $\delta \to 0$ , where  $\epsilon_k^m$  is the energy of a band *m* at wave vector  $k$  and  $f$  is the Fermi distribution function.  $M$  is the matrix element, which is set to unity. The real part of the susceptibility is shown in Fig. 4, and it shows peaks at  $\Gamma$ ,  $Z$ , and *X* with the peak at *X* having the highest magnitude. Note, however, that the cylinders around *Z* and *X* have different characters, which should reduce the peak at *X* and make it broader as well. The peak at  $\Gamma$  is equal to the DOS  $N(E_F)$ . The peak at *Z* reflects the nesting along the flat sections of the sheets along  $(0,0,1/2)$  direction, while the peak at *X* is due to the nesting between the hole cylinder and spheres centered around *Z* and the electron cylinder centered around *X*.

FIG. 4. (Color online) Real part of bare susceptibility calculated with the matrix element set to unity.

The bare Lindhard susceptibility is further enhanced due to the RPA interaction, and its real part is related to magnetism and superconductivity. It is found experimentally that pure  $YFe<sub>2</sub>Ge<sub>2</sub>$  does not order magnetically down to a temperature of 2 K although it shows non-Fermi liquid behavior in the transport and heat capacity measurements that are likely due to proximity to a magnetic quantum critical point [\[1\]](#page-4-0). As the temperature is lowered further, superconductivity manifests in the resistivity measurements at  $T_c^{\rho} = 1.8$  K and dc magnetization at  $T_c^{\text{mag}} = 1.5 \text{ K}$ . This superconductivity may arise due spin fluctuations associated with the peak in the susceptibility [\[14,15\]](#page-4-0). The pairing interaction has the form

$$
V(q = k - k') = -\frac{I^{2}(q)\chi_{0}(q)}{1 - I^{2}(q)\chi_{0}^{2}(q)}
$$

in the singlet channel and is repulsive. (In the triplet channel, the interaction is attractive and also includes an angular factor.) Here  $I(q)$  is the Stoner parameter which microscopically derives from Coulomb repulsion between electrons.

In the present case, the structure of the calculated susceptibility leads to a large negative value −*V* for the pairing interaction between the hole sheets at *Z* and electron cylinder at *X* in the singlet channel. The small  $q$  pairing  $V_0$  among the sheets at *Z* and *X* are small and ferromagnetic. (For simplicity, I have assumed that the density of states are same for the hole and electron sections.) This defines the pairing interaction matrix  $[V_0, -V; -V, V_0]$  for the sets of sheets at *Z* and *X*. The eigenvector corresponding to the largest eigenvalue of this interaction matrix has opposite signs between the hole sheets around *Z* and electron cylinder around *X*, and this is consistent with a singlet  $s_{\pm}$  superconductivity with a wave vector  $(1/2,1/2)$ . This superconductivity is similar to that of the previously discovered iron-based superconductors [\[8,9\]](#page-4-0).

The proposed superconductivity in  $YFe<sub>2</sub>Ge<sub>2</sub>$  and the previously discovered iron-based superconductor is similar, but the  $T_c = 1.8$  K for YFe<sub>2</sub>Ge<sub>2</sub> is much smaller than those reported for other iron-based superconductors. One reason for this may be the smaller nesting in this compound leading to a smaller peak in susceptibility. The hole cylinder around *Z* has mostly *dxy* character, whereas the hole spheres around *Z* and the electron cylinder around *X* have mostly  $d_{xz}$  and  $d_{yz}$  character.

TABLE I. Relative energies of various magnetic orderings and the moments within the Fe spheres. These are almost degenerate, indicating the proximity to quantum criticality is due to competing magnetic interactions.

|                     | Energy (meV/Fe) | Moment $(\mu_B/Fe)$ |
|---------------------|-----------------|---------------------|
| <b>NSP</b>          | $\theta$        | $\theta$            |
| <b>FM</b>           | $-6.29$         | 0.59                |
| AFM (0,0,1/2)       | $-11.63$        | 0.64                |
| SDW $(1/2,1/2,0)$   | $-6.52$         | 0.72                |
| SDW $(1/2,1/2,1/2)$ | $-9.95$         | 0.81                |

These factors should lead to a slightly smaller and broader peak at *X*. I note, however, that nesting in the other iron-based superconductors is also not perfect [\[8\]](#page-4-0) and the band characters between the nested sheets also vary [\[9\]](#page-4-0).

Another reason for the smaller  $T_c$  in YFe<sub>2</sub>Ge<sub>2</sub> may be due to the existence of competing magnetic fluctuations associated with the proximity to quantum criticality. The DOS from non-spin-polarized calculation is  $N(E_F) = 1.125$  eV<sup>-1</sup> per spin per Fe, which puts this material on the verge of a ferromagnetic instability according to the Stoner criterion. Ferromagnetism is pair breaking for the singlet pairing and will suppress the  $T_c$  in this compound. Furthermore, there is a peak in the susceptibility at *Z* as well. The presence of additional antiferromagnetic interactions might reduce the phase space available for the spin fluctuation associated with the pairing channel and may be pair breaking as well.

I performed magnetic calculations with various orderings on  $(1 \times 1 \times 2)$  and  $(\sqrt{2} \times \sqrt{2} \times 2)$  supercells to check the strength of competing magnetic interactions. The relative energies and the Fe moments are summarized in Table I. I was able to stabilize various magnetic configurations, and their energies are close to that of the non-spin-polarized configuration. However, I was not able to stabilize the checkerboard antiferromagnetic order in the *ab* plane. When the magnetic order is stabilized, the magnitude of the Fe moment is less than 1  $\mu_B$ , and the magnitudes vary between different orderings. This indicates that the magnetism is of itinerant nature. The calculated LDA moments in  $YFe<sub>2</sub>Ge<sub>2</sub>$  are smaller than those calculated in some of the previously discovered iron based superconductors like, for example,  $BaFe<sub>2</sub>As<sub>2</sub>$  [\[21\]](#page-4-0). This is likely due to a smaller value of DOS at the Fermi level and reduced nesting in  $YFe<sub>2</sub>Ge<sub>2</sub>$ . It is worthwhile to note that LDA calculations overestimate the magnetism in this compound as it does not exhibit any magnetic order experimentally. This disagreement between LDA and experiment is different from that for the Mott insulating compounds where LDA in general underestimates the magnetism.

Although this compound does not magnetically order experimentally, it nonetheless shows proximity to magnetism. It is found that partial substitution of Y by isovalent Lu causes the system to order antiferromagnetically, with 81% Lu substitution being the critical composition [\[7\]](#page-4-0). At substitution values below the critical composition, the system shows non-Fermi liquid behavior in the heat capacity and transport measurements [\[1\]](#page-4-0). The unusually high Sommerfeld coefficient of <sup>∼</sup>90 mJ*/*mol K2 at 2 K further increases as the temperature is lowered and the resistivity varies as  $\rho \propto T^{3/2}$  up to around 10 K. This non-Fermi liquid behavior and the large renormalization of the magnetic moments may happen because there is a large phase for competing magnetic tendencies in this compound. This is due to the fluctuation-dissipation theorem, which relates the fluctuation of the moment to the energy and momentum integrated imaginary part of the susceptibility [\[16–20\]](#page-4-0). If the quantum criticality is due to competing magnetic interactions, the inelastic neutron scattering experiments, which measure the imaginary part of the susceptibility, would exhibit the structure related to the competing interactions. Therefore, even though this compound does not show magnetic ordering, it would be useful to perform such experiments and compare with the results presented here.

In any case, I indeed find that various magnetic orderings and the non-spin-polarized configuration are close in energy (see Table I). The energy of the lowest magnetic configuration is only 11.6 meV*/*Fe lower than the non-spin-polarized one, and the energies of the different magnetic orderings are within 6 meV*/*Fe of each other. As a comparison, the difference in energy between the nonmagnetic configuration and the most stable magnetic ordering in BaFe<sub>2</sub>As<sub>2</sub> is 92 meV/Fe, and the energy of the magnetic ordering closest to the most stable one is higher by 51 meV [\[21\]](#page-4-0). Signatures of quantum criticality have been reported for  $BaFe<sub>2</sub>As<sub>2</sub>$  and related compounds  $[22–24]$ . YFe<sub>2</sub>Ge<sub>2</sub> should show pronounced effects of proximity to quantum criticality as the competition between magnetic interactions is even stronger.

Singh has performed similar first principles calculations on  $YFe<sub>2</sub>Ge<sub>2</sub>$  within the generalized gradient approximation (GGA) [\[25\]](#page-4-0). Although there are some differences between the LDA and GGA results, the important features of the electronic structure agree. The GGA increases the tendency to magnetism in the iron superconductors, which results in larger moments and energy gains compared to the LDA results for the magnetically ordered configurations of  $YFe<sub>2</sub>Ge<sub>2</sub>$ . Singh only considered the magnetic orderings in a  $(1 \times 1 \times 2)$  supercell, where an in-plane ferromagnetic state has the lowest energy [\[25\]](#page-4-0). This leads him to conjecture that the superconductivity in this compound is likely of triplet nature.

### **IV. CONCLUSIONS**

In summary, I have discussed the superconductivity and quantum criticality in  $YFe<sub>2</sub>Ge<sub>2</sub>$  in terms of its electronic structure and competing magnetic interactions. The electronic states near the Fermi level are derived from Fe 3*d* bands and show a rich structure with the presence of both linearly dispersive and heavy bands. The Fermi surface consists of five sheets. There is an open rectangular electron cylinder around *X*. A large disk shaped sheet encloses a hole cylinder and two hole spheres around*Z*. There is a peak in the bare susceptibility at (1*/*2*,*1*/*2) due to nesting between the hole sheets around *Z* and the electron cylinder around *X*. The superconductivity in  $YFe<sub>2</sub>Ge<sub>2</sub>$  is likely due to antiferromagnetic spin fluctuations associated with this peak. The resulting superconducting state has a  $s_{\pm}$  state similar to that of the previously discovered iron-based superconductors. I also find that different magnetic <span id="page-4-0"></span>configurations are close in energy, which suggests the presence of competing magnetic interactions that are responsible for the proximity to quantum criticality observed in this compound.
