We combine the effect of the electron-electron and electron-phonon interactions to study the electronic and optical properties of *zb*-GaN. We show that only by treating the two effects at the same time is it possible to obtain an unprecedented agreement of the zero- and finite-temperature electronic gaps and absorption spectra with the experimental results. Compared to the state-of-the-art results our calculations predict a large effect on the main absorption peak position and width as well as on the overall absorption line shape. These important modifications are traced back to the combined electron-phonon damping mechanism and nonuniform *GW* level corrections. Our results demonstrate the importance of treating on equal footing the electron and phonon mediated correlation effects to obtain an accurate description of the physical properties of group III nitrides.

I. INTRODUCTION

The group III-nitride semiconductors, i.e., GaN, AlN, InN, and their alloys are materials with many applications in the field of optoelectronics. These include, among others, light emitting diodes (LEDs), laser diodes (LDs), and heterojuction field-effect transistors (HFETs) $[1-5]$. This class of compounds is widely used, being characterized by the most stable wurtzite structure. They have built-in electric fields arising from the spontaneous and piezoelectric polarization along the *c* axis. These fields are, however, undesirable in the application of the heterostructures as quantum wells (QWs) or superlattices since they complicate the design and worsen the sample malleability. One of the approaches to eliminate these internal fields is the use of metastable nonpolar zinc-blende (*zb*) structures. It has also been reported that *zb* group III nitrides have a quantum confined Stark effect in low-dimensional heterostructures [\[6\]](#page-5-0), high *p*-type conductivity in (Ga,Mn)N thin films [\[7\]](#page-5-0), and negative differential resistance (NDR) at the resonant tunneling diode of the cubic Al(Ga)N/GaN [\[8,9\]](#page-5-0). Consequently a lot of interest is constantly attracted by this family of materials.

In the last few years *zb*-GaN with high phase-purity and crystalline quality has been fabricated as a nearly strain-free epitaxial layer on 3C-SiC(001)/Si pseudosubstrates by plasmaassisted molecular beam epitaxy [\[6,9–11\]](#page-5-0). This experimental achievement boosted the interest on fundamental optical properties such as photoluminescence, photoreflectance, and ellipsometry with particular attention on their temperature dependence.

In contrast to such abundance of experimental results the agreement with the state-of-the-art calculations of the optical properties of *zb*-GaN is still not satisfactory. In these approaches the absorption spectrum is calculated [\[12\]](#page-5-0) by including electron-hole interaction by solving the Bethe-Salpeter equation (BSE) derived within the many-body perturbation theory (MBPT) [\[13\]](#page-5-0). Nevertheless, the main peak position is strongly underestimated when compared to the experimental result. Also the complex temperature dependence observed experimentally is not captured at all. Similarly, the band structure of *zb*-GaN has been deeply investigated by using the most up-to-date theoretical approaches. In this case electronelectron correlation only has been included, by means of the well-known *GW* approximation [\[14\]](#page-5-0). The corresponding quasiparticle (QP) gap, calculated by using the one-shot *GW* approximation on top of Kohn-Sham (KS) Heyd-Scuseria-Ernzerhof (HSE) [\[15\]](#page-5-0) hybrid orbital (HSE + G_0W_0) [\[16\]](#page-5-0), is 3.427 eV, which overestimates the experimental value of 3.295 eV [\[6\]](#page-5-0).

The common denominator to these calculations of the electronic and optical properties is that electron-phonon (EP) interaction is not considered. As a natural consequence no temperature dependence is captured. More importantly, also the well-known zero-point motion effect is neglected. This assumption is, on the basis of very recent results $[17–21]$, not well motivated. Indeed the majority of the *ab initio* simulations of the electronic and optical properties of a wide class of materials are generally performed by keeping the atoms frozen in their crystallographic positions. Nevertheless, many years ago, Heine, Allen, and Cardona (HAC) [\[22,23\]](#page-5-0) pointed out the fact that the electronic states can be strongly affected by the lattice vibrations even when $T \rightarrow 0$ K through the quantum zero-point motion effect. In the HAC approach the EP interaction is treated in a static manner and the atomic displacements are considered as static perturbations. The HAC approach successfully explained the temperature dependence of the gap shift and peak broadening in semiconductors like Si or Ge [\[24\]](#page-5-0). BSE calculations on top of QP states including EP correction have also been performed, showing a remarkable EP effect on the excitonic states and explaining the finite temperature evolution of the optical absorption measured experimentally [\[25\]](#page-5-0).

Despite these successful results based on the HAC approach, the key importance of considering dynamical corrections to the static HAC picture has been recently discovered. For instance, diamond has been shown to have large dynamical EP effects, which explains the subgap states observed experimentally in the absorption spectrum [\[18\]](#page-5-0). Similarly, carbon polymer systems like *trans*-polyacetylene and polyethylene, show a severe breakdown of the QP picture induced by the EP interaction [\[18,19\]](#page-5-0).

In this work we calculate the electronic and optical properties of *zb*-GaN by including the EP and electronelectron interactions. Our results show a remarkable impact of EP interaction even at zero temperature which corrects the overestimation of the QP gap obtained within the $HSE + G_0W_0$ method. At the same time we prove that only by treating on the same level electron-electron and EP interactions is it possible to obtain an unprecedented agreement with experiment results, both at zero temperature and at finite temperature.

The paper is organized as follows. In Sec. II the EP interaction is briefly discussed in a MBPT framework. In Sec. [III](#page-2-0) the electronic gap and transition energies at highsymmetry points of the Brilloun zone of *zb*-GaN are studied. In Sec. [IV](#page-3-0) we analyze the zero- and finite-temperature optical absorption by including both electron-hole attraction and EP effects by using the BSE.

II. A MANY-BODY PERTURBATION THEORY APPROACH TO THE ELECTRON-PHONON PROBLEM

The total Hamiltonian of the coupled electron-nuclei system *H* can be divided into three parts,

$$
\widehat{H} = \widehat{H}_0 + \widehat{H}_1 + \widehat{H}_2, \tag{1}
$$

where H_0 is the electronic Hamiltonian corresponding to the case where the atoms are frozen at their equilibrium positions \mathbf{R}_0

$$
\widehat{H}_0 = \sum_i \left[-\frac{1}{2} \frac{\partial^2}{\partial \widehat{\mathbf{r}}_i^2} + \widehat{V}_{\text{ion}}[\{\mathbf{R}\}]|_{\mathbf{R} = \mathbf{R}_0}(\mathbf{r}_i) \right] + \widehat{W}_{e-e}.
$$
 (2)

 H_1 and H_2 represent, respectively, the first and second term in the Taylor expansion of H_0 when the atomic positions $\{R\}$ are expanded around the equilibrium positions ${R_0}$. At this stage electron-electron correlations (described by W_{e-e}) are treated at a mean-field level by using the standard density-functional theory (DFT). In DFT $\hat{H}_0 \approx \sum_i [\hat{h}(\mathbf{r}_i)]$ with

$$
\widehat{h}(\mathbf{r}) = -\frac{1}{2} \frac{\partial^2}{\partial \widehat{\mathbf{r}}^2} + \widehat{V}_{\text{scf}}[\{\mathbf{R}\}]|_{\mathbf{R} = \mathbf{R}_0}(\mathbf{r}),\tag{3}
$$

and the derivatives of the electronic effective potential $\hat{V}_{\text{scf}} =$ $V_{\text{ion}} + V_H + V_{xc}$ with respect to the atomic coordinates **R** can be calculated, self-consistently, by using density-functional perturbation theory (DFPT).

Within MBPT [\[18,19\]](#page-5-0) the exact single-particle excitation energies of the total Hamiltonian H are obtained as poles of the Green's function $[26]$ $G_{nk}(\omega)$ that is the solution of the Dyson equation:

$$
G_{n\mathbf{k}}(\omega) = G_{n\mathbf{k}}^{(0)}(\omega)[1 + \Sigma_{n\mathbf{k}}(\omega)G_{n\mathbf{k}}(\omega)].
$$
 (4)

MBPT allows one to calculate self-energy Σ in terms of H_1 and H_2 . We consider now the two lowest-order nonvanishing contributions to Σ written as functionals of the noninteracting Green's function $G_{n\mathbf{k}}^0(\omega)$. The second-order term in the perturbative expansion in powers of H_1 gives the Fan contribution [\[27\]](#page-5-0) to the self-energy:

$$
\Sigma_{n\mathbf{k}}^{\text{Fan}}(\omega, T) = \sum_{n'\neq \lambda} \frac{\left| g_{nn'\mathbf{k}}^{\mathbf{q}\lambda} \right|^2}{N_q} \left[\frac{N_{\mathbf{q}\lambda}(T) + 1 - f_{n'\mathbf{k} - \mathbf{q}}}{\omega - \varepsilon_{n'\mathbf{k} - \mathbf{q}} - \omega_{\mathbf{q}\lambda} - i0^+} + \frac{N_{\mathbf{q}\lambda}(T) + f_{n'\mathbf{k} - \mathbf{q}}}{\omega - \varepsilon_{n'\mathbf{k} - \mathbf{q}} + \omega_{\mathbf{q}\lambda} - i0^+} \right],
$$
 (5)

where $\varepsilon_{n'k-q}$ is Kohn-Sham energy of the *n*'th band at the point **k** − **q** in the Brillouin zone. $\omega_{q\lambda}$ is phonon energy relative to the mode λ and transferred momentum **q**. $N_{q\lambda}(T)$ is the Bose-Einstein distribution function of the phonon mode (**q***,λ*) at temperature *T* and $f_{n'k-q}$ is the occupation number of the bare electronic state at $(n', \mathbf{k} - \mathbf{q})$. $g_{n'n\mathbf{k}}^{\mathbf{q}\lambda}$ is the electron-phonon matrix element [\[19\]](#page-5-0) defined as

$$
g_{nn'\mathbf{k}}^{\mathbf{q}\lambda} = \sum_{s\alpha} (2M_s \omega_{\mathbf{q}\lambda})^{-1/2} e^{i\mathbf{q}\cdot\mathbf{r}_s} \langle n\mathbf{k}| \frac{\partial V_{\text{scf}}(\mathbf{r})}{\partial R_{s\alpha}} |n'\mathbf{k} - \mathbf{q} \rangle
$$

$$
\times \xi_{\alpha}(\mathbf{q}\lambda|s), \qquad (6)
$$

with M_s being the mass of the atom whose position in the unit cell is τ_s . $\xi_\alpha(\mathbf{q}\lambda|s)$ are the phonon polarization vectors. As already pointed out all ingredients of Eq. (6) are calculated by using DFPT.

Similarly to the Fan term, the Debye-Waller (DW) selfenergy arises from the first-order term in the perturbative expansion in powers of H_2 ,

$$
\Sigma_{n\mathbf{k}}^{\text{DW}}(T) = \frac{1}{N_q} \sum_{\mathbf{q}\lambda} \Lambda_{nn\mathbf{k}}^{\mathbf{q}\lambda, -\mathbf{q}\lambda} (2N_{\mathbf{q}\lambda}(T) + 1),\tag{7}
$$

where $\Lambda_{nnk}^{q\lambda,-q\lambda}$ is a second-order EP matrix element [\[19\]](#page-5-0):

$$
\Lambda_{nn'\mathbf{k}}^{\mathbf{q}\lambda,\mathbf{q}'\lambda'} = \frac{1}{2} \sum_{s} \sum_{\alpha,\beta} \frac{\xi_{\alpha}^{*}(\mathbf{q}\lambda|s)\xi_{\beta}(\mathbf{q}'\lambda'|s)}{2M_{s}(\omega_{\mathbf{q}\lambda}\omega_{\mathbf{q}'\lambda'})^{1/2}} \times \langle n\mathbf{k}| \frac{\partial^{2}\widehat{V}_{\text{scf}}(\mathbf{r})}{\partial R_{s\alpha}\partial R_{s\beta}} |n'\mathbf{k} - \mathbf{q} - \mathbf{q}'\rangle.
$$
 (8)

By solving explicitly Eq. (4) the fully interacting Green's function $G_{nk}(\omega, T)$ can be written as

$$
G_{n\mathbf{k}}(\omega,T) = \frac{1}{\omega - \varepsilon_{n\mathbf{k}} - \Sigma_{n\mathbf{k}}^{\text{Fan}}(\omega,T) - \Sigma_{n\mathbf{k}}^{\text{DW}}(T)}.
$$
(9)

The imaginary part of the Green's function $A_{nk}(\omega,T) \equiv$ π^{-1} |Im[$G_{n\mathbf{k}}(\omega,T)$]| gives the electronic spectral function (SF). In the quasiparticle approximation (QPA) the SF is assumed to be well described by a Lorentzian function. Mathematically this means that the self-energy frequency dependence can be expanded linearly around the bare electronic energy. In this case, $E_{nk}(T)$, the pole of $G_{nk}(\omega,T)$ is given by

$$
E_{n\mathbf{k}}(T) = \varepsilon_{n\mathbf{k}} + Z_{n\mathbf{k}}(T) \left[\Sigma_{n\mathbf{k}}^{\text{Fan}}(\varepsilon_{n\mathbf{k}}, T) + \Sigma_{n\mathbf{k}}^{\text{DW}}(T) \right],\tag{10}
$$

with $Z_{n\mathbf{k}}(T) = (1 - \frac{\partial \Sigma_{n\mathbf{k}}^{\text{Fau}}(\omega, T)}{\partial \omega}|_{\omega = \varepsilon_{n\mathbf{k}}})^{-1}$ representing the renormalization factor. The on-the-mass-shell (OMS) approximation represents the static limit of the QPA, obtained by

assuming $\Sigma_{n\mathbf{k}}^{\text{Fan}}(\omega,T) \approx \Sigma_{n\mathbf{k}}^{\text{Fan}}(\omega,T)|_{\omega=\varepsilon_{n\mathbf{k}}}$, which is equivalent to assume $Z_{n\mathbf{k}}(T) = 1$ in the QPA. The Fan and DW selfenergies are complex and real functions, respectively; thus the former gives both an EP-induced energy shift and broadening while the latter contributes only with a constant energy shift. Both self-energies depend explicitly on the temperature *T* via the $N_{\mathbf{q}\lambda}(T)$ factor.

III. RENORMALIZATION OF THE SINGLE-PARTICLE ENERGY LEVELS: THE COMBINED EFFECT OF THE ELECTRON-ELECTRON AND ELECTRON-PHONON INTERACTIONS

zb-GaN is a polar material and, as a consequence, large static EP effects are expected [\[28\]](#page-5-0). As mentioned above, a strong EP coupling might eventually induce the breakdown of the QPA. A clear and simple way to test the QPA validity is to calculate the renormalization factors $Z_{n\mathbf{k}}(T)$. Indeed, by using Eqs. [\(9\)](#page-1-0) and [\(10\)](#page-1-0) it turns out that, within the QPA, the Green's function $G_{n\mathbf{k}}^{\mathbf{QP}}(\omega,T)$ can be written as

$$
G_{n\mathbf{k}}^{\mathbf{QP}}(\omega,T) = \frac{Z_{n\mathbf{k}}(T)}{\omega - E_{n\mathbf{k}}(T)},
$$
\n(11)

with $E_{n\mathbf{k}}(T)$ evaluated by means of Eq. [\(10\)](#page-1-0). When $Z_{n\mathbf{k}} = 1$, the SF reduces to a Lorentzian function with a pole at $\omega =$ $\text{Re}[E_{n\mathbf{k}}(T)]$ and width $\Gamma_{n\mathbf{k}}(T) = \text{Im}[E_{n\mathbf{k}}(T)]$. Thus, the $Z_{n\mathbf{k}}$ values measure the strength of the QP pole; i.e., the QP picture is well motivated when the SF can be well approximated with a single Lorentzian-like function.

In our EP calculations the optimized geometry and the electronic state are obtained by using the PWSCF code [\[29\]](#page-5-0). EP calculations are performed with the YAMBO code [\[30\]](#page-5-0) by using the phonons frequencies and $g_{nn'k}^{\mathbf{q}\lambda}$ matrix elements calculated with PWSCF within DFPT. An energy cutoff on the plane-wave expansion of 80 Ry and a uniform **k**-point sampling of $8 \times 8 \times 8$ are used in the ground-state and DFPT calculations. In order to obtain converged EP self-energies, a large number of **q** points and unoccupied bands are required. Therefore we used 400 bands to evaluate the energy shift (related to Re $[\Sigma(\omega)]$) and 700 randomly generated **q** points for the broadening (linked to the Im $[\Sigma(\omega)]$), respectively. As a result of our simulations the majority of the states that contribute to the optical absorption are well described by Lorentzian-like SF, as shown in Fig. 1. In addition most of the states show values of Z_{nk} very close to 1. For example, the states corresponding to the valence band maximum and the conduction band minimum at the Γ point have $Z_{n\mathbf{k}} = 0.91$ and $Z_{nk} = 0.98$, respectively.

This indicates that, in *zb*-GaN, the OMS approximation is well motivated and most of the weight can be safely assumed to be in one single peak. There is, however, another and more stringent motivation in favor of OMS as far as the calculation of the optical properties is concerned. A Z_{nk} factor smaller than 1 is known to reduce the intensity of the absorption spectrum. At the same time, however, it is well known that such reduction is compensated by the dynamical electron-hole interactions [\[31,32\]](#page-5-0). As far as these dynamical effects are neglected (as is commonly done in the state-of-the-art implementation of the BSE used in this work)

FIG. 1. (Color online) Spectral function of a valence band state. This well represents the general trend of the majority of spectral functions covering the energy range involved in the absorption process, as discussed in the text. The blue line with dots is the calculated SF. This is compared with two Lorentzian functions corresponding to the OMS (red solid line) and to the QPA (black dashed line). Both approximations reproduce the calculated SF quite well and the use of the OMS is, therefore, well motivated.

the OMS assumption of $Z_{nk} = 1$ is well motivated also from a purely theoretical point of view.

In order to describe the impact of the EP interaction on the electronic states we consider the energies corresponding to the lowest transitions at several high-symmetry points. These energies are compared with the experimental results in Table I. DFT is well known to underestimate the band gaps by about \simeq 40%. In fact, our DFT calculation [performed with the local density approximation (LDA)] yields 2*.*231 eV as the band gap of *zb*-GaN. This is clearly less than the experimental value, that is 3.295 eV at 10 K [\[6\]](#page-5-0). Our LDA + G_0W_0 calculations within the plasmon-pole approximation [\[14\]](#page-5-0) open the gap to 3*.*239 eV, which well agrees with the experiment. Still, however, the $LDA + G_0W_0$ largely underestimates the transition energies at *L* and *X*. In our G_0W_0 calculation the energy cutoff in the Fourier expansion of the response function is 13 Ry and 80 bands are included.

This underestimation can be traced back to the local treatment of electron-electron correlation effects in the selfconsistent DFT-LDA calculation. This limitation can be

TABLE I. Lowest transition energies at high-symmetry points in the Brillouin zone of *zb*-GaN. The values obtained from LDA, $LDA + G_0W_0$, HSE + G_0W_0 [\[16\]](#page-5-0), and HSE + G_0W_0 + OMS calculations are compared with the experimental values [\[6\]](#page-5-0). All values are in eV.

			X
LDA	2.231	5.952	6.034
$LDA + G_0W_0$	3.239	7.117	7.105
$HSE + G_0W_0$	3.427	7.707	7.755
$HSE + G_0W_0 + OMS$	3.300	7.517	7.624

overcome by using the AM05 [\[33\]](#page-5-0) functional to calculate the optimized geometry and the HSE [\[15\]](#page-5-0) functional for the start point of the G_0W_0 calculation, as previously reported [\[16\]](#page-5-0).

From Table [I](#page-2-0) it is evident that $HSE + G_0W_0$ opens the band gaps further and overestimates the transition energies at all three high-symmetry points [\[16\]](#page-5-0). However, the combination of EP interaction with HSE $+$ G_0W_0 greatly compensates this overestimation leading to an excellent agreement with the experimental results. Our calculation at the OMS level gives a gap correction of −0*.*127 eV at , which reduces the HSE $+ G_0 W_0$ gap to 3.300 eV, in agreement with the experiment. Similarly, at the L and X points, the EP-induced corrections are −0*.*190 and −0*.*132 eV, resulting in transition energies of 7*.*517 and 7*.*624 eV, again in very good agreement with the experiment. Such moderate EP corrections result from the large cancellation between the Fan and the DW contributions to the total self-energy. For instance, the gap correction −0.127 eV at the Γ point is decomposed into a Fan contribution $(+2.101 \text{ eV})$ and a DW contribution (-2.228 eV) . This large cancellation clearly points to the importance of including, at the same time, both contributions to the total self-energy. Moreover, our result indicates the significance of the EP correction in *zb*-GaN, pointing to similar and potentially important corrections in the whole III-nitrides group of materials.

IV. FINITE-TEMPERATURE OPTICAL ABSORPTION SPECTRA INCLUDING ELECTRON-HOLE EFFECTS

The optical absorption spectrum is defined as the imaginary part of the macroscopic dielectric function $\text{Im}[\epsilon_M(\omega)]$. This can be easily expressed, in the long wavelength limit, as

$$
\epsilon_M(\omega) = 1 - \lim_{\mathbf{q} \to 0} v_0(\mathbf{q}) \int d\mathbf{r} d\mathbf{r}' e^{-i\mathbf{q}(\mathbf{r} - \mathbf{r}')} \overline{\chi}(\mathbf{r}, \mathbf{r}'; \omega), \qquad (12)
$$

with $v_{\mathbf{G}}(\mathbf{q}) = 4\pi/|\mathbf{G} + \mathbf{q}|^2$ being the Coulomb potential and $\bar{\chi}$ (**r**; **r**[']; ω) the two-point polarizability. The equation of motion for the polarizability [\[13\]](#page-5-0) can be rewritten by introducing a single-particle basis set $({\phi_{n,k}})$ to expand the density operator. This is equivalent to define the electron-hole probability functions $\Phi_{\mathbf{K}}(\mathbf{r}) = \phi_{c\mathbf{k}}(\mathbf{r})\phi_{v\mathbf{k}}^*(\mathbf{r})$. Here **K** represents the general conduction-valence pairs, $\mathbf{K} = (c, v, \mathbf{k})$. In this basis $\overline{\chi}$ is

$$
\overline{\chi}(\mathbf{r}; \mathbf{r}'; \omega) = -\left(\frac{i}{\Omega N}\right) \sum_{\mathbf{K}_1, \mathbf{K}_2} \Phi_{\mathbf{K}_1}^*(\mathbf{r}) L_{\mathbf{K}_1 \mathbf{K}_2}(\omega) \Phi_{\mathbf{K}_2}(\mathbf{r}').
$$
\n(13)

Equation (13) introduces the electron-hole Green's function $L_{\mathbf{K}_1\mathbf{K}_2}(\omega)$ that satisfies the BSE equation [\[13\]](#page-5-0):

$$
L_{\mathbf{K}_1\mathbf{K}_2}(\omega) = L_{\mathbf{K}_1\mathbf{K}_2}^0(\omega) + L_{\mathbf{K}_1\mathbf{K}_3}^0(\omega) \Xi_{\mathbf{K}_3\mathbf{K}_4}(\omega) L_{\mathbf{K}_4\mathbf{K}_2}(\omega).
$$
\n(14)

The Bethe-Salpeter kernel Ξ is defined as $\Xi = -iV + iW$, with *V* and *W* being the exchange and the screened Coulomb interactions, respectively. $L_{\mathbf{K}_1\mathbf{K}_2}^0(\omega)$, in Eq. (14), is the free electron-hole Green's function, defined in Eq. (15).

As previously described by Marini [\[25\]](#page-5-0) it is possible to include the finite-temperature effect in the BSE by using as

FIG. 2. (Color online) Theoretical and experimental absorption spectra of zb -GaN at $T = 10$ K. The spectrum obtained by solving the BSE including both HSE $+$ G_0W_0 and EP corrections (thick black line) is in excellent agreement with the experimental results [\[6\]](#page-5-0) (bold dashed green line). Compared to the state-of-the-art calculation of Benedict and Shirley [\[12\]](#page-5-0) (dashed red line), the agreement is largely improved. A blue line shows the BSE spectrum only with the $HSE + G_0W_0$ correction.

reference the single-particle energies and the temperaturedependent and complex QP energies $E_{n\mathbf{k}}(T)$. In this way the free electron-hole Green's function $L^0_{\mathbf{K}_1\mathbf{K}_2}(\omega,T)$ depends explicitly on the temperature:

$$
L_{\mathbf{K}_{1}\mathbf{K}_{2}}^{0}(\omega, T) = i \left[\frac{f_{c_{1}\mathbf{k}_{1}} - f_{v_{1}\mathbf{k}_{1}}}{\omega - E_{c_{1}\mathbf{k}_{1}}(T) + E_{v_{1}\mathbf{k}_{1}}(T) + i0^{+}} \right] \delta_{\mathbf{K}_{1}\mathbf{K}_{2}}.
$$
\n(15)

Equation (15) ensures that also the fully interacting electronhole Green's function and the absorption spectra depend explicitly on the temperature, thanks to Eqs. (12) and (13).

In order to solve the BSE we adopt two standard approximations. The first is the Tamm-Dancoff approximation which corresponds to neglecting the coupling between the resonant and the antiresonant part of the BSE kernel. The second is the use of the statically screened electron-hole potential *W*.

In Fig. 2 we show the calculated absorption spectrum. In addition to the G_0W_0 corrections, as described in Sec. [III,](#page-2-0) we include EP effects. To obtain a converged absorption spectra we employed the random-integration method (RIM) [\[30\]](#page-5-0) by selecting around 30 000 random **k** points in the whole Brillouin zone. The energy cutoffs for the exchange and screened Coulomb interactions are set to 60 and 3 Ry, respectively. The artificial damping parameter 0^+ in Eq. (15), which is introduced only for numerical reasons, is 10 meV. The resulting spectrum (thick black line) is compared to the previous calculation of Benedict and Shirley [\[12\]](#page-5-0) (dashed red line) which is performed in a LDA basis without including the EP interaction. The BSE spectrum, obtained by including only the HSE + G_0W_0 correction, is also shown (blue line).

We notice, indeed, that, compared to the Benedict's calculation, the calculated position and width of the main peak are in very good agreement with the experimental spectrum at $T = 10$ K $[6]$ (bold dashed green line). This pronounced

FIG. 3. (Color online) Absorption spectra of zb -GaN at $T = 0$, 300, and 600 K. Red circles are experimental results at 10 and 295 K [\[6\]](#page-5-0).

peak, located at around 7*.*62 eV in the experiment, is due to interband transitions in a region of the Brillouin zone near the *X* point. These transitions extend over regions where the valence and conduction bands are parallel with a similar energy distance [\[6\]](#page-5-0). Therefore the present improvement is largely due to the correction from $HSE + G_0W_0$ that induces a large stretching of the bands. In the BSE spectrum only with $HSE + G_0W_0$, the peak position is clearly shifted to higher energies and it is much less energetically wide.

Indeed, one of the most significant effects of the EP interaction is the broadening of the QP states that fully dictates the smooth energy dependence of the absorption spectrum. We use a very small artificial damping (10 meV) in Eq. [\(15\)](#page-3-0) that leads, when the EP interaction is neglected, to a very spiky absorption spectrum. To avoid this unphysical behavior an arbitrary 200 meV broadening is chosen in the previous BSE calculations. In the present case, instead, the effect of the EP interaction correctly describes both the main peak and the steep absorption edge.

Finally we investigate how the optical spectrum evolves as the temperature is increased. In Fig. 3 we show the calculated absorption spectra at $T = 0$, 300, and 600 K. In the first two cases the numerical simulation is compared with the available experimental results [\[6\]](#page-5-0). The agreement is fairly good and confirms that the present approach is able to correctly capture the finite-temperature effects. The energy shifts of the first excitation peaks due to electron-hole transitions occurring at Γ , *L*, and *X* are experimentally -63 , −100, and −110 meV, respectively, when the temperature is increased from 10 to 295 K [\[6\]](#page-5-0). Our calculations give -83 , −144, and −106 meV, respectively, which show a quantitative agreement with experiment. Also the general trend observed experimentally that the peak shift is larger at critical points with higher transition energy is reproduced.

On the other hand, from Fig. 3 we deduce that the broadening of the main peak at the *X* point is slightly overestimated at $T = 300$ K compared to the experiment. In order to understand the source of this overestimation we notice that, in the QP picture, the EP-induced broadening of the valence band top and the conduction band bottom at the *X* point is 121.8 and 12.1 meV, respectively, at $T = 300$ K. In the independent particle approximation (where $L_{\mathbf{K}_1\mathbf{K}_2} \approx$ $L_{\mathbf{K}_1\mathbf{K}_2}^0 \delta_{\mathbf{K}_1\mathbf{K}_2}$) the electron-hole broadening is simply the sum of the two. Now, as also in the case where electron-hole attraction is included, the main absorption peak originates from the lowest transitions concentrated around *X*. Thus we deduce that the overestimation is due to too large broadening of the underlying QP states.

In the experimental work by Logothetidis *et al.* [\[34\]](#page-5-0) the broadening at the main absorption peak is described by a phenomenological model,

$$
\Gamma(T) = \Gamma_1 + \Gamma_0 \left[1 + \frac{2}{\exp(\Theta/T) - 1} \right],\tag{16}
$$

with $\Gamma_1 = 27$ meV, $\Gamma_0 = 44$ meV, and $\Theta = 522$ K. The first term in Γ_1 is ascribed to a temperature-independent mechanism, such as surface scattering; thus we set it to 0 to be compared with our theoretical results. Equation (16), indeed, predicts $\Gamma(T = 300 \text{ K}) \sim 62.7 \text{ meV}$ that is half of the value of our results.

A reasonable explanation of this deviation is in the underlying unperturbed band structure. The band curvature has a large impact on the EP-induced broadening through the denominator of Eq. [\(5\)](#page-1-0), especially by the dominant intraband-scattering terms with $\omega = \varepsilon_{n\mathbf{k}}$, $n' = n$, and small **q**. Since our EP self-energies are calculated on top of Kohn-Sham states from the LDA, the resulted band widths are too small. As shown in previous calculations [\[16\]](#page-5-0) the valence band at the *X* point is characterized by a large curvature that is underestimated by the LDA calculations. We expect that the broadening would be improved by EP calculations performed on top of the $HSE + G_0W_0$ band structure, but it is prohibitively expensive from the computational point of view. Nevertheless our approach, based on the LDA, gives excellent results especially at the low temperature.

V. CONCLUSION

In this work we study the zero- and finite-temperature electronic and optical properties of *zb*-GaN. The effect of EP interaction, treated in a fully dynamical approach based on the MBPT, shows that the simple on-the-mass-shell approximation to the QP energies and widths is well motivated for the low-energy states involved in the absorption spectrum.

By including, in an *ab initio* manner, the combined effect of the electron-electron interaction and the EP interaction we obtain an excellent agreement with the experimental fundamental band gaps.

The solution of the BSE calculated on top of the $HSE + G_0W_0$ band structure including EP effects leads to an excellent agreement also for the optical absorption spectrum measured on high phase-purity samples. Both the position and the broadening of the most intense absorption peak are correctly reproduced in the low-temperature regime. In the room-temperature case, instead, the red-shift of the main peak position is well described while the broadening is slightly overestimated. Despite this overestimation the present results still represent a major improvement with respect to the state-of-the-art simulations.

Our results clearly point to the crucial importance of including at the same time electron-electron and electronphonon correlation effects for a comprehensive and quantitative understanding of the electronic and optical properties of group III nitrides.
