Solar cells based on a light absorbing layer of the organometal halide perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$ have recently surpassed 15% conversion efficiency, though how these materials work remains largely unknown. We analyze the electronic structure and optical properties within the quasiparticle self-consistent GW approximation. While this compound bears some similarity to conventional sp semiconductors, it also displays unique features. Quasiparticle self-consistency is essential for an accurate description of the band structure: Band gaps are much larger than what is predicted by the local-density approximation (LDA) or GW based on the LDA. Valence band dispersions are modified in a very unusual manner. In addition, spin-orbit coupling strongly modifies the band structure and gives rise to unconventional dispersion relations and a Dresselhaus splitting at the band edges. The average hole mass is small, which partially accounts for the long diffusion lengths observed. The surface ionization potential (work function) is calculated to be 5.7 eV with respect to the vacuum level, explaining efficient carrier transfer to TiO_2 and Au electrical contacts.

I. INTRODUCTION

One of the most promising third-generation photovoltaic technologies is based on metal-organic halide perovskites [1–10]. The materials physics of inorganic (ABX_3) perovskites is well developed; however, the replacement of the inorganic cation by an isoelectronic organic moiety provides an opportunity for tuning the chemical bonding and optical response. We apply a range of electronic structure techniques to calculate and predict the band structure of hybrid perovskites, demonstrating how the rich and unusual physics of these materials accounts for their widely reported success as absorber layers in solar cells.

It has been established that similar to traditional dielectric perovskites, these hybrid analogs have a range of accessible polymorphs with variations in the tilting and rotation of the BX_6 polyhedra in the lattice [11]. A large family of hybrid perovskites have been reported with inorganic networks ranging from one to three dimensions [12–15]. However, the methylammonium (MA) cation (i.e., CH_3NH_3^+) has been widely applied, resulting in the highest-performance perovskite-structured solar absorbers [2,3]. The polar MA cation can also be replaced by ammonium (NH_4^+) as a smaller nonpolar analog.

A large number of density-functional theory (DFT) studies have been reported that examine the electronic properties of hybrid perovskites [15–22]. The majority neglect spin-orbit coupling [15–20], while a relativistic treatment based on local or semilocal exchange-correlation functionals results in severe band gap underestimations [21,22]. Both approaches are insufficient to describe the complexity of the electronic

structure of these hybrid semiconductors, with large errors expected in predicted properties such as carrier effective mass and dielectric function.

An alternative approach is the GW formalism, which can be used to correct errors in the one-electron Kohn-Sham eigenvalues within a many-body quasiparticle framework. Here we employ quasiparticle self-consistent GW theory [23] (QSGW) to study the electronic structure of $\text{CH}_3\text{NH}_3\text{PbI}_3$ and NH_4PbI_3 , including the effect of spin-orbit coupling (SOC) $\lambda\mathbf{L}\cdot\mathbf{S}$, on the both the kinetic energy and electron self-energy Σ (see the Appendix). As Pb and I are heavy elements, SOC is large and has a major effect on spectral properties. SOC predominantly modifies the kinetic energy; however, in this case relativistic effects are large enough to induce a modest reduction in Σ as well, in contrast to the vast majority of semiconductors, e.g., elemental Sn. As a consequence of large relativistic effects, the conduction and valence bands near the band extrema deviate strongly from parabolic behavior. Effective masses are no longer constant, but depend on doping, temperature, and the property being measured. Average effective masses are nevertheless light, and the dielectric constants large, accounting for the long diffusion lengths that have been recently reported [7,9].

In many respects these perovskites are similar to conventional sp semiconductors: Conduction and valence bands near the Fermi level have sp character, and local- (and semilocal-) density approximation (LDA) to DFT systematically underestimate the band gap E_G because they do not include spatial nonlocality in the exchange-correlation potential. There are other significant points of departure: In sharp contrast to tetrahedral semiconductors, DFT also poorly describes valence band dispersions. This surprising result, which we discuss further below, indicates that the usual explanations invoked to account for deficiencies in DFT's description of semiconductors are not sufficient here.

*a.walsh@bath.ac.uk

†mark.van_schilfgaarde@kcl.ac.uk

We show that there is a strong feedback between dielectric response and quasiparticle levels, as occurs for CuInSe_2 [24]. Thus self-consistency in GW is essential: E_G calculated from $G^{\text{LDA}}W^{\text{LDA}}$, i.e., LDA as the starting Hamiltonian, picks up only a little better than half the gap correction to the LDA. Moreover, the QSGW and LDA valence bands, which the LDA describes reasonably well in tetrahedral semiconductors, are significantly different. These differences underscore the limitations of density-functional-based approaches (LDA, hybrid functionals, or $G^{\text{LDA}}W^{\text{LDA}}$) in describing the properties of these materials. QSGW does not depend on the LDA: Self-consistency renders it more reliable and universally applicable than other forms of GW , which will be important for *in silico* design of hybrid systems. Moreover, QSGW can determine some ground-state properties, e.g., the charge density and electric field gradient. Errors in QSGW tend to be small and highly systematic; most notably there is a tendency to slightly overestimate semiconductor band gaps. Limited data is available for organic-inorganic halide perovskites, but at least for $\text{CH}_3\text{NH}_3\text{PbI}_3$ the universal tendency found in other materials is consistent with recent measurements.

Finally, based on the work function calculated for $\text{CH}_3\text{NH}_3\text{PbI}_3$ within DFT (including an estimate for quasiparticle corrections) we show that band alignments are consistent with efficient electron transfer to TiO_2 and Au electrical contacts.

II. RESULTS

Optimization of the crystal structures of NH_4PbI_3 and $\text{CH}_3\text{NH}_3\text{PbI}_3$ have recently been reported [18] in DFT using the PBEsol [25] exchange-correlation functional. Atomic forces were converged to within 5 meV/Å, and the bond lengths are in good agreement with experiment. The representative $\langle 100 \rangle$ configuration of MA is considered here. Lattice vectors of these perovskites are approximately cubic ($a = 6.29$ and 6.21 Å for the MA and NH_4 perovskites, respectively), with small distortions of the simple cubic ones. The valence band maximum and conduction band minimum falls close to a zone boundary point, the analog of the R point ($\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$) in cubic symmetry. We denote this point as R in the remainder of the paper.

A. Band structure

The quasiparticle (QP) band structures for $\text{CH}_3\text{NH}_3\text{PbI}_3$ and NH_4PbI_3 , with colors denoting the orbital character of the states, are shown in Fig. 1. The ions within the inorganic (PbI_3)⁻ cage have formal electronic configurations of Pb: $5d^{10}6s^26p^0$ and I: $5p^6$. As can be seen from the color coding, the valence band maximum consists of approximately 70% I $5p$ and 25% Pb $6s$ (the Pb $6s$ forms a band centered around -8 eV), while the conduction band consists of a mixture of Pb $6p$ and other orbitals. The molecular units CH_3NH_3 and NH_4 form σ bonds deep in the valence band. They are essentially dispersionless: They do not hybridize with the cage until energies exceed $E_F + 5$ eV. Thus their interaction with the host is largely electrostatic and structural; they provide charge compensation to the PbI_3 ⁻ cage.

FIG. 1. (Color online) QSGW band structure for $\text{CH}_3\text{NH}_3\text{PbI}_3$ (left) and NH_4PbI_3 (right). Zero denotes valence band maximum. Bands are colored according to their orbital character: green depicts I $5p$, red depicts Pb $6p$, and blue depicts Pb $6s$. Points denoted M and R are zone-boundary points close to $(\frac{1}{2}, \frac{1}{2}, 0)$ and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$, respectively. The valence band maximum and conduction band minimum are shifted slightly from R as a consequence of the $\mathbf{L} \cdot \mathbf{S}$ coupling. Valence bands near -2 eV (conduction bands near $+3$ eV) are almost purely green (red) showing that they consist largely of I $5p$ (Pb $6p$) character. Bands nearer the gap are darker as a result of intermixing with other states. Light-gray dashed lines show corresponding bands in the LDA. The dispersionless state near -5 eV corresponds to a molecular level of methylammonium. In QSGW this state is pushed down to -7.7 eV. The dispersion of the highest valence bands is very poorly described by the LDA, as described in the text.

The results presented in Table I demonstrate the various contributions to the band energies around the fundamental gap. The contribution from SOC (~ 1 eV), is extraordinarily large, of the order of the gap itself; so large that screening is enhanced. As a result there is a smaller, but nonetheless non-negligible contribution of SOC to the electron self-energy ($\Sigma = iGW$), apparent from the difference between “SO(T)” and “SO(Σ).” Furthermore, Table I emphasizes the importance of the feedback between W and QP when calculating the band structure of these systems. The “ GW^0 ” gap is based on a perturbation of the LDA gap; and it is significantly smaller. Because the LDA gap is too small, W is overscreened, and GW underestimated. The role of feedback is important in other semiconductors: It is particularly strong in InN [26] and Cu(In,Ga)Se_2 . In the latter case the interplay between W and E_G was shown explicitly by comparing functionals that did or did not include the dependence of W on band structure [24]. W and the gap correction is not a function of the fundamental gap alone: All the bands (including valence band dispersions) shift in a nontrivial manner. To reliably determine the electronic structure including the fundamental gap, self-consistency is essential.

TABLE I. Fundamental band gaps (in eV) of $\text{CH}_3\text{NH}_3\text{PbI}_3$ and NH_4PbI_3 calculated at varying levels of approximation. Top rows show DFT results using PBEsol (reported in Ref. [18]) and the Barth-Hedin LDA functional. First columns show that semilocal and local functionals generate similar gaps. $\lambda\mathbf{L}\cdot\mathbf{S}$ (column “LDA+SO”) strongly reduces the gap. GW gaps are shown without spin-orbit coupling ($\text{SO} = 0$), with $\lambda\mathbf{L}\cdot\mathbf{S}$ added to a fixed potential, modifying the kinetic energy only [$\text{SO}(T)$], and included in the QSGW self-consistency cycle [$\text{SO}(\Sigma)$]. Column “ GW^0 ” is similar to $\text{SO}(\Sigma)$ but G and W are generated from the LDA. (In this calculation the full Σ matrix was generated, not just the diagonal part as is customary. A Z factor of 1 was used to take partial account of self-consistency, which brings the gap in better agreement with the QSGW result; see Appendix A in Ref. [30]). An error of order 0.1 eV might be associated with the treatment of SOC (see the Appendix). Room temperature (RT) band gap data is only available for $\text{NH}_3\text{CH}_3\text{PbI}_3$ [27].

	DFT			Expt. [27]
	PBEsol	LDA	LDA+SO	
$\text{NH}_3\text{CH}_3\text{PbI}_3$	1.38	1.46	0.53	1.61 (RT)
NH_4PbI_3	1.20	1.13	0.09	
	QSGW			
	$\text{SO} = 0$	$\text{SO}(T)$	$\text{SO}(\Sigma)$	GW^0
$\text{NH}_3\text{CH}_3\text{PbI}_3$	2.73	1.78	1.67	1.27
NH_4PbI_3	2.30	1.36	1.38	0.76

Recent measurements place the room temperature band gap of $\text{NH}_3\text{CH}_3\text{PbI}_3$ at 1.61 eV [27], which falls slightly below the QSGW result. Some tendency for QSGW to overestimate gaps is expected. In any case theory and experiment cannot be compared to better than 0.1 eV resolution for several reasons. There are small issues with k -point convergence [28], and with the shape of local wave functions determined by solving a scalar relativistic equation rather than the Dirac equation (see the Appendix). On the experimental side there may be some temperature dependence of the gap given the structural flexibility of the material [29]; this has yet to be explored.

Figure 1 also shows the LDA energy bands. Remarkably, the LDA badly underestimates not only the gap but poorly describes the dispersion in the valence bands. The tendency for LDA to underestimate band gaps is traditionally associated with the energy cost for an excited electron-hole pair. The exchange-correlation potential should distinguish between a neutral excitation (e.g., a hole shifting from one k point in the valence band to another) and one where charge is separated (excitation of an electron-hole pair). Such a distinction is problematic for a local potential, which is by necessity the same for all electrons. Such an error is seen in the present case, as the LDA gap is too small. As Fig. 1 clearly shows, LDA and QSGW valence bands also deviate strongly from one another. Note, in particular, the states at R between 0 and -2 eV. This behavior allows us to deduce that the hopping matrix elements between I $5p$ (and to some extent Pb $6s$) states are poorly described by the LDA.

B. Carrier effective mass

Typically light hole masses are too small in the LDA because, according to $k\cdot p$ theory, $m_v^* \propto E_G/V^2$; V is a matrix element of the gradient operator between the conduction and valence bands. m_v^* is expected to be too small because E_G is underestimated; indeed for traditional narrow gap tetrahedral semiconductors, the proportionality between m_v^* and E_G is reasonably well obeyed. The LDA predicts the light hole mass to be too small, while other masses (which do not couple to the nearest conduction band) are reasonably described. For example, GaAs has a gap similar to $\text{CH}_3\text{NH}_3\text{PbI}_3$, and LDA underestimates it by a comparable amount (~ 1 eV). Following expectations, the LDA underestimates the light hole mass in GaAs by a factor of ~ 3 . But for $\text{CH}_3\text{NH}_3\text{PbI}_3$ the situation is reversed: the LDA *overestimates* m_v^* even while it severely underestimates E_G . For NH_4PbI_3 the LDA and QSGW masses are comparable, but only because the LDA gap is very small.

Spin-orbit coupling greatly complicates both valence and conduction bands within $k_B T$ of the band edges. We focus on the two valence bands of $\text{NH}_3\text{CH}_3\text{PbI}_3$, as these are the ones that govern transport in hole-based devices. As these two bands approach the R point, they must merge to the same value by symmetry. However, they approach the R point with a linear dispersion in some directions; as a consequence the dispersions in the upper and lower bands are nonanalytic. The upper band is maximum in some directions but increases with a linear slope in the $\pm[11\bar{2}]$ direction. Two maxima form near $R \pm 0.005 \times [11\bar{2}]$ [Fig. 2(a)], arising from Dresselhaus spin-orbit coupling,

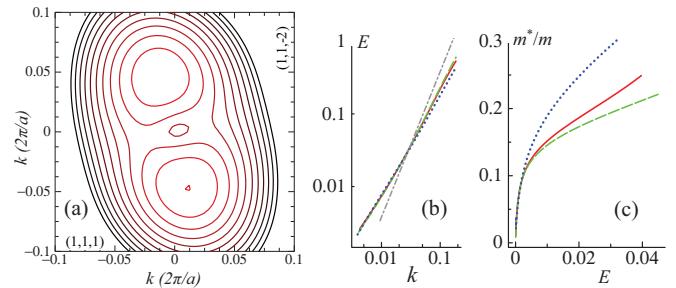

FIG. 2. (Color online) Left: constant energy contours in the $(1\bar{1}0)$ plane for the upper valence band of $\text{CH}_3\text{NH}_3\text{PbI}_3$. The origin corresponds to the R point and $[111]$ and $[11\bar{2}]$ are the horizontal and vertical axes of k . Energy contours are in increments of 2.5 meV, so that the outermost contour corresponds approximately to RT. Corresponding contours in the (111) plane (not shown) appear similar. Valence bands have two maximal points near $R \pm 0.005 [11\bar{2}]$. At low temperature and low doping, ($E_F < 5$ meV) the two extrema act as independent centers with approximately spherical effective masses. At high doping ($E_F > 20$ meV) or high temperature, holes effectively see a single band maximum with roughly elliptical constant energy surfaces. Panels (b) and (c) show energy $E_v(k) \equiv E(R) - E(k)$ for the lower valence band. This band has a single maximum at R , with approximately spherical dispersion. Panel (b) shows $E_v(k)$, on a log-log scale in the $[1\bar{1}0]$, $[111]$, and $[11\bar{2}]$ directions as red solid, green dashed, and blue dotted lines, respectively. For comparison a parabolic band with effective mass $0.1m$ is shown as a gray dot-dashed line. Panel (c) plots $\hbar^2 k^2 / (2m E_v)$ against E_v , which may be taken as a definition of the effective mass (see text). E_v is in eV; k is in units $2\pi/a$.

which is even more pronounced in the lower conduction band. The lower band has a single maximum at R , and its constant energy surfaces deviate only modestly from spheres for k near R [Fig. 2(b)]. Yet, the right panels of Fig. 2 show $E_v(k) \equiv E(R) - E(k)$ deviates markedly from a parabolic dispersion. This has important consequences for the device behavior of this material. Figure 2(c) shows that, provided $E_v > 10$ meV, the band dispersion can be expressed approximately as a k -dependent mass:

$$\frac{\hbar^2 k^2}{2m} = m^*(k)E_v(k), \quad \frac{m^*(k)}{m} = m_0[1 + \alpha E_v(k)] \quad (1)$$

with $m_0^* \sim 0.12$ and α independent of $|\mathbf{k}|$ but dependent on orientation. For E_v large enough, the upper valence band can also be described by an effective mass of roughly the same size. The lower conduction band exhibits a similar behavior, with $m_0^* \sim 0.15$. The small masses explain how these materials can exhibit high mobility and long diffusion lengths. Bands of NH_4PbI_3 differ in important details from $\text{NH}_3\text{CH}_3\text{PbI}_3$ (the influence of SOC is less pronounced), but the basic structure is similar. Both the band gap and effective masses are reduced relative to $\text{NH}_3\text{CH}_3\text{PbI}_3$, as can be seen directly by inspecting Fig. 1.

C. Optical and dielectric response

It is known that these compounds strongly absorb visible light. We confirm this through a random phase approximation (RPA) calculation of $\alpha(\omega)$ from the imaginary part of the macroscopic dielectric function $\epsilon_M(\omega) = [\epsilon_{G,G'=0}^{-1}(\mathbf{q} \rightarrow 0, \omega)]^{-1}$. As Fig. 3 shows, α is somewhat smaller than—but comparable to—that of GaAs. This explains why very thin layers of the hybrid perovskites have been found to give high photovoltaic efficiencies. Indeed combined with the low carrier effective masses, the resulting electron-hole diffusion lengths exceed the typical film thickness.

Some static (ϵ_0) and high-frequency (ϵ_∞) dielectric constants are shown in Table II. These values are unusually sensitive to the k -point sampling density and require dense meshes for convergence. Those calculated by density-functional perturbation theory (e.g., PBEsol) leave out SOC and thus get

FIG. 3. (Color online) Optical absorption spectrum calculated within the RPA from the QSGW potential, for $\text{CH}_3\text{NH}_3\text{PbI}_3$ and NH_4PbI_3 . The absorption is smaller than, but comparable to that of GaAs, shown for comparison. Note that similar measurements have been reported in Ref. [31].

TABLE II. Dielectric constants (isotropic average of the tensor) and band gaps (eV), calculated in density-functional perturbation theory without SOC (from Ref. [18]), and in the RPA with SOC.

	PBEsol			QSGW	
	E_G	ϵ_0	ϵ_∞	E_G	ϵ_∞
$\text{NH}_3\text{CH}_3\text{PbI}_3$	1.38	25.7	6.1	1.67	4.5
NH_4PbI_3	1.20	18.4	6.5	1.38	5.0

fortuitously good band gaps. As a result ϵ_∞ is not so different from the QSGW case (which includes SOC). Contributions to ϵ_0 from lattice polarization are significantly larger than seen in typical tetrahedral semiconductors (compare ϵ_0 to ϵ_∞). For $\text{NH}_3\text{CH}_3\text{PbI}_3$, the average value of the static dielectric constant, including QP corrections from Table II, of 24.1, is in very good agreement with permittivity measurements of 23.3 [32]. These values exclude contributions from orientational disorder of the methylammonium ions, which is the subject of further study [33].

D. Surface ionization potential

In order to place the electronic bands on an absolute energy scale, we have aligned the quasiparticle energies with respect to the vacuum level of a nonpolar (110) termination of the perovskite, generated using METADISE [34]. We take the Pb 1s core level as an energy reference and use a planar average of the electrostatic potential following the standard procedure [35,36]. The slab model consisted of four perovskite layers with the dipole of the methylammonium cations aligned parallel to the surface termination, which ensure no macroscopic electric field. The resulting ionization potential is 5.7 eV (5.9 eV from LDA, which is corrected by the GW^0 self-energy), with a corresponding electron affinity of 4.0 eV. These values are in good agreement with initial photoemission measurements of thin films (5.4 eV) and explain the success of TiO_2 (electron) and Au (hole) contacts [37].

III. CONCLUSION

We have explored the electronic structure of two key hybrid halide perovskites. Relativistic and many-body corrections are shown to be essential for a quantitative description of the bulk properties important for photovoltaics: band gap, band dispersion, effective mass and dielectric response. These organic-inorganic materials display quantum-mechanical behavior atypical of traditional semiconductors, which begins to explain their remarkable performance in mesoporous and thin-film solar cells.

APPENDIX: SIMPLIFIED TREATMENT OF SPIN-ORBIT COUPLING IN QSGW

Aryasetiwan and Biermann [38] developed a formalism for GW with spin-dependent interactions. Rather than proceed with a completely noncollinear treatment, we take advantage of the fact that $\lambda \mathbf{L} \cdot \mathbf{S}$ is relatively small, and moreover that the noncollinear part of the eigenfunctions is unimportant for these semiconductors. We present a simplified treatment that generates results essentially as good as adding $\lambda \mathbf{L} \cdot \mathbf{S}$ nonperturbatively to the scalar Dirac Hamiltonian for M - PbI_3 compounds.

Partitioning $\mathbf{L} \cdot \mathbf{S}$ into components, the noninteracting QSGW Hamiltonian reads

$$H_0 = H_0(\lambda = 0) + \lambda L^z S^z + \lambda(\mathbf{L}^+ \cdot \mathbf{S}^- + \mathbf{L}^- \cdot \mathbf{S}^+).$$

The first two terms are spin diagonal and can be diagonalized nonperturbatively in the same manner as $H_0(\lambda = 0)$. The eigenvalues ϵ_i and eigenfunctions ψ_i contain the $L^z S^z$ portion of $\mathbf{L} \cdot \mathbf{S}$, keeping ψ_i spin diagonal. The latter two terms, when treated exactly, further shift the ϵ_i and also introduce spin off-diagonal parts to the ψ_i . We allow the former but omit the latter.

The lowest order of correction to the eigenvalues is second order and we follow the spirit of second-order perturbation theory. Let δ_{ij} be the initial splitting in ϵ_i and ϵ_j , $\Delta_{ij} = |\epsilon_i - \epsilon_j|/2$. If H_{ij}^{+-} couples i and j , Δ_{ij} increases by $\delta\Delta_{ij} = |H_{ij}^{+-}|^2/|\epsilon_i - \epsilon_j|$, in lowest order.

Second-order perturbation theory can be problematic when $\epsilon_i \rightarrow \epsilon_j$. We instead obtain $\delta\Delta_{ij}$ from

$$\delta\Delta_{ij} = \sqrt{\Delta_{ij}^2 + |H_{ij}^{+-}|^2} - |\Delta_{ij}|.$$

This expression is exact if i and j are isolated from the rest of the system. The final expression (the net shift for each ϵ_i is obtained by summing over each ij pair) is nevertheless correct

only to second order because terms involving three or more states are not included.

We carefully tested our quasiperturbative approach in the LDA or LDA + U context for a wide range of materials, e.g., Fe, Sn, Au, GdN, Pu, and the perovskites addressed in this paper. In all cases except Pu ($Z = 94$) the difference between the perturbation expression resulted in ϵ_i very close to $\mathbf{L} \cdot \mathbf{S}$ treated nonperturbatively. For $\text{CH}_3\text{NH}_3\text{PbI}_3$, for example, E_G changed by less than 0.01 eV. Self-consistency carried through with both approaches generate a slight difference in density, but no significant difference in the ϵ_i .

Tests of the adequacy of the quasiperturbative $\mathbf{L} \cdot \mathbf{S}$ in the QSGW were performed as follows: Self-consistency was reached with $\mathbf{L} \cdot \mathbf{S}$ included quasiperturbatively, and for a given Σ , the quasiparticle levels with $\mathbf{L} \cdot \mathbf{S}$ calculated nonperturbatively were compared to the perturbative treatment. As in the LDA case, negligible differences were found for all compounds studied except for Pu, where modest differences were found. As in the LDA case, the nonperturbative treatment generated a slight change in density. Since the ϵ_i are reliably determined, it is unlikely that a better treatment of $\mathbf{L} \cdot \mathbf{S}$ (noncollinear eigenfunctions) will further affect Σ appreciably in these compounds. On the other hand, fully relativistic treatment might affect H_0 a little, since the relativistic radial functions vary as r^γ for small r , where $\gamma^2 = \kappa^2 - (2Z/c)^2$, κ playing the role of the l quantum number. γ reduces the scalar relativistic case only when $c \rightarrow \infty$. A better treatment of the small- r behavior of the partial waves modifies spin-orbit splitting of the p levels for Pb by about 10%, which is not included here. An appreciable effect of $\mathbf{L} \cdot \mathbf{S}$ on Σ is observed only for compounds with large- Z constituents. For semiconductors as heavy as Sn ($Z = 50$), and for metals as heavy as Au ($Z = 79$), the effect of $\mathbf{L} \cdot \mathbf{S}$ on Σ appears to be very small. But for the iodide perovskites studied here, $\mathbf{L} \cdot \mathbf{S}$ has a noticeable effect on Σ (Table I) because of the interplay between E_G and ϵ present in semiconductors but not in metals.

- [28] Careful convergence checks were made of the eigenfunction and product basis. A $4 \times 4 \times 4$ k mesh was used for the M -PbI₃ compounds. A one-shot calculation with a $6 \times 6 \times 6$ mesh as perturbation to the QSGW result showed that the k -converged gap is about 0.1 eV larger than what is reported in Table I.
