The quantum phase diagram of disordered electron systems as a function of the concentration of magnetic impurities n_m and the local exchange coupling *J* is studied in the dilute limit. We take into account the Anderson localization of the electrons by a nonperturbative numerical treatment of the disorder potential. The competition between Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction *J*_{RKKY} and the Kondo effect, as governed by the temperature scale T_K , is known to give rise to a rich magnetic quantum phase diagram, the Doniach diagram. Our numerical calculations show that in a disordered system both the Kondo temperature T_K and J_{RKKY} as well as their ratio J_{RKKY}/T_K is widely distributed. However, we find a sharp cutoff of that distribution, which allows us to define a critical density of magnetic impurities *nc* below which Kondo screening wins at all sites of the system above a critical coupling *Jc*, forming the Kondo phase [see Fig. 3(b)]. As disorder is increased, *Jc* increases and a spin coupled phase is found to grow at the expense of the Kondo phase. From these distribution functions we derive the magnetic susceptibility which show anomalous power-law behavior. In the Kondo phase that power is determined by the wide distribution of the Kondo temperature, while in the spin coupled phase it is governed by the distribution of J_{RKKY} . At low densities and small $J < J_c$ we identify a local-moment phase (LM). We also report results on a honeycomb lattice, graphene, where we find that the spin coupled phase is more stable against Kondo screening, but is more easily destroyed by disorder into a LM phase.

I. INTRODUCTION

Phenomena which emerge from the interplay of strong correlations and disorder remain a challenge for condensedmatter theory. Spin correlations and disorder effects are however relevant for a wide range of materials, including doped semiconductors like Si:P close to metal-insulator transitions [\[1\]](#page-4-0), and heavy Fermion systems, materials with 4*f* or 5*f* atoms, notably Ce, Yb, or U [\[2\]](#page-4-0). Many of these materials show a remarkable magnetic quantum phase transition which can be understood by the competition between indirect exchange interaction, the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction between localized magnetic moments [\[3–5\]](#page-4-0) and their Kondo screening. Thereby, one finds a suppression of long-range magnetic order when exchange coupling *J* is increased and Kondo screening succeeds. This results in a typical quantum phase diagram with a quantum critical point where the T_c of the magnetic phase is vanishing, the Doniach diagram [\[6\]](#page-4-0).

Recently, controlled studies of magnetic adatoms on the surface of metals [\[7\]](#page-4-0), on graphene [\[8\]](#page-5-0), and on the conducting surface of topological insulators $[9-12]$ with surface sensitive experimental methods like (spin resolved) scanning tunnelling microscope (STM) and angle-resolved photoemission spectroscopy (ARPES) became possible. This demands a theoretical study of the Doniach diagram for magnetically doped disordered electron systems (DES), in particular 2D systems.

In any material there is some degree of disorder. In doped semiconductors it arises from the random positioning of the

dopants themselves, in heavy Fermion metals and in twodimensional (2D) metals it may arise from structural defects or impurities. Disorder is known to cause Anderson localization, which therefore has to be taken into account when deriving the Doniach diagram of disordered electrons systems. Moreover, as noted already earlier $[13]$, the physics of random systems is fully described by probability distributions, not just averages. This must be particularly true for systems with random local magnetic impurities (MIs) [\[14\]](#page-5-0), since the magnetic impurities are exposed to the local density of states of the conduction electrons, which is widely distributed itself. In fact, it has been noticed that a wide distribution of the Kondo temperature T_K of MIs in disordered host metals gives rise to non-Fermi-liquid behavior, such as the low-temperature power-law divergence of the magnetic susceptibility [\[14–22\]](#page-5-0). Nonmagnetic disorder quenches the Kondo screening of MIs due to Andersonlocalization and the formation of local pseudogaps at the Fermi energy $[21,23-25]$ $[21,23-25]$, resulting in bimodal distributions of T_K and a finite concentration of free local moments (LMs). However, in these studies the RKKY interaction J_{RKKY} between different MIs has not yet been taken into account. *J*_{RKKY} is mediated by the conduction electrons, and aligns the spins of the MIs ferromagnetically or antiferromagnetically, depending on their distance *R*. This is a long-ranged interaction, with a power-law decay $J_{RKKY} \sim 1/R^d$, where *d* is the dimension, and its typical value is not changed by weak disorder [\[26–29\]](#page-5-0). However, its amplitude has a wide log-normal distribution in disordered metals [\[26,30\]](#page-5-0). In this paper we therefore intend to study the competition between RKKY interaction and the Kondo effect in disordered electron systems.

In the next section we introduce the model, and provide the equations for the Kondo temperature and the RKKY coupling. In Sec. [III,](#page-1-0) we derive numerically the distribution function

^{*}hyunyong.rhee@gmail.com

[†] s.kettemann@jacobs-university.de

of *J*_{RKKY}, and compare it with an analytical result, based on a perturbative expansion of the nonlinear *σ* model. We derive next numerically the distribution function of T_K finding excellent agreement with approximate analytical results which were obtained, taking into account the multifractality and power-law correlations of wave functions. In Sec. [IV](#page-2-0) we present the main results, the distribution function of the ratio of Kondo temperature and RKKY interaction, for various distances between magnetic impurities *R*. From that we show how to derive the zero-temperature magnetic quantum phase diagram as a function of magnetic impurity density and exchange coupling, for 2D disordered electronic systems. At low densities and small $J < J_c$ we identify a paramagnetic phase. For graphene we find that the spin coupled phase is more stable against Kondo screening, but is more easily destroyed by disorder into a LM phase. In Sec. [V](#page-3-0) we derive from the distribution functions the magnetic susceptibility as a function of temperature, which show anomalous power-law behavior. In the Kondo phase that power is found to be determined by the wide distribution of the Kondo temperature, while at small exchange coupling there we identify spin coupled phase where the magnetic susceptibility is governed by the distribution of J_{RKKY} . In the final section we conclude and discuss the relevance and limitations of our results.

II. MODEL

In order to obtain the Doniach diagram of random electron systems we extend the approach of Doniach [\[6\]](#page-4-0) by calculating the distribution functions of T_K and J_{RKKY} and their ratio. Thus, in our approach we try to draw conclusions on the quantum phase diagram of an electron system with a finite density of magnetic impurities, by considering the Kondo temperature of single impurities and the RKKY coupling of pairs of magnetic moments.

We start from a microscopic description of the MIs, the Anderson impurity model coupled to a noninteracting disordered electronic Hamiltonian with on-site disorder. Then, we map it with the Schrieffer-Wolff transformation on a model of Kondo impurity spins coupled to the disordered host electron spins by the local coupling *J* [\[25\]](#page-5-0). We consider the single-impurity T_K and the coupling J_{RKKY} between a pair of spins. For the numerical calculations we employ the single-band Anderson tight-binding model on a square lattice of size *L* and lattice spacing *a*,

$$
H = -t \sum_{\langle i,j \rangle} c_i^{\dagger} c_j + \sum_i (w_i - \tilde{E}_F) c_i^{\dagger} c_i, \tag{1}
$$

where *t* is the hopping energy between nearest neighbors $\langle i, j \rangle$, w_i is the on-site disorder potential distributed in the interval $[-W/2, W/2]$. $E_F = E_F + \varepsilon_{\text{edge}}$, where E_F is the Fermi energy measured from the band edge, in 2D $\varepsilon_{\text{edge}} = -4t$. We use periodic boundary conditions.

In the dilute limit, one can calculate the T_K of a single magnetic impurity at position \mathbf{R}_i from the Nagaoka-Suhl one-loop equation [\[31,32\]](#page-5-0).

$$
1 = \frac{J}{2} \int_0^D d\varepsilon \frac{\tanh[(\varepsilon - E_F)/2T_K]}{\varepsilon - E_F} \rho_{ii}(\varepsilon), \tag{2}
$$

with bandwidth *D*. $\rho_{ii}(\varepsilon) = \langle i | \delta(\varepsilon - H) | i \rangle$ is the local density of states (LDOS). The RKKY coupling $J_{RKKY_{ij}}$ between two MIs located at positions \mathbf{R}_i , \mathbf{R}_j is in the zero-temperature limit $(T = 0)$ given by [\[29,33\]](#page-5-0)

$$
J_{\text{RKKY}_{ij}} = -J^2 \frac{S(S+1)}{2S^2} \int_{\varepsilon < E_F} d\varepsilon \int_{\varepsilon' > E_F} d\varepsilon' \frac{F(\varepsilon, \varepsilon')_{ij}}{\varepsilon - \varepsilon'},\quad (3)
$$

where $F(\varepsilon, \varepsilon')_{ij} = \text{Re}[\rho_{ij}(\varepsilon)\rho_{ji}(\varepsilon')]$, and *S* is the magnitude of the MI spin.

III. DISTRIBUTION FUNCTIONS

Using the Kernel polynomial method (KPM) [\[33,34\]](#page-5-0), one can evaluate the matrix elements of the density matrix $\rho_{ij}(\varepsilon) =$ $\langle i|\delta(\varepsilon - \hat{H})|i\rangle$ [\[29,](#page-5-0)34[,35\]](#page-5-0) with a polynomial expansion of order *M*. Here, we increase the cutoff degree *M* linearly with the linear system size *L* based on our analysis for the convergence of RKKY interaction with respect *M* in Ref. [\[30\]](#page-5-0). It has been also carefully discussed in Ref. [\[36\]](#page-5-0) that the choice of $M \propto L$, not $M \propto L^2$, gives proper DOS and LDOS results avoiding finite-size effect.

Equation (3) yields in a clean 2D system

$$
J_{2D}^0 = -\frac{m^*}{8\pi} \sin(2k_F R)/(k_F R)^2
$$

in the asymptotic limit $k_F R \gg 1$ with effective electron mass $m^* = 1/(2a^2t)$, and Fermi wave vector k_F [\[3\]](#page-4-0). Its geometrical average is close to the clean limit for distances *R* smaller than localization length *ξ* , and decays exponentially at larger distances [\[29,37\]](#page-5-0), $e^{((1/2) \ln J_{RKKY}^2)} \sim e^{-R/\xi}$. As shown in Figs. $1(a)$ and $1(b)$, the distribution of the absolute value of *J*_{RKKY} is well fitted by a log-normal,

$$
N(x) = \frac{N}{\sqrt{2\pi\sigma}} \exp\left[-\frac{(x-x_0)^2}{2\sigma^2}\right],
$$

FIG. 1. (Color online) $N(|J_{RKKY}|)$ at (a) fixed disorder strength $W = 2t$, (b) fixed $R = 5a$ ($N = 30000$, $L = 100a$, $M = 1000$). Black dashed lines: fit to log-normal distribution. (c) $P(T_K)$ at fixed $j = J/D = 0.25$, (d) $P(T_K)$ at fixed $W = 5t$ ($N = 30000$, $L = 40a$, $M = 200$. $E_F = 2t$ in (a)–(d).

FIG. 2. (Color online) Quantum phase diagram with local moment phase (LM) and Kondo screened phase: Critical exchange coupling J_c/D ($L = 100$) (a) as function of *W* ($M = 300$, $E_F = 2t$). Red dashed line: Eq. (6); (b) as function of Fermi energy E_F ($M = 200$); black dotted line: (DOS).

where $x = \ln |J_{RKKY}|$ and the fitting gives for $R = 5a$ and $W = 2t, 4t, x_0 = 5, 6$ and width $\sigma = 5.3 + 0.85W/t$ increasing with the disorder strength *W*. This is qualitatively consistent with analytical results obtained at weak disorder [\[26\]](#page-5-0), while analytical calculations at strong disorder have not been performed yet. This distribution width hardly depends on the distance *R*. We used $N = 30000$ disorder configurations.

The distribution of T_K is shown in Fig. [1\(c\),](#page-1-0) as obtained from the numerical solution of Eq. [\(2\)](#page-1-0) for $L = 40a$, $j =$ $J/D = 0.25$. Since for every sample only one single site is taken to avoid a distortion of the distribution due to intersite correlations, we had to use a huge number of $N = 30000$ different random disorder configurations to get sufficient statistics. It has a strongly bimodal shape where the low T_K peak becomes more distinctive with larger disorder amplitude *W* $[20,21,38]$ $[20,21,38]$ $[20,21,38]$. In Fig. [1\(d\)](#page-1-0) we show these results for fixed disorder strength $W = 5t$ for various exchange couplings *j*. Recently, an analytical derivation of the low T_K tail of $P(T_K)$ was done, using the multifractal distribution and correlations of intensities [\[25\]](#page-5-0). These correlations are 2D logarithmic with an amplitude of order $1/g$, where $g = E_F \tau$. For weak disorder, $g \gg 1$, it corresponds to a power-law correlation with power $\eta_{2D} = 2/\pi g$. The correlation energy is of the order of the elastic scattering rate $E_c \sim 1/\tau$. Thus, for $T_K \ll \text{Max}\{\Delta_{\xi} =$ D/ξ^2 , $\Delta = D/L^2$ [\[25\]](#page-5-0),

$$
P(T_K) = (1 - p_{FM}) \left(\frac{E_c}{T_K}\right)^{1-j} (\text{Min}\{\xi, L\})^{-d^2 j^2 / 2\eta_{2D}}, \quad (4)
$$

where $p_{FM} = n_{FM}(0)/n = (Min{\xi, L})^{-d^2 j^2/2\eta_{2D}}$, the ratio of free LMs. Equation (4) has a power-law tail with power $\beta_j = 1 - j$ in good agreement with the numerical results, $\text{Fig. 1(d), for } T_K/T_K^0 < 0.03. \text{ For } T_K^0 > T_K > \text{Max}\{\Delta_{\xi} =$ $\text{Fig. 1(d), for } T_K/T_K^0 < 0.03. \text{ For } T_K^0 > T_K > \text{Max}\{\Delta_{\xi} =$ $\text{Fig. 1(d), for } T_K/T_K^0 < 0.03. \text{ For } T_K^0 > T_K > \text{Max}\{\Delta_{\xi} =$ D/ξ^2 , $\Delta = D/L^2$ } one finds [\[25\]](#page-5-0)

$$
\frac{P(T_K)}{1 - p_{FM}} = \left(\frac{E_c}{T_K}\right)^{1 - \eta_{2D}/2d} \exp\left[-\frac{\left(\frac{T_K}{E_c}\right)^{\eta_{2D}/d}}{2c_1} \ln^2\left(\frac{T_K}{T_K^0}\right)\right],\tag{5}
$$

where $c_1 = 7.51$. This expression is in agreement with the numerical results, see Fig. [1\(d\),](#page-1-0) using $\xi = g \exp(\pi g)$, and $1/\tau = \pi W^2/6D$, fitting only $E_c \approx 0.73t$ and the prefactor.

Thus, we confirm that the power-law tail is governed by the multifractal correlation with power *η*2*^D*.

The quantum phase transition between the free local moment phase (LM) and a Kondo screened phase can be studied by calculating the critical exchange coupling J_c above which there is no more than one free magnetic moment in the sample volume L^d [\[23\]](#page-5-0). From the multifractality of the eigenfunction intensities it is found to be related to the power *η*2*^D* of the power-law correlations in the 2D DES as $J_c = \sqrt{\eta_{2D}}D$ and thus to increase in two dimensions linearly with disorder strength *W* as [\[25\]](#page-5-0)

$$
J_c = \sqrt{D/(3E_F)}W.
$$
 (6)

In Fig. $2(a)$, Eq. (6) is plotted together with numerical results as function of disorder strength *W*. We find good agreement. There are only deviations at large disorder, g *<* 1, where the $1/q$ expansion breaks down. We plot J_c as function of E_F in Fig. 2(b), together with the density of states (DOS). We in Fig. 2(b), together with the density of states (DOS). We find that J_c is increasing towards the band edge as $1/\sqrt{E_F}$ in agreement with Eq. (6). Far outside of *ε*edge of the clean system it increases as $J_c/D = 1/\ln |\varepsilon_{\text{edge}} - E_F|$ due to the gap in the DOS. For $J > J_c$ there are Kondo singlets which consist of the local spin and a Kondo cloud of conduction electrons. Indeed, if the Fermi energy is outside of the band the local spin can be only screened if $J > Jc > D$, which implies that it forms a singlet with a single electron. Conceptually this can be considered as the $N \rightarrow 1$ limit of a Kondo cloud consisting of *N* electrons [\[39–41\]](#page-5-0).

IV. MAGNETIC PHASE DIAGRAM AT $T = 0$

In clean systems the critical density $n_c = 1/R_c^d$ above which the MIs are coupled with each other can be obtained from the condition that $|J_{\text{RKKY}}^0(R_c)| = T_K$ [\[6\]](#page-4-0). Thus, in two dimensions with $|J_{RKKY}^0|_{kFR \gg 1} = J^2 \frac{m}{8\pi^2 k_F^2 R^2}$ and $T_K = cE_F \exp(-D/J)$, $c \approx 1.14$, one finds $n_c =$ $16\pi^2 c \frac{E_F^2}{J^2} \exp(-\frac{D}{J})$.

In disordered systems, T_K of an MI at a given site competes with the RKKY coupling to another MI at distance *R*. Thus, the distribution function $N(x_{JK})$ of the ratio of these two energy scales $x_{JK} = |J_{RKKY}(R)|/T_K$ for a given disordered sample with density of MIs $n = 1/R^2$, where *R* is the average

FIG. 3. (Color online) (a) Distribution of the ratio between $|J_{RKKY}(R)|$ and T_K for various distances R between two arbitrary magnetic impurities. Black dashed arrow: sharp cutoff of each distribution. (b) Magnetic quantum phase diagram: critical MI density n_c as function of J/D for various disorder strengths *W* as determined by the distance *R* below which $|J_{RKKY}(R)|/T_K$ does not exceed 1 at any site. Horizontal dashed line: density n_{ξ} below which there is a local moment phase (LM). Here, n_{ξ} is computed only for $W = 3t$ since it becomes too small to plot for smaller *W*. CM: phase with coupled magnetic moments. A linear system size $L = 100a$, the cutoff degree $M = 300$, and the number of disorder configurations $N = 30000$ are used in this calculation.

distance between the MIs, is crucial to determine its magnetic state. The distribution of x_{JK} for $W = 3t$ and $J/D = 0.2$ is shown for several distances *R* in Fig. $3(a)$ ($N = 10000$, $L = 100a$, $E_F = t$, and $M = 300$). Likewise for $N(T_K)$ and $N(J_{\text{RKKY}})$, the distribution of x_{JK} has an exponentially wide width characterized by a small- x_{JK} tail and a sharp upper cutoff in x_{JK} as shown in Fig. 3(a). As increasing the distance *R* between the magnetic impurities the distribution $N(x_{JK})$ is shifted to the left (smaller x_{JK}), since the RKKY interaction decreases with R . The sharp upper cutoff in x_{JK} allows us to define a critical density $n_c(J) = 1/R_c^2$ below which the Kondo effect dominates in the competition with RKKY interaction at all sites. $n_c(J)$ is plotted in Fig. 3(b) for various values of disorder strength *W*. When the MI density *n* exceeds n_c , magnetic clusters start to form at some sites and the MIs may be coupled by J_{RKKY} . We see that this coupled moment phase (CM) expands at the expense of the Kondo phase with increasing *W*. When *R* is larger than localization length *ξ* the coupling J_{RKKY} is exponentially small and there is a *local*

FIG. 4. (Color online) Critical MI density n_c as function of J/D for graphene ($\varepsilon_F = 3t$, Dirac point). A linear system size $L = 100a$, the cutoff degree $M = 300$, and the number of disorder configurations $N = 30000$ are used in this calculation.

moment phase (LM) below $n_{\xi} = 1/\xi(g)^2$, where MIs remain free un to exponentially small temperatures free up to exponentially small temperatures.

In graphene the pseudogap at the Dirac point quenches the Kondo effect below $J_c = D/2$, independently on disorder amplitude *W*. Thus, in graphene there is a larger parameter space where the MIs are coupled (CM) than in a normal 2DES; see Fig. 4. However, short-range disorder localizes the electrons, cutting off the RKKY interaction and for $n < n_{\xi}$ there is a LM phase. Thus, the magnetic phase in graphene is more stable against Kondo screening but is more easily destroyed by disorder.

V. DONIACH PHASE DIAGRAM OF DISORDERED 2DES AND GRAPHENE

We find that the Kondo phase splits at finite temperature into a *Kondo Fermi-liquid (FL) phase*, where all MIs are screened, and a *Kondo non-Fermi-liquid (NFL) phase*, at *T > T*[∗](*n*), where some MIs remain unscreened and contribute to the magnetic susceptibility with an anomalous temperature dependence, given by [\[25\]](#page-5-0)

$$
\chi(T) \sim \frac{n}{E_c} \frac{2d}{\eta_{2D}} \left(\frac{T}{E_c}\right)^{\eta_{2d}/2d-1}
$$
 for $T > T^*(n) > \frac{D}{\xi^2}$. (7)

The temperature $T^*(n)$, plotted schematically in Fig. [5](#page-4-0) (blue line), is given by the position of the low T_K peak in the distribution $P(T_K)$; see Fig. [1\(c\).](#page-1-0) We note that *J* may be distributed itself and may add a nonuniversal, material dependent contribution to the distribution of T_K [\[18\]](#page-5-0) and *J*RKKY.

For $n > n_c$ there is a succession of phases, starting with the *RKKY phase* where clusters are formed locally due to the widely distributed RKKY coupling. Anomalous power laws are observed when clusters are broken up successively as temperature is raised. From the log-normal distribution $N(|J_{RKKY}|)$ one obtains for the magnetic susceptibility,

$$
\chi(T)T = n_{FM}(T) = \int_0^T d|J_{\text{RKKY}}|N(|J_{\text{RKKY}}|)
$$

$$
\sim n \exp\left[-\ln^2\left(\frac{T}{|J_{\text{RKKY}}|}\right) / \left[\frac{2\sigma(W)}{2}\right],\tag{8}
$$

FIG. 5. (Color online) Schematic Doniach diagram: temperature *T* divided by J^2 versus J/D . Vertical dotted line: critical point $J_c(n)$ separating RKKY phase from Kondo phase. Blue line: $T^*(n)$ separating Kondo FL phase from Kondo NFL phase. For $n < n_{\xi}$ and $J < J_c$ a local moment phase (LM) appears.

where width $\sigma(W)$ increases with disorder strength *W*. Accordingly, the excess specific heat is

$$
C(T) = T \frac{dn_{FM}}{dT} \sim \exp\left[-\ln^2\left(\frac{T}{|J_{\text{RKKY}}^0|}{\right)}/[2\sigma(W)]^2\right].\tag{9}
$$

The detailed analysis of the quantum phase diagram at higher concentrations *n* requires us to go beyond our present analysis. One expects that at $n > n_{SG}$ a *spin-glass phase* appears, where the magnetic susceptibility shows a peak at spin-glass temperature T_{SG} as studied in Refs. [\[42,43\]](#page-5-0). Above a critical density n_F a phase with long-range order may form below a critical temperature $T_c(n, J)$ [\[43–46\]](#page-5-0).

VI. CONCLUSIONS AND DISCUSSION

We conclude that it is the full distribution function $N(x_{JK})$ of the ratio of the RKKY coupling and the Kondo temperature which determines the magnetic phase diagram of magnetic moments in disordered electron systems, especially at low concentrations. We identified a critical density of magnetic impurities n_c below which Kondo wins at all positions in a disordered sample above a critical coupling *Jc*, which increases with the disorder amplitude. As a result, the Kondo phase is diminished as the disorder is increased, favoring a phase where the MI spins are coupled. The magnetic susceptibility obeys an anomalous power-law behavior, which crosses over as a function of *J* from the Kondo regime where that power is determined by the wide distribution of the Kondo temperature T_K , to a spin coupled phase where it is governed by the log-normal distribution of J_{RKKY} . At low densities and small $J < J_c$, we identify a paramagnetic phase. The distribution function of $|J_{RKKY}|/T_K$ is expected to determine also the magnetic phase diagram of magnetically doped graphene and the surface of topological insulators with magnetic adatoms; see Fig. [4.](#page-3-0) This distribution function may also be crucial to explain the anomalous magnetic properties of doped semiconductors in the vicinity of metal-insulator transition $[1]$, where we expect that *η* is replaced by the universal value $\eta = 2(\alpha_0 - d)$, $d = 3$ with the universal multifractality parameter α_0 .

In this work we considered the distribution function of the Kondo temperature of single impurities and the RKKY coupling of pairs of magnetic moments and extracted information on the quantum phase diagram of systems with finite concentrations of MIs. This approach has its limitations, for example at finite concentration the RKKY coupling can reduce T_K as has been already found by Tsay and Klein in the 1970s [\[47,48\]](#page-5-0). However, they concluded that this reduction is minor. More importantly, later work revealed that the Kondo lattice of a finite density of magnetic moments, which is coupled to the conduction electrons, has a coherent lowtemperature heavy fermion phase, and a Kondo insulator phase at half filling of the magnetic moment levels. More recently, the Kondo lattice in one dimension was studied more rigorously (see the review by Tsunetsugu *et al.* [\[49\]](#page-5-0)), and it was shown that, at least in one dimension, the ground state of this system can not be understood by the mere extension of the singleand two-magnetic impurity problem, where the physics is governed by the competition between these two energy scales, the Kondo temperature and the RKKY coupling. However, the higher temperature behavior was found to be still governed by the competition between these two energy scales. Therefore, we expect that the consideration of the reduced problem of two impurity spins will give important information on the physics of disordered electron systems at finite concentration of magnetic moments, which becomes more meaningful the lower the density and the higher the temperature is. Going beyond the limitations of this approach, one will have to study the disordered Kondo lattice where a finite density of magnetic moments is coupled to the conduction electrons. For a clean Kondo lattice it is known that a coherent low-temperature heavy fermion phase, and a Kondo insulator phase at half filling of the magnetic moment levels appears [\[50,51\]](#page-5-0). It remains to see how these low-temperature phases are modified by the presence of nonmagnetic disorder.
