We present a diagrammatic approach to construct self-energy approximations within many-body perturbation theory with positive spectral properties. The method cures the problem of negative spectral functions which arises from a straightforward inclusion of vertex diagrams beyond the GW approximation. Our approach consists of a two-step procedure: We first express the approximate many-body self-energy as a product of half-diagrams and then identify the minimal number of half-diagrams to add in order to form a perfect square. The resulting self-energy is an unconventional sum of self-energy diagrams in which the internal lines of half a diagram are time-ordered Green's functions, whereas those of the other half are anti-time-ordered Green's functions, and the lines joining the two halves are either lesser or greater Green's functions. The theory is developed using noninteracting Green's functions and subsequently extended to self-consistent Green's functions. Issues related to the conserving properties of diagrammatic approximations with positive spectral functions are also addressed. As a major application of the formalism we derive the minimal set of additional diagrams to make positive the spectral function of the GW approximation with lowest-order vertex corrections and screened interactions. The method is then applied to vertex corrections in the three-dimensional homogeneous electron gas by using a combination of analytical frequency integrations and numerical Monte Carlo momentum integrations to evaluate the diagrams.

I. INTRODUCTION

Many-body perturbation theory (MBPT) has provided a systematic way to study electron-electron (electron-phonon) interactions in various systems ranging from molecules to solids [1,2]. Within MBPT the interaction effects are included via a self-energy term which is treated perturbatively. One of the widely used self-energy approximations is the GW approximation [3] which consists of replacing the bare interaction with the screened interaction in the first-order exchange diagram. Diagrammatically the GW approximation can be viewed as an infinite summation of polarization diagrams. It is well known that for solids the GW approximation (usually not implemented self-consistently) tends to give band gap values close to the experimental values, thus improving over the density functional calculations (which instead underestimate the values for the band gaps) [4]. In spite of some improvements over complementary theories, the self-consistent GW approximation is known to have a number of deficiencies like the washing out of plasmon features and broadened bandwidths in the electron-gas-like metals [5]. For many decades the common argument has then been that the inclusion of vertex corrections would act as a balancing force for the self-consistency [6–9], thus, e.g.,

hampering the washing out of plasmon satellites. Several people have worked on this issue on various levels [10–16], but the most interesting result from our point of view is that the straightforward inclusion of vertex corrections beyond the GW level yields negative spectra in some frequency regions, as noticed by Minnhagen for the electron gas [10]. This deficiency not only prohibits the usual probability interpretation of the spectral function but also generates Green's functions with the wrong analytic properties. In particular, the latter feature prevents an iterative self-consistent solution of the Dyson equation since the analytic properties deteriorate with every self-consistency cycle. This unpleasant situation is not limited to the electron gas as it has also been observed in a study of vertex corrections in finite systems [17,18]. As we will explain in depth in this work the problem lies in the structure of the vertex correction and therefore the solution must be sought in the way we use MBPT. There has been very little work on how to generate positive spectral functions from MBPT. The only work on the issue of positivity that we are aware of has been done by Almladh but in the context of photoemission. Almladh showed that the positivity of the photocurrent was guaranteed by expressing the photoemission triangle diagrams as a square of half-diagrams [19]. This, however, was done only for a certain selection of low-order diagrams and it was

not indicated how the idea could be applied to the spectral function.

In this paper we put forward a diagrammatic approach to generate self-energy approximations beyond GW yielding positive spectral functions. We start from an expression of the self-energy derived by Danielewicz [20] and use the Keldysh formalism [21] to extract the lesser/greater components (these components are needed to construct the spectral function). Every lesser/greater diagram is partitioned into different contributions, each with internal times integrated over either the forward or the backward branch of the Keldysh contour. The full lesser/greater diagram corresponds to the sum of all possible partitions. We then factorize each partition into half-diagrams by using the Lehmann representation of the Green's function [22,23], where the one half of the partition consists of time-ordered quantities and the other half consists of anti-time-ordered quantities. The partitioning can be seen as cutting the diagram in half along the lesser/greater Green's function lines. A similar cutting procedure is used in high-energy physics to calculate the imaginary part of diagrams contributing to the scattering amplitudes [24–29]. Our cutting rules agree with those of high-energy physics but our derivation is based on the Keldysh formalism, which allows us to advance the theory further. In fact, the positivity of the spectral function entails that the sum of the products of the half-diagrams is the sum of perfect squares. In some situations the MBPT approximation is already a sum of perfect squares, like for the GW approximation. For other self-energy approximations we instead need to add missing half-diagrams to complete the square, like for the $GWGW$ self-energy, i.e., the lowest-order vertex correction. We acknowledge here that Danielewicz [30] also studied a cutting procedure for the lesser/greater self-energy diagrams and derived a manifestly positive exact formula for the spectral function in terms of retarded/advanced n -point functions, but the issue of how to cure negative spectral functions of approximate self-energies was not discussed in his work. The focus of our work is to study approximate MBPT self-energies and give simple drawing rules to decide whether or not the approximation generates a positive spectral function. If not we provide extra, but still simple, drawing rules to extend to a minimal set of diagrams the MBPT approximation and turn the spectral function positive.

This paper is organized as follows. In Sec. II we derive the Lehmann form of the lesser/greater self-energy and relate it to a diagrammatic representation in terms of half-diagrams. Then we describe how to construct a self-energy approximation with a positive spectral function from a given MBPT approximation by a minimal selection of additional self-energy diagrams. The theory is developed using noninteracting Green's functions and subsequently extended to self-consistent Green's functions. In Sec. III we illustrate the formalism with text-book examples. In Sec. IV we derive the simplest self-energy with *vertex corrections* and *screened interaction* yielding a positive spectral function. We then apply the theory to the three-dimensional homogeneous electron gas in Sec. V. We evaluate the self-energy diagrams by using a combination of analytical frequency integrations and numerical Monte Carlo momentum integrations, and show how the minimal selection of additional diagrams cures the problem of negative spectra. We finally present our conclusions and outlooks in Sec. VI.

II. THEORETICAL FRAMEWORK

Within the realm of Green's function theory the most common techniques to study equilibrium problems are either the zero-temperature formalism or the Matsubara formalism. These are two special cases of the more general Keldysh formalism which is usually applied in the context of nonequilibrium physics beyond linear response. In this work we show that the Keldysh formalism is also the natural tool to develop a diagrammatic theory for *positive-definite* spectral functions of systems in *equilibrium*. We consider a system of interacting fermions with Hamiltonian

$$\hat{H} = \int d\mathbf{x} \hat{\psi}^\dagger(\mathbf{x}) h(\mathbf{x}) \hat{\psi}(\mathbf{x}) + \frac{1}{2} \int d\mathbf{x} d\mathbf{x}' \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}^\dagger(\mathbf{x}') v(\mathbf{x}, \mathbf{x}') \hat{\psi}(\mathbf{x}') \hat{\psi}(\mathbf{x}), \quad (1)$$

where the field operator $\hat{\psi}$ ($\hat{\psi}^\dagger$) with argument $\mathbf{x} = \mathbf{r}\sigma$ annihilates (creates) a fermion in position \mathbf{r} with spin σ . In the Keldysh formalism the field operators evolve on the time-loop contour \mathcal{C} shown in Fig. 1. Operators on the *minus* branch are ordered chronologically while operators on the *plus* branch are ordered antichronologically. Letting z_1 and z_2 be two contour times, the Green's function $G(\mathbf{x}_1 z_1, \mathbf{x}_2 z_2)$ can be divided into different components $G^{\alpha\beta}(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2)$ depending on the branch $\alpha, \beta = +/-$ to which z_1 and z_2 belong. For $\alpha = \beta = -$ we have the *time-ordered* Green's function

$$G^{--}(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = -i \langle T[\hat{\psi}_H(\mathbf{x}_1 t_1) \hat{\psi}_H^\dagger(\mathbf{x}_2 t_2)] \rangle. \quad (2)$$

In this expression T is the time-ordering operator and the symbol $\langle \dots \rangle$ implies a trace with some density matrix $\hat{\rho}$. For systems at zero temperature the trace reduces to a ground-state average. The subscript “ H ” attached to a general operator \hat{O} signifies that the operator is in the Heisenberg picture

$$\hat{O}_H(t) = \hat{U}(t_0, t) \hat{O} \hat{U}(t, t_0), \quad (3)$$

where \hat{U} is the time-evolution operator and t_0 is an arbitrary initial time. The time-ordered G^{--} in Eq. (2) is the building block of the zero-temperature formalism and the object calculated in most MBPT codes.

Reversing the time arrow the G^{--} is converted into the *anti-time-ordered* Green's function

$$G^{++}(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = -i \langle \bar{T}[\hat{\psi}_H(\mathbf{x}_1 t_1) \hat{\psi}_H^\dagger(\mathbf{x}_2 t_2)] \rangle, \quad (4)$$

where \bar{T} orders the operators antichronologically. Finally, choosing z_1 and z_2 on different branches we have

$$G^{-+}(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = i \langle \hat{\psi}_H^\dagger(\mathbf{x}_2 t_2) \hat{\psi}_H(\mathbf{x}_1 t_1) \rangle, \quad (5a)$$

$$G^{+-}(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = -i \langle \hat{\psi}_H(\mathbf{x}_1 t_1) \hat{\psi}_H^\dagger(\mathbf{x}_2 t_2) \rangle. \quad (5b)$$

FIG. 1. The closed time-loop contour \mathcal{C} . The (forward) minus branch is denoted with a “ $-$ ” label while the (backward) plus branch is denoted by a “ $+$ ” label.

These two last components are equivalently written as $G^{-+} = G^<$ (*lesser* Green's function) and $G^{+-} = G^>$ (*greater* Green's function), and describe the propagation of an added hole ($G^<$) or particle ($G^>$) in the medium. In frequency space and at zero temperature $-iG^<(\omega)$ is the spectral function below the Fermi energy and zero otherwise, whereas $iG^>(\omega)$ is the spectral function above the Fermi energy and zero otherwise.

The four Green's functions $G^{\alpha\beta}$ are not independent of each other. The G^{-+} and G^{+-} are indeed given in terms of G^{\lessgtr} according to the equations below (omitting the position-spin variables):

$$\begin{aligned} G^{-+}(t_1, t_2) &= \theta(t_1 - t_2)G^>(t_1, t_2) + \theta(t_2 - t_1)G^<(t_1, t_2), \\ G^{+-}(t_1, t_2) &= \theta(t_1 - t_2)G^<(t_1, t_2) + \theta(t_2 - t_1)G^>(t_1, t_2). \end{aligned}$$

Thus the four Green's functions can all be extracted from the spectral function.

A. Positive semidefiniteness of the exact self-energy

In equilibrium the Green's function $G^{\alpha\beta}$ depends on the time difference only. Omitting the dependence on the position and spin coordinates \mathbf{x}_1 and \mathbf{x}_2 the spectral function is defined according to

$$A(\omega) = i[G^>(\omega) - G^<(\omega)], \quad (6)$$

where here and in the following $G^{\alpha\beta}(\omega)$ denotes the Fourier transform of the Green's function with respect to the time difference. From the Lehmann representation it is easy to show that $iG^>(\omega)$ and $-iG^<(\omega)$, as matrices in the \mathbf{x} space, are positive semidefinite (PSD). From the Dyson equation on the Keldysh contour one can also show that [2]

$$G^{\lessgtr}(\omega) = G^R(\omega)\Sigma_c^{\lessgtr}(\omega)G^A(\omega), \quad (7)$$

where

$$G^{R/A}(\omega) = i \int \frac{d\omega'}{2\pi} \frac{G^>(\omega') - G^<(\omega')}{\omega - \omega' \pm i\eta} \quad (8)$$

are the retarded/advanced Green's function and Σ_c is the correlation self-energy. Since $G^A(\omega) = [G^R(\omega)]^\dagger$ the PSD of $\mp iG^{\lessgtr}$ implies that $\mp i\Sigma_c^{\lessgtr}$ is PSD and vice versa. Even though one can prove the PSD property of the self-energy using the corresponding property of the Green's function and the Dyson equation, a direct proof starting from a Lehmann representation is not possible since Σ_c is *not* the average of a correlator.

In this section we use the Keldysh formalism to provide an alternative proof of the PSD property of Σ_c . For the proof we derive a Lehmann-like representation of Σ_c^{\lessgtr} and highlight the connection with the diagrammatic expansion. This connection will be extremely useful to generate approximate PSD self-energies from diagrammatic theory. We advance that the diagrammatic rules to evaluate a lesser/greater diagram will differ from the standard zero-temperature diagrammatic rules to evaluate a time-ordered diagram. A time-ordered diagram is entirely expressed in terms of time-ordered G 's, whereas a lesser/greater diagram is expressed in terms of the four Green's functions $G^{\alpha\beta}$.

The starting point is the following expression [2,20] for $\Sigma_c^<$ and $\Sigma_c^>$:

$$\Sigma_c^<(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = i \langle \hat{\gamma}_H^\dagger(\mathbf{x}_2 t_2) \hat{\gamma}_H(\mathbf{x}_1 t_1) \rangle_{\text{irr}}, \quad (9a)$$

$$\Sigma_c^>(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = -i \langle \hat{\gamma}_H(\mathbf{x}_1 t_1) \hat{\gamma}_H^\dagger(\mathbf{x}_2 t_2) \rangle_{\text{irr}}, \quad (9b)$$

where the operator $\hat{\gamma}$ is defined according to

$$\hat{\gamma}(\mathbf{x}_1) \equiv \int d\mathbf{x} v(\mathbf{x}_1, \mathbf{x}) \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}(\mathbf{x}) \hat{\psi}(\mathbf{x}_1), \quad (10)$$

and the subscript ‘‘irr’’ signifies that only one-particle irreducible diagrams should be retained. That is, the expansion of the self-energy (9) contains all the diagrams of the two-particle–one-hole correlation function [31] in which the entrance and exit channels cannot be separated by cutting one Green's function line [32,33]. Unlike the definitions (5) of the Green's functions G^{\lessgtr} , Eq. (9) are not averages of a correlator due to the exclusion of reducible diagrams. Nevertheless a Lehmann-like representation for the self-energy can be derived using diagrammatic methods.

Let us study, e.g., $\Sigma_c^<$, as the same reasoning applies to $\Sigma_c^>$. For simplicity we restrict the discussion to systems at zero temperature and assume a nondegenerate ground state Ψ_0 . Using Eq. (3) and introducing the short-hand notation $1 = \mathbf{x}_1 t_1$, $2 = \mathbf{x}_2 t_2$, etc. we can rewrite Eq. (9a) as

$$\begin{aligned} \Sigma_c^<(1, 2) &= i \langle \Psi_0 | \hat{U}(t_0, t_2) \hat{\gamma}^\dagger(\mathbf{x}_2) \hat{U}(t_2, t_0) \\ &\quad \times \hat{U}(t_0, t_1) \hat{\gamma}(\mathbf{x}_1) \hat{U}(t_1, t_0) | \Psi_0 \rangle_{\text{irr}}. \end{aligned} \quad (11)$$

Next we assume that Ψ_0 can be obtained by evolving backward the noninteracting ground state Φ_0 from a distant future time τ (with $\tau \rightarrow \infty$) to the arbitrary initial time t_0 using an interaction which is switched-on adiabatically, i.e., $|\Psi_0\rangle = \hat{U}(t_0, \tau) |\Phi_0\rangle$, where the evolution operator is calculated with the time-dependent interaction $e^{\eta|t-t_0|} v$ (η being an infinitesimal negative energy). This is the standard assumption of the zero-temperature Green's function formalism. Then Eq. (11) becomes (the limit $\tau \rightarrow \infty$ is implied)

$$\begin{aligned} \Sigma_c^<(1, 2) &= i \left[\sum_i \langle \Phi_0 | \hat{U}(\tau, t_2) \hat{\gamma}^\dagger(\mathbf{x}_2) \hat{U}(t_2, \tau) | \chi_i \rangle \right. \\ &\quad \left. \times \langle \chi_i | \hat{U}(\tau, t_1) \hat{\gamma}(\mathbf{x}_1) \hat{U}(t_1, \tau) | \Phi_0 \rangle \right], \end{aligned} \quad (12)$$

where we inserted a completeness relation $\sum_i |\chi_i\rangle \langle \chi_i| = 1$ (the sum runs over all states χ_i in Fock space) and used the group property $\hat{U}(t_1, t_0) \hat{U}(t_0, \tau) = \hat{U}(t_1, \tau)$ and $\hat{U}^\dagger(t_0, \tau) \hat{U}(t_0, t_2) = \hat{U}^\dagger(\tau, t_2)$. Let $\hat{c}_k, \hat{c}_k^\dagger$ denote the annihilation and creation operators of a fermion in the k th eigenstate of the noninteracting problem. In Eq. (12) only states $|\chi_i\rangle$ of the form

$$\hat{c}_{q_N}^\dagger \cdots \hat{c}_{q_1}^\dagger \hat{c}_{p_{N+1}} \cdots \hat{c}_{p_1} | \Phi_0 \rangle \equiv | \chi_{\underline{pq}}^{(N)} \rangle \quad (13)$$

contribute since the operator $\hat{\gamma}$ ($\hat{\gamma}^\dagger$) annihilates (creates) a fermion. The indices $\underline{p} = (p_1, \dots, p_{N+1})$ and $\underline{q} = (q_1, \dots, q_N)$ in $\chi_{\underline{pq}}^{(N)}$ specify the quantum numbers of the \hat{c} and \hat{c}^\dagger operators, respectively. We conclude that Eq. (12) does

not change under the replacement

$$\sum_i |\chi_i\rangle\langle\chi_i| \rightarrow \sum_{N=0}^{\infty} \frac{1}{(N+1)!N!} \sum_{\underline{pq}} |\chi_{\underline{pq}}^{(N)}\rangle\langle\chi_{\underline{pq}}^{(N)}|. \quad (14)$$

Here the inner sum denotes integrations or summations over sets of \underline{p} and \underline{q} quantum numbers with the restriction that \underline{p} integration runs over the occupied and \underline{q} integration runs over the unoccupied states, respectively. The prefactor stems from the inner product of the intermediate states, i.e.,

$$\langle\chi_{\underline{pq}}^{(N)}|\chi_{\underline{p'q'}}^{(N')}\rangle = \delta_{N,N'} \sum_{P \in \pi_{N+1}} \sum_{Q \in \pi_N} (-)^{P+Q} \delta_{P(\underline{p}), \underline{p'}} \delta_{Q(\underline{q}), \underline{q'}},$$

where P and Q run over all possible permutations of $N+1$ and N indices with parities $(-)^P$ and $(-)^Q$, respectively. We further denoted the permutation group of N elements by π_N .

$$\begin{aligned} S_{N,\underline{pq}}^*(1) &= \langle\Phi_0|\hat{c}_{p_1}^\dagger \cdots \hat{c}_{p_{N+1}}^\dagger \hat{c}_{q_1} \cdots \hat{c}_{q_N} \hat{U}(\tau, t_1) \hat{\gamma}(\mathbf{x}_1) \hat{U}(t_1, -\tau)|\Phi_0\rangle e^{-i\alpha} \\ &= \frac{\langle\Phi_0|T\{e^{-i\int_{-\tau}^{\tau} dt \hat{H}(t)} \hat{c}_{p_1}^\dagger(\tau^+) \cdots \hat{c}_{p_{N+1}}^\dagger(\tau^+) \hat{c}_{q_1}(\tau) \cdots \hat{c}_{q_N}(\tau) \hat{\gamma}(\mathbf{x}_1 t_1)\}| \Phi_0\rangle}{\langle\Phi_0|T\{e^{-i\int_{-\tau}^{\tau} dt \hat{H}(t)}\}| \Phi_0\rangle}, \end{aligned} \quad (17)$$

where the time argument in the operators specifies their position along the interval $(-\tau, \tau)$. The time τ^+ is infinitesimally greater than τ , which assures the correct ordering of the operators. Taking into account that the operator $\hat{\gamma}(\mathbf{x}_1 t_1)$ is composed of an annihilation operator in \mathbf{x}_1 , a density operator in some internal point \mathbf{x} , and an interaction line connecting \mathbf{x}_1 to \mathbf{x} , see Eq. (10), we see that the amplitude S_N^* is an interacting *time-ordered* $(N+2)$ -Green's function multiplied by $v(\mathbf{x}_1, \mathbf{x})$ and integrated over \mathbf{x} . Therefore, S_N^* can be expanded in powers of the interparticle interaction v by means of Wick's theorem. The generic term of the expansion is a connected diagram of noninteracting *time-ordered* Green's functions g^{--} with external vertices $1 = \mathbf{x}_1 t_1$ and $\underline{p}, \underline{q}$ at time τ , and the general structure of this diagram is represented on the left-hand side of Fig. 2. Here the gray region symbolizes scattering processes of arbitrary complexity occurring between $N+2$ particles. Following the same steps it is easy to show that

$$S_{N,\underline{pq}}(2) = \frac{\langle\Phi_0|\bar{T}\{e^{i\int_{-\tau}^{\tau} dt \hat{H}(t)} \hat{\gamma}^\dagger(\mathbf{x}_2 t_2) \hat{c}_{q_N}^\dagger(\tau) \cdots \hat{c}_{q_1}^\dagger(\tau) \hat{c}_{p_{N+1}}(\tau^+) \cdots \hat{c}_{p_1}(\tau^+)\}| \Phi_0\rangle}{\langle\Phi_0|\bar{T}\{e^{i\int_{-\tau}^{\tau} dt \hat{H}(t)}\}| \Phi_0\rangle}, \quad (18)$$

which can also be expanded using Wick's theorem, and the generic term of the expansion is a connected diagram of noninteracting *anti-time-ordered* Green's functions g^{++} with external vertices $2 = \mathbf{x}_2 t_2$ and $\underline{p}, \underline{q}$ at time τ , see right diagram in Fig. 2. Let us investigate the result of multiplying a diagram of $S_{N,\underline{pq}}^*(1)$ by a diagram of $S_{N,\underline{pq}}(2)$ and then sum

FIG. 2. (Color online) Diagrammatic structure of the functions $S^*(1)$ and $S(2)$ for the lesser self-energy. The external vertex points 1 and 2 have times on the minus and plus branch, respectively. Green's functions are denoted by the lines with arrows, while wavy lines correspond to the bare interparticle interaction.

Defining the amplitudes

$$\begin{aligned} S_{N,\underline{pq}}^*(1) &\equiv \langle\chi_{\underline{pq}}^{(N)}|\hat{U}(\tau, t_1) \hat{\gamma}(\mathbf{x}_1) \hat{U}(t_1, \tau)|\Phi_0\rangle, \\ S_{N,\underline{pq}}(2) &\equiv \langle\Phi_0|\hat{U}(\tau, t_2) \hat{\gamma}^\dagger(\mathbf{x}_2) \hat{U}(t_2, \tau)|\chi_{\underline{pq}}^{(N)}\rangle, \end{aligned}$$

the lesser self-energy takes the following compact form:

$$\Sigma_c^<(1,2) = i \left[\sum_{N=0}^{\infty} \frac{1}{(N+1)!N!} \sum_{\underline{pq}} S_{N,\underline{pq}}(2) S_{N,\underline{pq}}^*(1) \right]_{\text{irr}}. \quad (15)$$

To proceed further we need to analyze the amplitudes S and their complex conjugate S^* . Under the adiabatic assumption the evolution of the noninteracting ground state Φ_0 from $-\tau$ to τ yields Φ_0 up to a phase factor, i.e.,

$$\hat{U}(\tau, -\tau)|\Phi_0\rangle = e^{i\alpha}|\Phi_0\rangle, \quad (16)$$

with $e^{i\alpha} = \langle\Phi_0|\hat{U}(\tau, -\tau)|\Phi_0\rangle$. Therefore, we can write

over \underline{p} and \underline{q} . In a diagram of $S_{N,\underline{pq}}^*$ the outgoing Green's functions with \underline{q} labels and the ingoing Green's functions with \underline{p} labels are calculated at the latest possible time τ . Therefore,

$$\begin{aligned} g_{q\mathbf{x}}^{--}(\tau, t_x) &= g_{q\mathbf{x}}^>(\tau, t_x), \\ g_{\mathbf{x}p}^{--}(t_x, \tau) &= g_{\mathbf{x}p}^<(t_x, \tau), \end{aligned}$$

where (\mathbf{x}, t_x) is an internal space-spin-time vertex and we introduced the short-hand notation g_{ij} for the matrix elements of g between two spin-orbital states i and j , hence $g^{\alpha\beta}(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = g_{\mathbf{x}_1 \mathbf{x}_2}^{\alpha\beta}(t_1, t_2)$. Similarly in a diagram of $S_{N,\underline{pq}}$ the ingoing Green's functions with \underline{q} labels and the outgoing Green's functions with \underline{p} labels are calculated at the latest possible time τ and therefore,

$$\begin{aligned} g_{yq}^{++}(t_y, \tau) &= g_{yq}^>(t_y, \tau), \\ g_{py}^{++}(\tau, t_y) &= g_{py}^<(\tau, t_y). \end{aligned}$$

Thus the multiplication of a S diagram by a S^* diagram and the subsequent sum over \underline{p} and \underline{q} involves the sum over

q of $g_{qx}^>g_{yq}^>$ and the sum over p of $g_{xp}^<g_{py}^<$. The noninteracting lesser/greater Green's functions can be expanded in the basis of the noninteracting one-particle eigenstates according to [2]

$$g_{ij}^<(t,t') = i \sum_p f(\epsilon_p) e^{-i\epsilon_p(t-t')} \langle i|p\rangle \langle p|j\rangle, \quad (19)$$

$$g_{ij}^>(t,t') = -i \sum_q \bar{f}(\epsilon_q) e^{-i\epsilon_q(t-t')} \langle i|q\rangle \langle q|j\rangle, \quad (20)$$

where ϵ_p is the energy of the one-particle eigenstate $|p\rangle$, f is the zero-temperature Fermi function, and $\bar{f} = 1 - f$. Taking into account that $f^2(\epsilon_p) = f(\epsilon_p)$ and $\bar{f}^2(\epsilon_q) = \bar{f}(\epsilon_q)$ one can easily verify that

$$\sum_q g_{yq}^>(t_y, \tau) g_{qx}^>(\tau, t_x) = -i g_{yx}^>(t_y, t_x), \quad (21)$$

$$\sum_p g_{xp}^<(t_x, \tau) g_{py}^<(\tau, t_y) = i g_{xy}^<(t_x, t_y). \quad (22)$$

When taking the product of the left and the right half-diagram in Fig. 2 we can use relation (21) to replace each of the N products of $g^>$ functions by a single $g^>$ connecting two internal times in each half-diagram. Similarly we can use relation (22) to replace each of the $N + 1$ products of a $g^<$ by a single $g^<$. The result of this gluing procedure is a diagram with external vertices 1 and 2. The structure of the diagram is such that all internal vertices to the left of the glued lines have time labels on the minus branch and all internal vertices to the right of the glued lines have time labels on the plus branch. The gluing procedure can be reversed by cutting all Green's function lines between a vertex labeled $-$ and a vertex labeled $+$. We will refer to this procedure as the *cutting rule* for a diagram.

At this point we observe that the self-energy in Eq. (15) is not the sum of all possible S - S^* diagrams due to the subscript irr. This means that from the diagrams obtained by the gluing procedure we still have to remove the reducible diagrams, i.e., the diagrams which fall apart into two disjoint pieces by cutting a single Green's function line. An obvious case of a reducible diagram is when there is only a single line to glue in Fig. 2. This happens when $N = 0$ and we only have the single label p_1 . This case is easily taken care of by letting the sum in Eq. (15) start at $N = 1$ instead. For $N > 1$ the gluing procedure leads to reducible diagrams whenever the S diagram can be separated into a piece which contains *only* vertex 1 and a piece which contains the pq vertices by cutting a single Green's function line. We call these S diagrams reducible and define \tilde{S} as the sum of irreducible S diagrams. Note that the \tilde{S} diagrams *can* be separated into two disjoint pieces by cutting a single Green's function line, but then one of the pieces would contain 1 *and* some of the pq vertices. For instance, half-diagrams with a self-energy insertion on the lines we glue together belong to \tilde{S} . An example is shown in Fig. 3 where a tadpole is inserted into one of the p lines. This half-diagram can be separated into disjoint pieces by a single cut but then the vertex 1 would not be isolated from all the pq . Consequently this half-diagram belongs to \tilde{S} and produces irreducible diagrams for the self-energy. From this

FIG. 3. (Color online) Minimal example of irreducible S^* diagram with self-energy insertions. When glued with some irreducible S diagram it yields an irreducible self-energy diagram. Notice that this diagram is reducible in the “correlation function” sense because cutting a single Green's function line produces disconnected pieces.

analysis we conclude that the self-energy can be written as

$$\Sigma_c^<(1,2) = i \sum_{N=1}^{\infty} \frac{1}{(N+1)!N!} \sum_{pq} \tilde{S}_{N,pq}(2) \tilde{S}_{N,pq}^*(1). \quad (23)$$

Equation (23) is the Lehmann-like representation of the self-energy and the main result of this section. The irreducible part of products in Eq. (15) has been transformed into products of irreducible parts in Eq. (23). The product of a \tilde{S} diagram and a \tilde{S}^* diagram yields an irreducible self-energy diagram in which the internal times are either integrated over the minus branch or over the plus branch. We call this product a *partition* of the self-energy diagram. It is now easy to show that the Fourier transform of $-i\Sigma_c^<$ has the PSD property. Fourier transforming \tilde{S} and \tilde{S}^* and omitting the dependence on the position-spin variables we find

$$-i\Sigma_c^<(1,2) = \sum_{N=1}^{\infty} \frac{1}{(N+1)!N!} \int \frac{d\omega}{2\pi} \frac{d\omega'}{2\pi} \times e^{-i\omega t_2 + i\omega' t_1} \sum_{pq} \tilde{S}_{N,pq}(\omega) \tilde{S}_{N,pq}^*(\omega'). \quad (24)$$

In this equation the Fourier transform of $\tilde{S}(t_2)$ [and similarly of $\tilde{S}^*(t_1)$] is performed over the time argument t_2 and not over the time difference $t_2 - \tau$, which is ill-defined for $\tau \rightarrow \infty$. For the right-hand side to depend only on $t_1 - t_2$ the following property:

$$\sum_{N=1}^{\infty} \frac{1}{(N+1)!N!} \sum_{pq} \tilde{S}_{N,pq}(\omega) \tilde{S}_{N,pq}^*(\omega') = \mathcal{F}(\omega) \delta(\omega - \omega')$$

has to be fulfilled. Since for $\omega = \omega'$ the left-hand side is the sum of modulus squares we have that $\mathcal{F}(\omega) \geq 0$, and inserting this result back into Eq. (24) we see that $\mathcal{F}(-\omega)$ is the Fourier transform of the function $-i\Sigma_c^<(1,2)$ with respect to the time difference $t_1 - t_2$.

So far we have restricted ourselves to the exact self-energy. In the following section we will explain how a given approximate diagrammatic expression for the self-energy can be extended, if necessary, to a similar form as in Eq. (23) by an appropriate selection of additional half-diagrams, thereby ensuring the positivity of its spectral function.

B. Diagrammatic theory of positive spectral functions

The Lehmann-like representation of Eq. (23) brings to light a general and simple rule to calculate the lesser component of a self-energy diagram. A diagram for $\Sigma_c^<(1,2)$ has two external vertices, one with time t_1 on the minus branch and the other with time t_2 on the plus branch, and a certain number of internal vertices with times to be integrated over the Keldysh contour. If we assign to each internal vertex a $-$ or a $+$ sign to signify that the corresponding time is integrated over the minus or plus branch then we obtain a division of the original self-energy diagram, and the full self-energy diagram is the sum of all of them. Since the two-particle interaction is local in time, i.e.,

$$v(\mathbf{x}_1 t_1, \mathbf{x}_2 t_2) = v(\mathbf{x}_1, \mathbf{x}_2) \delta(t_2 - t_1),$$

it only connects two vertices with times on the same branch of the Keldysh contour. Since the external vertices are fixed there are 2^{n-2} divisions ($n \geq 2$) for a diagram with n interaction lines. However, not all such divisions contribute. As shown in Fig. 2 and in Eq. (23) the only divisions appearing in the expansion of the self-energy are those in which one side of the diagram only contains “ $-$ ” vertices and the other side of the diagram only contains “ $+$ ” vertices. All other divisions can therefore be discarded since they sum up to zero. These are the divisions for which we get a piece disconnected from the external vertices 1 and 2 upon cutting the $+/-$ g lines (hence these divisions cannot be written as the product of a \tilde{S} - \tilde{S}^* diagram). The number of contributing divisions clearly depends on the topological structure of the diagram. In Sec. II A we called such divisions partitions. As an example consider the $\Sigma_c^<$ diagram shown in Fig. 4. The third division vanishes since we get a piece disconnected from 1 and 2 upon cutting the $+/-$ g lines. This simple diagrammatic rule to extract the lesser self-energy can be viewed as a generalization of the Langreth rules [34] to diagrams which are neither a product nor a convolution of Green’s functions [13]. The same diagrammatic rule can alternatively be derived by working in frequency space and by taking into account the conservation of energy at each vertex [25,26]. As a side remark we observe that according to this diagrammatic rule there exists only one partition in a *time-ordered* diagram (i.e., a diagram where

FIG. 4. (Color online) An example of the distribution of $+$ and $-$ labels over the internal vertices of a lesser fourth-order self-energy diagram. Divisions with lines v^{+-} or v^{-+} vanish due to the time locality of the interaction and therefore are not shown. The third term after the equality sign must be discarded because it contains an isolated island of plus signs upon cutting the $+/-$ g lines (see explanation in the text).

the times of the external vertices 1 and 2 are both $-$). In fact, a division with one or more vertices on the plus branch inevitably generates disconnected pieces. Only the division with all internal vertices on the minus branch is a partition, and consequently in this partition all internal Green’s functions are time-ordered G ’s. We thus recover the standard rule of the zero-temperature formalism. Such simplification does not occur in lesser (or greater) diagrams where all four Green’s functions $G^{\alpha\beta}$ are needed.

There remains one issue to address before introducing our diagrammatic theory of PSD spectral functions: How many \tilde{S} - \tilde{S}^* diagrams do lead to the same partition of a self-energy diagram? To answer this question we need to investigate the expansion of \tilde{S} in terms of Feynman diagrams. Due to the anticommutation rules for the creation and annihilation operators it follows from the definition of $S_{N,pq}$ in Eq. (18) that a permutation P of the labels \underline{p} and a permutation Q of the labels \underline{q} simply changes the sign of $S_{N,pq}$, and hence also $\tilde{S}_{N,pq}$, by a factor $(-1)^{P+Q}$. Therefore, if we let $\{D_{\underline{pq}}^{(j)}\}$ with $j \in \overline{1}_N$ be the set of all topologically inequivalent diagrams for $\tilde{S}_{N,pq}$ that differ by more than a permutation of the \underline{p} or \underline{q} labels, then we can write

$$\tilde{S}_{N,pq} = \sum_{j \in \overline{1}_N} \sum_{\substack{P \in \pi_{N+1} \\ Q \in \pi_N}} (-1)^{P+Q} D_{P(\underline{p})Q(\underline{q})}^{(j)}, \quad (25)$$

where P and Q run over all permutations π_{N+1} and π_N of $N+1$ and N indices, respectively. Inserting Eq. (25) back into Eq. (23) we find

$$\begin{aligned} \Sigma_c^<(1,2) &= i \sum_{N=1}^{\infty} \sum_{j_1, j_2 \in \overline{1}_N} \sum_{\substack{P_1, P_2 \in \pi_{N+1} \\ Q_1, Q_2 \in \pi_N}} \frac{(-1)^{P_1+Q_1+P_2+Q_2}}{(N+1)!N!} \\ &\times \sum_{\underline{pq}} D_{P_2(\underline{p})Q_2(\underline{q})}^{(j_2)}(2) D_{P_1(\underline{p})Q_1(\underline{q})}^{(j_1)*}(1). \end{aligned} \quad (26)$$

This expression can be simplified further by noticing that the composite permutations $P \circ P_i$ and $Q \circ Q_i$ with $i = 1, 2$ yield the same contribution as the permutations P_i and Q_i , i.e.,

$$\begin{aligned} D_{P \circ P_2(\underline{p})Q \circ Q_2(\underline{q})}^{(j_2)}(2) D_{P \circ P_1(\underline{p})Q \circ Q_1(\underline{q})}^{(j_1)*}(1) \\ = D_{P_2(\underline{p})Q_2(\underline{q})}^{(j_2)}(2) D_{P_1(\underline{p})Q_1(\underline{q})}^{(j_1)*}(1), \end{aligned} \quad (27)$$

since the effect of P and Q is equivalent to a relabeling of the \underline{p} and \underline{q} . There are $N!(N+1)!$ such relabelings and they all give the same contribution. We can therefore simplify Eq. (26) to

$$\begin{aligned} \Sigma_c^<(1,2) &= i \sum_{N=1}^{\infty} \sum_{j_1, j_2 \in \overline{1}_N} \sum_{\substack{P_1 \in \pi_{N+1} \\ Q_1 \in \pi_N}} (-1)^{P_1+Q_1} \\ &\times \sum_{\underline{pq}} D_{\underline{pq}}^{(j_2)}(2) D_{P_1(\underline{p})Q_1(\underline{q})}^{(j_1)*}(1). \end{aligned} \quad (28)$$

Every term of the form $\sum_{\underline{pq}} D_{\underline{pq}}^{(j_2)}(2) D_{P_1(\underline{p})Q_1(\underline{q})}^{(j_1)*}(1)$ in Eq. (28) corresponds to a unique partition of a $\Sigma_c^<$ diagram. Vice versa, every partition of a $\Sigma_c^<$ diagram can be written as the product of a unique D - D^* diagram, otherwise there should

FIG. 5. (Color online) An approximate self-energy of many-body perturbation theory.

exist more than one way to cut the self-energy along the $+/-g$ lines.

Equation (28) is an exact rewriting of $\Sigma_c^<$ in terms of D diagrams. MBPT approximations to the self-energy consist of the sum of a (finite or infinite) subset of diagrams. An exotic approximation could be, e.g., the one of Fig. 5. Each diagram contains four interaction lines ($n = 4$) and, therefore, it is divided in $2^{n-2} = 4$ different ways. It is a simple exercise to see that the left diagram is the sum of three partitions with three $+/-g$ lines and one partition with five $+/-g$ lines, whereas the right diagram is the sum of two partitions with three $+/-g$ lines and two partitions with five $+/-g$ lines. In Fig. 6 we display, e.g., all partitions with five $+/-g$ lines [$N = 2$ in Eq. (28)] and how to write them as D - D^* diagrams. There are two different D diagrams, say $D^{(a)}$ and $D^{(b)}$, which are glued as

$$\sum_{\frac{pq}{pq}} [D_{p_1 p_2 p_3 q_1 q_2}^{(a)}(2) (D_{p_1 p_2 p_3 q_1 q_2}^{(b)*}(1) - D_{p_1 p_2 p_3 q_2 q_1}^{(b)*}(1)) - D_{p_1 p_2 p_3 q_1 q_2}^{(b)}(2) D_{p_1 p_2 p_3 q_2 q_1}^{(a)*}(1)].$$

The products of the half-diagrams is represented in the same order as they appear in this mathematical expression in Fig. 6 after the equality sign. The diagrams $D^{(b)}$ in the first line differ only in a permutation of the labels q_1 and q_2 as shown in the left

FIG. 6. (Color online) Partitions of the self-energy diagrams of Fig. 5 with five $+/-g$ lines and decomposition in terms of D - D^* diagrams.

half-diagrams of Fig. 6. Furthermore, the right half-diagram of the first term ($D^{(a)}$) and the left half-diagram of the last term ($D^{(a)*}$) have the same topological structure but differ in the labeling of q_1 and q_2 .

This example is instructive since it highlights the general structure of a MBPT approximation to the self-energy. The partitioning leads to an expression of the form of Eq. (28) where the domains of the summation indices and the set of permutations are restricted. The couple (j_1, j_2) runs over a subset $\mathcal{I}_N \subset I_N \times I_N$ of the product set of the topologically inequivalent half-diagrams. In the example of Fig. 6 we have $\mathcal{I}_2 = \{(a,b), (b,a)\}$. Given the couple $(j_1, j_2) \in \mathcal{I}_N$ the permutations P_1 and Q_1 run over a subset $\pi_{N+1,p}^{(j_1, j_2)} \subset \pi_{N+1}$ and $\pi_{N,q}^{(j_1, j_2)} \subset \pi_N$ of the permutation groups π_{N+1} and π_N . In the example of Fig. 6 for the couple (b,a) (the first two terms after the equality sign) we have the subsets $\pi_{3,p}^{(ba)} = \{1\}$ and $\pi_{2,q}^{(ba)} = \{1, Q\}$ with $Q(q_1, q_2) = (q_2, q_1)$, whereas for the couple (a,b) (the last term after the equality sign) we have the subsets $\pi_{3,p}^{(ab)} = \{1\}$ and $\pi_{2,q}^{(ab)} = \{Q\}$. In Fig. 6 we considered in detail the D - D^* diagrams of the self-energy of Fig. 5 belonging to the set \mathcal{I}_2 . The set \mathcal{I}_N in which we cut three $+/-g$ lines can be analyzed similarly. All other sets \mathcal{I}_N with $N > 2$ are empty in this case. In general, however, we have for an approximate MBPT self-energy

$$\Sigma_c^<(1,2) = i \sum_{N=1}^{\infty} \sum_{(j_1, j_2) \in \mathcal{I}_N} \sum_{\substack{P_1 \in \pi_{N+1,p}^{(j_1, j_2)} \\ Q_1 \in \pi_{N,q}^{(j_1, j_2)}}} (-)^{P_1 + Q_1} \times \sum_{\frac{pq}{pq}} D_{pq}^{(j_2)}(2) D_{P_1(p)Q_1(q)}^{(j_1)*}(1), \quad (29)$$

where the sets \mathcal{I}_N may contain zero, a finite, or an infinite number of elements.

An important remark to be made regarding Eq. (29) is that it does not, in general, fulfill the PSD property. Our analysis shows, however, how to formulate the diagrammatic rules to transform a MBPT self-energy into a PSD self-energy by adding the minimal number of partitions. For the PSD property to be fulfilled the self-energy should have the structure of Eq. (23) with some approximate $\tilde{S}_{N,pq}$. Let $\tilde{I}_N \subset I_N$ be the smallest subset such that

$$\tilde{I}_N \times \tilde{I}_N \supset \mathcal{I}_N, \quad (30)$$

and $\tilde{\pi}_{N+1,p}$ and $\tilde{\pi}_{N,q}$ be the smallest *subgroups* of the permutation groups π_{N+1} and π_N with the property

$$\tilde{\pi}_{N+1,p} \supset \bigcup_{(j_1, j_2) \in \mathcal{I}_N} \pi_{N+1,p}^{(j_1, j_2)}, \quad (31)$$

$$\tilde{\pi}_{N,q} \supset \bigcup_{(j_1, j_2) \in \mathcal{I}_N} \pi_{N,q}^{(j_1, j_2)}. \quad (32)$$

Mathematically $\tilde{\pi}_{N+1,p}$ and $\tilde{\pi}_{N,q}$ are given by the *intersection* of all subgroups containing the subsets $\pi_{N+1,p}^{(j_1, j_2)}$ and $\pi_{N,q}^{(j_1, j_2)}$. The

self-energy

$$\begin{aligned} \Sigma_{c,\text{PSD}}^<(1,2) &= i \sum_{N=1}^{\infty} \sum_{j_1, j_2 \in \tilde{I}_N} \sum_{\substack{P_1 \in \tilde{\pi}_{N+1,p} \\ Q_1 \in \tilde{\pi}_{N,q}}} (-)^{P_1+Q_1} \\ &\times \sum_{\underline{pq}} D_{\underline{pq}}^{(j_2)}(2) D_{P_1(\underline{p})Q_1(\underline{q})}^{(j_1)*}(1) \end{aligned} \quad (33)$$

contains all partitions of Eq. (29) plus other partitions, and each partition is counted only once. Furthermore, taking into account that $\tilde{\pi}_{N+1,p}$ and $\tilde{\pi}_{N,q}$ are two subgroups, Eq. (27) is valid for all $P \in \tilde{\pi}_{N+1,p}$ and $Q \in \tilde{\pi}_{N,q}$. Hence we can rewrite Eq. (33) to bring out its product structure. We have

$$\begin{aligned} \Sigma_{c,\text{PSD}}^<(1,2) &= i \sum_{N=1}^{\infty} \sum_{j_1, j_2 \in \tilde{I}_N} \sum_{\substack{P_1, P_2 \in \tilde{\pi}_{N+1,p} \\ Q_1, Q_2 \in \tilde{\pi}_{N,q}}} \frac{(-)^{P_1+Q_1+P_2+Q_2}}{d_{N+1,p} d_{N,q}} \\ &\times \sum_{\underline{pq}} D_{P_2(\underline{p})Q_2(\underline{q})}^{(j_2)}(2) D_{P_1(\underline{p})Q_1(\underline{q})}^{(j_1)*}(1), \end{aligned} \quad (34)$$

where $d_{N+1,p}$ and $d_{N,q}$ are the dimensions of the subgroups $\tilde{\pi}_{N+1,p}$ and $\tilde{\pi}_{N,q}$ respectively. The self-energy in Eq. (34) has the same mathematical structure of the exact self-energy in Eq. (26). Since the Fourier transform is a sum of modulus squares the self-energy in Eq. (34) is PSD. It is also clear that any reduction of the sets \tilde{I}_N , $\tilde{\pi}_{N+1,p}$, and $\tilde{\pi}_{N,q}$ would either not include the original MBPT diagrams or would not fulfill the PSD property [35]. Thus Eq. (34) contains the minimal number of partitions of self-energy diagrams to correct the MBPT self-energy.

This concludes the diagrammatic theory to generate PSD spectral functions. In the next sections we work out explicitly some textbook examples and derive the leading PSD self-energy diagrams with *vertex corrections* and *screened interaction*, thus going beyond the *GW* approximation.

C. Self-consistency

Before we discuss some examples in detail we would first like to address the issue of self-consistency which plays an important role in the so-called conserving approximations [2,36]. So far we used the noninteracting Green's functions g to evaluate the diagrams. Suppose that a specific selection of partitions guarantees the positivity of the spectral function for $\Sigma_{c,\text{PSD}}^{\geq}[g]$, where we indicate explicitly the functional dependence of the self-energy on g . Then we can use this self-energy in the Dyson equation to evaluate a new Green's function, which we may call G to distinguish it from the noninteracting g . In the next step we can evaluate our approximate diagrammatic expression for the self-energy in terms of G , i.e., we evaluate $\Sigma_{c,\text{PSD}}^{\geq}[G]$. The natural question to ask then is whether $\Sigma_{c,\text{PSD}}^{\geq}[G]$ still has the PSD property. We now demonstrate that this is indeed the case by a modification of the derivation in Secs. II A and II B.

The largest modification involves relations (21) and (22) since they are not valid anymore for general dressed Green's functions. This is, for example, easily demonstrated for the exact interacting lesser Green's function of an N -particle system with ground state energy E_0 , which has the Lehmann

representation

$$G_{\mathbf{xx}'}^<(t,t') = i \sum_{\alpha} e^{-i\Omega_{\alpha}(t-t')} f_{\alpha}(\mathbf{x}) f_{\alpha}^*(\mathbf{x}'). \quad (35)$$

Here α labels the many-body eigenstates $\Psi_{\alpha,N-1}$ with energy $E_{\alpha,N-1}$ of the system with $N-1$ particles, $\Omega_{\alpha} = E_{\alpha,N-1} - E_{0,N}$ are the removal energies, and $f_{\alpha}(\mathbf{x}) = \langle \Psi_{\alpha,N-1} | \hat{\psi}(\mathbf{x}) | \Psi_0 \rangle$ are the so-called Dyson orbitals. Although the Lehmann representation (35) looks formally identical to the expansion in Eq. (19) for g , it does not allow us to derive Eq. (21) anymore since the nonvanishing $f_{\alpha}(\mathbf{x})$ form an overcomplete and nonorthonormal one-particle basis set [in a noninteracting system most $f_{\alpha}(\mathbf{x})$ are zero and the nonvanishing ones form an orthonormal basis set]. Our strategy, therefore, is to replace Eqs. (19) and (20) with a different relation that still allows us to formulate a cutting rule. Crucial in our reasoning is that a PSD self-energy generates a PSD spectral function for G , as was explained just below Eq. (8). This implies that $G^<$ has the form

$$G_{\mathbf{xx}'}^<(t,t') = i \int \frac{d\omega}{2\pi} A_{\mathbf{xx}'}^<(\omega) e^{-i\omega(t-t')},$$

where the removal part of the spectral function $A_{\mathbf{xx}'}^<(\omega) \equiv f(\omega) A_{\mathbf{xx}'}(\omega)$ is a self-adjoint and PSD matrix in the one-particle indices for every ω . Denoting by $\langle \mathbf{x} | a_i(\omega) \rangle$ the eigenstates of $A_{\mathbf{xx}'}^<(\omega)$ with eigenvalue $a_i(\omega)$, the spectral representation of this matrix can be written as

$$A_{\mathbf{xx}'}^<(\omega) = \sum_i \langle \mathbf{x} | a_i(\omega) \rangle a_i(\omega) \langle a_i(\omega) | \mathbf{x}' \rangle.$$

Without loss of generality we shall assume that the eigenstates $|a_i(\omega)\rangle$ form an orthonormal basis set for every ω . Due to the PSD property of $A^<$ the eigenvalues $a_i \geq 0$, and therefore we can define the square root of the spectral function according to

$$\sqrt{A^<}_{\mathbf{xx}'}(\omega) = \sum_i \langle \mathbf{x} | a_i \rangle \sqrt{a_i} \langle a_i | \mathbf{x}' \rangle,$$

where for notational convenience we suppressed the ω dependence of the eigenvalues and eigenvectors. Correspondingly we can define the square root of the lesser Green's function according to

$$\sqrt{G^<}_{\mathbf{xx}'}(t,t') = i \int \frac{d\omega}{2\pi} \sqrt{A^<}_{\mathbf{xx}'}(\omega) e^{-i\omega(t-t')}.$$

This function has the property that

$$i G_{\mathbf{xx}'}^<(t,t') = \int dy d\bar{t} \sqrt{G^<}_{\mathbf{xy}}(t,\bar{t}) \sqrt{G^<}_{\mathbf{yx}'}(\bar{t},t') \quad (36)$$

as follows from a quick calculation using the definitions above. Similarly $G^>$ is the integral over a positive spectral function, and we can therefore define the square root $\sqrt{G^>}$ with the property that

$$-i G_{\mathbf{xx}'}^>(t,t') = \int dy d\bar{t} \sqrt{G^>}_{\mathbf{xy}}(t,\bar{t}) \sqrt{G^>}_{\mathbf{yx}'}(\bar{t},t'). \quad (37)$$

The relations (36) and (37) provide a new cutting rule for a self-energy diagram with a dressed Green's function. Whenever we cut a self-energy diagram we obtain half-diagrams with outgoing lines $\sqrt{G^<}$ and $\sqrt{G^>}$. Using these modified half-diagrams we obtain an equation that is identical in structure

to Eq. (33). The only thing that changes in Eq. (33) is that the sums over pq are replaced by integrals over \mathbf{y} 's and \bar{t} 's. However, this does not change the quadratic structure of the equation. We therefore conclude that $\Sigma_{c,\text{PSD}}^<[G]$ also is PSD. From this new self-energy we can use the Dyson equation to calculate a new Green's function which has again a PSD spectral function and can be decomposed as in Eqs. (36) and (37), thereby yielding yet another PSD self-energy. By repeating the procedure we obtain a series of PSD Green's functions. If this series converges to a limiting Green's function then we have solved the Dyson equation self-consistently for our approximate $\Sigma_{c,\text{PSD}}^<$ in which both the Green's function and the self-energy are PSD.

The conclusion of this analysis is that our diagrammatic approach to PSD spectral functions also applies to self-consistent perturbation theory. Of course, in order to avoid double countings, the partitions of which $\Sigma_{c,\text{PSD}}^<$ is made of should be skeletal, i.e., should not contain self-energy insertions [2]. An important approximation that has this structure is the GW approximation which we study in more detail below. In general, however, it should be emphasized that a PSD self-energy made exclusively of all the partitions of conserving diagrams is rare. In fact, approximations which are simultaneously conserving and PSD are exceptional.

III. EXAMPLES

In this section we apply the formalism developed in Sec. II to some illustrative examples.

A. Single bubble diagram

Let us first consider the first bubble diagram shown in Fig. 7(a). The lesser component of this self-energy reads

$$\begin{aligned} \Sigma_c^<(1,2) &= \int d\mathbf{x}_3 \int d\mathbf{x}_4 v(\mathbf{x}_1, \mathbf{x}_3) g_{\mathbf{x}_1 \mathbf{x}_2}^<(t_1, t_2) \\ &\quad \times g_{\mathbf{x}_3 \mathbf{x}_4}^<(t_1, t_2) g_{\mathbf{x}_4 \mathbf{x}_3}^>(t_2, t_1) v(\mathbf{x}_2, \mathbf{x}_4), \end{aligned} \quad (38)$$

which can be partitioned in only one way. Upon cutting along the $+/-$ g lines we find

$$\Sigma_c^<(1,2) = i \sum_{pq} D_{p_1 p_2 q_1}^{(a)}(2) D_{p_1 p_2 q_1}^{(a)*}(1), \quad (39)$$

where the D diagram reads

$$\begin{aligned} D_{p_1 p_2 q_1}^{(a)*}(1) &= \int d\mathbf{x}_3 v(\mathbf{x}_1, \mathbf{x}_3) g_{\mathbf{x}_1 p_1}^<(t_1, \tau) \\ &\quad \times g_{\mathbf{x}_3 p_2}^<(t_1, \tau) g_{q_1 \mathbf{x}_3}^>(\tau, t_1). \end{aligned} \quad (40)$$

Equation (39) is already of the form in Eq. (33) and therefore the first bubble diagram produces a PSD spectrum.

B. Second-order exchange

The exchange diagram of the first bubble diagram is shown in Fig. 7(b) and the application of the formalism is more interesting. The lesser component of the self-energy now reads

$$\begin{aligned} \Sigma_c^<(1,2) &= - \int d\mathbf{x}_3 \int d\mathbf{x}_4 v(\mathbf{x}_1, \mathbf{x}_3) g_{\mathbf{x}_1 \mathbf{x}_4}^<(t_1, t_2) \\ &\quad \times g_{\mathbf{x}_4 \mathbf{x}_3}^>(t_2, t_1) g_{\mathbf{x}_3 \mathbf{x}_2}^<(t_1, t_2) v(\mathbf{x}_4, \mathbf{x}_2). \end{aligned}$$

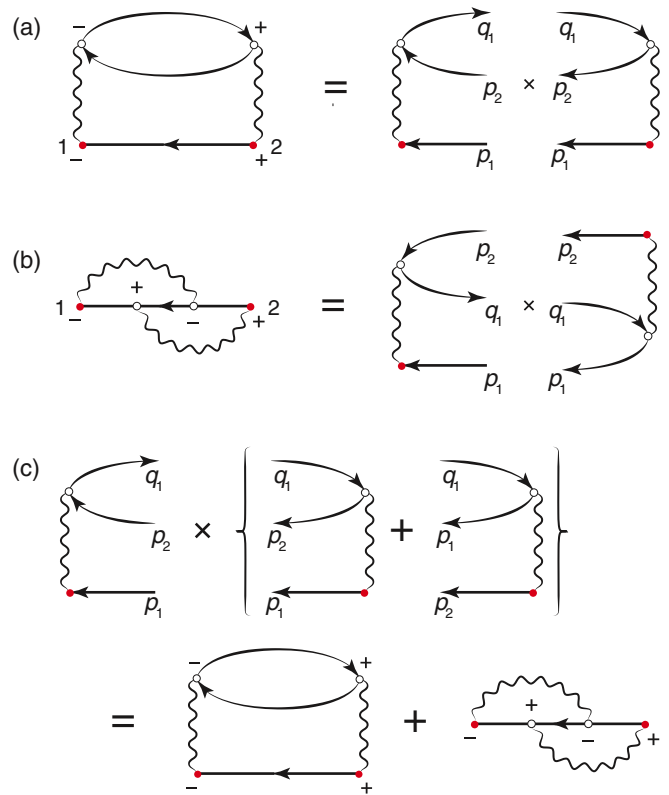

FIG. 7. (Color online) (a) Partition of the first bubble diagram and the resulting half-diagrams. (b) Partition of the second-order exchange diagram and the resulting half-diagrams. (c) In order to form a complete square with the second-order exchange diagram we need to add the right half-diagram with permuted p_1 and p_2 labels. This yields the 2B approximation.

This diagram too can be partitioned in only one way. However, upon cutting the $+/-$ g lines we find a product of D diagrams differing by a permutation $P(p_1, p_2) = (p_2, p_1)$,

$$\Sigma_c^<(1,2) = i \sum_{pq} (-)^P D_{p_1 p_2 q_1}^{(a)}(2) D_{p_2 p_1 q_1}^{(a)*}(1),$$

where $D_{p_1 p_2 q_1}^{(a)}$ is the same as in Eq. (40). Thus the second-order exchange self-energy is not PSD. This is the simplest example of a conserving self-energy which is not PSD, see the discussion in the last paragraph of Sec. II C. The smallest subgroup of π_2 which contains P is π_2 itself and the domain $j_1 = a$ and $j_2 = a$ is already of the form $\tilde{I}_1 \times \tilde{I}_1$. Therefore, we can form a PSD self-energy by taking $\tilde{I}_1 = \{a\}$, $\tilde{\pi}_{2,p} = \pi_2$, and $\tilde{\pi}_{1,q} = \{1\} = \pi_1$. In this way we end up with the diagrams shown in Fig. 7(c). This is the second-Born (2B) approximation, which we have now shown to give a PSD spectrum. The second-order exchange diagram is particularly instructive since it shows that the PSD outcome of the sum of MBPT diagrams is not the sum of the PSD outcome of the MBPT diagrams taken separately. Indeed the PSD outcome of the first-bubble diagram is the first-bubble diagram itself, whereas the PSD outcome of the second-order exchange diagram is the 2B approximation. This implies that if we had summed the PSD outcomes of these two separate diagrams we would have counted the first-bubble diagram twice. No

double counting occurs if we apply the rules in Eqs. (30)–(32) to the 2B approximation; the PSD outcome would be the 2B approximation itself.

C. Two bubbles

As a third example let us consider another conserving approximation which consists in the sum of the first- and second-bubble diagrams as shown in Fig. 8(a). After distributing the pluses and minuses over the internal vertices we find that the lesser self-energy diagram can be written in terms of two types of D diagrams,

$$\Sigma_c^<(1,2) = i \sum_{pq} [D_{p_1 p_2 q_1}^{(a)}(2) D_{p_1 p_2 q_1}^{(a)*}(1) + D_{p_1 p_2 q_1}^{(b)}(2) D_{p_1 p_2 q_1}^{(a)*}(1) + D_{p_1 p_2 q_1}^{(a)}(2) D_{p_1 p_2 q_1}^{(b)*}(1)].$$

The three D - D^* diagrams in this expression are represented in the bottom line of Fig. 8(a). We observe that the only permutation appearing is the identity permutation. Therefore, according to the rules in Eqs. (30)–(32), we only need to find the smallest \tilde{I}_1 such that $\tilde{I}_1 \times \tilde{I}_1 \supset \{(a,a), (a,b), (b,a)\}$. This is simply $\tilde{I}_1 = \{a,b\}$. Thus the PSD outcome of the self-energy is

$$\Sigma_{c,\text{PSD}}^<(1,2) = \sum_{j_1, j_2 \in \tilde{I}_1} \sum_{pq} D_{p_1 p_2 q_1}^{(j_2)}(2) D_{p_1 p_2 q_1}^{(j_1)*}(1)$$

and the corresponding diagrams are shown in Fig. 8(b). In accordance with our notation a diagram with no plus/minus on

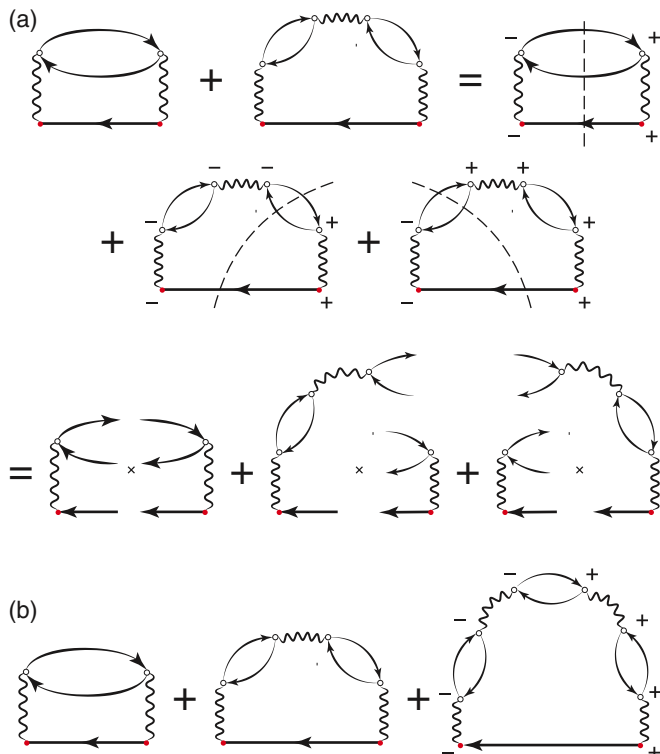

FIG. 8. (Color online) (a) Partitions of the first and second bubble diagrams and the resulting half-diagrams. (b) The minimal completion of the square which yields a PSD spectrum.

the internal vertices represents the full diagram, i.e., the sum of all possible partitions.

D. GW and T -matrix approximations

Unlike the conserving “second-order exchange” and “two bubbles” approximations the GW and T -matrix approximations are both conserving and PSD. Let us start from the GW approximation. We take the RPA $W = v + vPW$ with

$$P_{\mathbf{x}_1 \mathbf{x}_2}(z_1, z_2) = -i g_{\mathbf{x}_1 \mathbf{x}_2}(z_1, z_2) g_{\mathbf{x}_2 \mathbf{x}_1}(z_2, z_1). \quad (41)$$

Then

$$W^< = v(P^< + P^{--}vP^< + P^<vP^{++} + P^{--}vP^{--}vP^< + P^{--}vP^<vP^{++} + P^<vP^{++}vP^{++} + \dots)v, \quad (42)$$

where we took into account that if P^{++} appears to the left of $P^<$ and/or P^{--} appears to the right of $P^<$ then the division is not a partition since a cut along the $+/-g$ lines generates a disconnected $+$ and/or $-$ island, see Sec. II B. It is a matter of simple algebra to prove that

$$\Sigma_{\text{GW}}^<(1,2) \equiv i g^<(1,2) W^<(1,2) = i \sum_{j_1, j_2=1}^{\infty} \sum_{pq} D_{p_1 p_2 q_1}^{(j_2)}(2) D_{p_1 p_2 q_1}^{(j_1)*}(1), \quad (43)$$

where the diagrams $D^{(j)}$ are defined as in Fig. 9(a). Equation (43) is clearly of the form in Eq. (33). In a similar fashion it can be shown that the symmetrized version of the T -matrix approximation also has the PSD property since it can be written as in the second row of Eq. (43) with D diagrams given in Fig. 9(b).

IV. PSD SELF-ENERGY BEYOND GW

The GW self-energy is the leading order approximation in the screened interaction W [3,37,38]. Despite the numerous successful applications of the GW approximation in reproducing experimental spectra, there is also a commensurable number of examples for which the GW approximation fails, pointing out the importance of including vertex corrections. The next to leading order approximation in the RPA W is represented by the diagram Σ_{vert} of Fig. 10 and contains

FIG. 9. (Color online) (a) Bubble half-diagrams of the GW approximation. (b) Ladder half-diagrams of the T -matrix approximation.

FIG. 10. (Color online) Next to leading order self-energy in the screened interaction W . Since W is nonlocal in time, the thick wavy lines denoting the screened interaction can connect points on different branches of the Keldysh contour.

a vertex correction. Unfortunately the self-energy $\Sigma_{GW+v} \equiv \Sigma_{GW} + \Sigma_{\text{vert}}$ is not PSD and the resulting spectral function has the undesired feature of being negative in some region of the frequency space. In this section we use the rules of Eqs. (30)–(32) to construct the leading order beyond- GW self-energy with an RPA screened interaction and the PSD property.

On the right-hand side of Fig. 10 the self-energy Σ_{vert} is written as the sum of four partitions. Let us determine the underlying D diagrams. We observe that the screened interactions W^{++} or W^{--} can be partitioned in only one way with all internal polarizations P^{++} or P^{--} . Indeed a partition of W^{++} in which appears a $P^>$ does necessarily contain also a $P^<$ and hence the cut along the $+/-$ g lines would generate a disconnected island. A similar argument applies to W^{--} . Accordingly the first diagram on the right-hand side of Fig. 10 is the sum of the partitions shown in Fig. 11(a), and can be written as the sum of products between the $D^{(j)}$ diagrams of the GW approximation, see Fig. 9(a), and the $\tilde{D}^{(j)}$ diagrams displayed in Fig. 11(b). The same is true for the second diagram of Fig. 10 provided we exchange $D^{(j)}$ with $\tilde{D}^{(j)}$. The partitions of the third diagram of Fig. 10 are very simple due to the presence of only W^{++} and W^{--} , see Fig. 12. The result is the

FIG. 11. (Color online) (a) Partitions of the first diagram on the right-hand side of Fig. 10. (b) Definition of the $\tilde{D}^{(j)}$ diagrams.

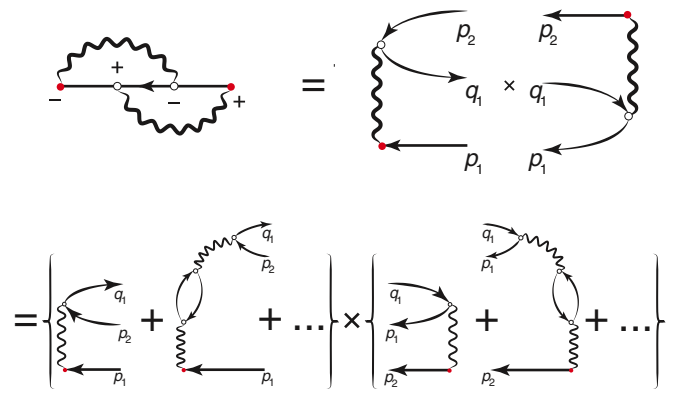

FIG. 12. (Color online) Partitions of the third diagram on the right-hand side of Fig. 10.

sum of products between $D^{(j)}$ diagrams and permuted $D^{(j)}$ diagrams. Finally, the fourth diagram of Fig. 10 is partitioned as illustrated in Fig. 13(a), and can be written as the sum of products between two $D^{(ij)}$ diagrams, see Fig. 13(b), where i refers to the number of top bubbles and j to the number of bottom bubbles. In conclusion (omitting the dependence on 1 and 2)

$$\begin{aligned} \Sigma_{GW+v}^< &= i \sum_{j_1 j_2=1}^{\infty} \sum_{pq} (D_{p_1 p_2 q_1}^{(j_2)} D_{p_1 p_2 q_1}^{(j_1)*} + D_{p_1 p_2 q_1}^{(j_2)} \tilde{D}_{p_1 p_2 q_1}^{(j_1)*} \\ &+ \tilde{D}_{p_1 p_2 q_1}^{(j_2)} D_{p_1 p_2 q_1}^{(j_1)*} - D_{p_1 p_2 q_1}^{(j_2)} D_{p_2 p_1 q_1}^{(j_1)*}) \\ &+ i \sum_{i_1 j_1 i_2 j_2=1}^{\infty} \sum_{pq} D_{p_1 p_2 p_3 q_1 q_2}^{(i_2 j_2)} D_{p_1 p_2 p_3 q_1 q_2}^{(i_1 j_1)*}. \end{aligned} \quad (44)$$

Thus Σ_{GW+v} is the sum of a contribution Σ_3 containing partitions with three $+/-$ g lines and a contribution Σ_5 [the last term in Eq. (44)] containing partitions with five $+/-$ g lines. From the rules in Eqs. (30)–(32) we see that Σ_5 has already a PSD structure. Instead Σ_3 should be corrected according to $\Sigma_3 \rightarrow \Sigma_{3,\text{PSD}}$ with

$$\begin{aligned} \Sigma_{3,\text{PSD}}^< &= i \sum_{j_1 j_2=1}^{\infty} \sum_{P \in \pi_2} (-)^P \sum_{pq} (D_{p_1 p_2 q_1}^{(j_2)} + \tilde{D}_{p_1 p_2 q_1}^{(j_2)}) \\ &\times (D_{P(p_1)P(p_2)q_1}^{(j_1)*} + \tilde{D}_{P(p_1)P(p_2)q_1}^{(j_1)*}). \end{aligned} \quad (45)$$

This self-energy contains the original four partitions of Σ_3 plus four more partitions arising from the permutation of the two p dangling lines. The latter are explicitly worked out in Fig. 14. Collecting all the results together we conclude that the leading order self-energy diagrams with screened interactions and vertex corrections yielding a PSD spectral function are those in Fig. 15. Here we recall that a diagram with no $+/-$ on the internal vertices is the full diagram (hence the sum over all possible partitions). Noteworthy the minimal completion of the square requires a *fourth-order* diagram in W .

FIG. 13. (Color online) (a) Partitions of the fourth diagram on the right-hand side of Fig. 10. (b) Definition of the $D^{(i,j)}$ diagrams.

V. VERTEX CORRECTIONS IN THE HOMOGENEOUS ELECTRON GAS

The numerical implementation of the full self-energy of Fig. 15 is rather demanding. We observe, however, that the exclusion of the last two partitions of Fig. 10 leads to a much simpler PSD self-energy since no permuted D diagrams appear. It is straightforward to show that in this case the rules of Eqs. (30)–(32) lead to the following PSD self-energy:

$$\Sigma_c^<(1,2) = i \sum_{j_1, j_2=1}^{\infty} \sum_{pq} (D_{p_1 p_2 q_1}^{(j_2)} + \tilde{D}_{p_1 p_2 q_1}^{(j_2)}) \times (D_{p_1 p_2 q_1}^{(j_1)*} + \tilde{D}_{p_1 p_2 q_1}^{(j_1)*}), \quad (46)$$

where the corresponding D diagrams are defined in Figs. 9(a) and 11(b). The diagrammatic representation of Eq. (46) is shown in Fig. 16. This self-energy too goes beyond the GW

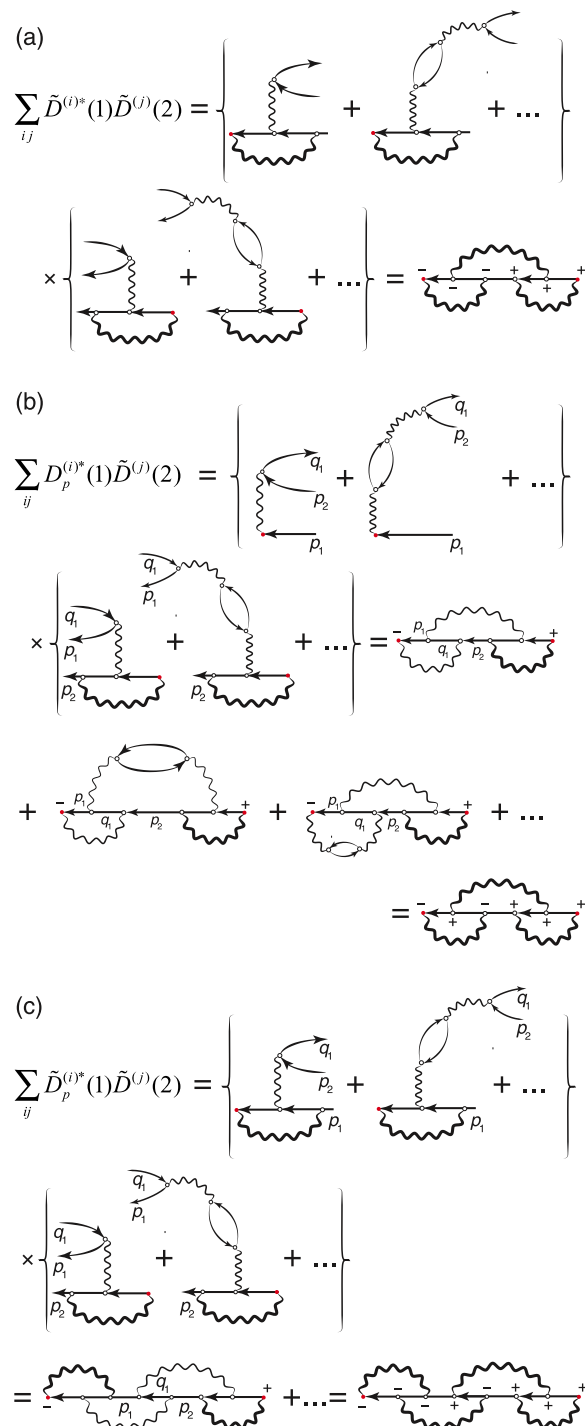

FIG. 14. (Color online) There are four extra diagrams that correct the self-energy with three $+/-$ g lines (Σ_3). They have (a) $\tilde{D}^*(1)\tilde{D}(2)$, (b) $D_p^*(1)\tilde{D}(2)$, $\tilde{D}_p^*(1)D(2)$ [similar to diagram (b) and thus not shown], and (c) $\tilde{D}_p^*(1)\tilde{D}(2)$ structures. Subscript P denotes a diagram with permuted p indices.

approximation, but the vertex correction is only partial (since the last two partitions of Fig. 10 are discarded).

The three-dimensional homogeneous electron gas (3D HEG) is one of the most studied correlated many-body system [39]. We still lack detailed knowledge of one directly observable quantity—the spectral function $A(k, \omega)$ —when departing

FIG. 15. (Color online) Leading order beyond- GW self-energy with the PSD property. Thick wavy lines denote the screened Coulomb interaction in the random phase approximation.

from the on-shell energy, i.e., when $\omega \not\approx \epsilon_k$. Discrepancies with experimental measurements contributed to the debates on the position of satellites [40,41], bandwidth of simple metals [14,42], cancellation of vertex function and self-consistency effects [5,43,44], and the spectral function shape [45,46].

Despite numerous efforts there are just a few results that go beyond the GW approximation in the study of quasiparticle properties. Analytically these are the results of Onsager *et al.* [47] on the second-order exchange energy and of Ziesche [48] and of Glasser and Lamb [49] on the second-order exchange self-energy. These works only contain analytic results for

FIG. 16. (Color online) The sum of the four self-energy partitions (a) + (b) + (c) + (d) yields a positive spectral function. Lines with arrows denote the electron propagator $G_0(k, \omega)$, whereas wavy lines stand for the screened Coulomb interaction $W_0(k, \omega)$. Vertices are labeled with + (−) if the time lies on the minus (plus) branch of the Keldysh contour. Diagrams are translated into analytic expressions according to the definitions (47) and (48) and notations below Eq. (49). For instance $g_5(z - y_3)$, connecting vertices with “−” labels as in (c) and (d), corresponds to the time-ordered Green’s function [see also Eq. (2)]: $\frac{\mathcal{B}(k_5)}{z - \Omega(y_3) - \epsilon_{k_5} - i\eta} + \frac{\mathcal{A}(k_5)}{z - \Omega(y_3) - \epsilon_{k_5} + i\eta}$.

on-shell self-energy and only a contribution of the bare Coulomb interaction is included. The screened Coulomb interaction is possible to treat numerically. The non-self-consistent calculations were performed by Hedin [3] and Lundqvist [50–52]. It took three decades to implement the same approach partially or fully self-consistently. This was achieved in works by von Barth and Holm [5,53]. The nonpositivity of the spectral function first observed by Minnhagen [10,43] hindered systematic diagrammatic explorations and stimulated development of synthetic approaches: analyzing real time Kadanoff-Baym dynamics [54], neglecting the incoherent part of the electron spectral function [12], employing the Ward identities and a model form of the exchange-correlation kernel [14,15,55,56], or the self-consistent cumulant expansion [40].

Using the presented formalism it is now possible to pursue the diagrammatic route. In this section we present the results of a non-self-consistent calculation. Thus we evaluate the diagrams in Fig. 16 for the 3D HEG using the analytical frequency and numerical Monte Carlo momentum integrations. The method was developed in a prior publication [46], however, especially the analytical frequency integration part had to be substantially extended. For the HEG the bare time-ordered Green’s function can be written as a function of frequency ω and momentum k as

$$G_0^{--}(k, \omega) = \frac{\mathcal{B}(k)}{\omega - \epsilon_k - i\eta} + \frac{\mathcal{A}(k)}{\omega - \epsilon_k + i\eta}. \quad (47)$$

For self-consistent calculations this equation can be extended to include multiple poles (e.g., to describe quasiparticle satellites) for each momentum value. In this work we perform a one-shot calculation and therefore set $\mathcal{B}(k) = n_k$ and $\mathcal{A}(k) = 1 - n_k$ with $0 \leq n_k \leq 1$ denoting the occupation number and ϵ_k is the energy of the state with momentum k . For the energy dispersion we used the prescription by Hedin [2,3,57] to put the pole of the dressed $G = G_0 + G_0 \Sigma_c [G_0] G$ with Fermi momentum $k = k_F$ correctly at the Fermi surface, i.e., $\epsilon_k = k^2/2 + \mu - \epsilon_F$, where μ is the chemical potential and $\epsilon_F = k_F^2/2$ is the Fermi energy. Analogous definitions have been used for the anti-time-ordered, lesser and greater Green’s functions.

Generally each interaction line in Fig. 16 can designate either the bare Coulomb interaction or include scattering with generation of a plasmon or a particle-hole pair. On the RPA level the plasmon oscillator strength $t(q)$ vanishes when its dispersion curve $\Omega(q)$ enters the particle-hole continuum at the critical wave number q_c . Because plasmonic excitations exist on the bounded momentum interval they are especially convenient for numerics: Momentum integrations need to be performed on the finite interval. Physically plasmons also dominate the particle-hole response in electron liquids with typical metallic densities. Therefore, in the present work we only treat the plasmonic contributions. The screened Coulomb interaction is treated in the plasmon pole approximation, i.e., $W(k, \omega) \approx W_0(k, \omega)$ (cf. Eq. 25.11 of Ref. [57]):

$$W_0^{--}(k, \omega) = \frac{v(k)}{2} \left[\frac{w(k)}{\omega - \Omega(k) + i\eta} - \frac{w(k)}{\omega + \Omega(k) - i\eta} \right], \quad (48)$$

where we denote $w(q) = t(q)\Omega^2(0)/\Omega(q)$ and $0 \leq t(q) \leq 1$ is the plasmonic spectral weight with $t(0) = 1$ and $t(q_c) = 0$. Analogous definitions have been used for the other Keldysh components of W_0 . Our numerical approach also allows us to include contributions from the particle-hole continuum to exhaust the f -sum rule for the dielectric function $\varepsilon(q, \omega)$:

$$\int_0^\infty \omega \text{Im}\varepsilon^{-1}(q, \omega) d\omega = -\frac{\pi}{2}\Omega^2(0),$$

where $\Omega(0) = 4\sqrt{\frac{\alpha r_s}{3\pi}}\epsilon_F$, with $\alpha = [4/(9\pi)]^{1/3} \approx 0.521$ and $r_s = 1/(\alpha k_F)$ the Wigner-Seitz radius. Monte Carlo momentum integration of these terms is, however, more involved as it requires an extra integration for each interaction line.

The frequency integrations can be done completely analytically (facilitated by the MATHEMATICA computer algebra system), whereas for the remaining momentum integrations one has to rely on numerics. The frequency integration is implemented for a general case of time-ordered $G_0(k, \omega)$ and $W_0(k, \omega)$. Since each correlator in the self-energy expression comprises two terms the total number of terms grows geometrically with the order of the diagrams. In order to optimize the calculation we implemented an approach where for each ω integration the program closes the integration contour in such a way that the least number of terms is generated. One might argue that the Hedin set of equations gives a prescription on which half of the complex plane the integration should be closed (see for example Eqs. (A30) of Ref. [3]). However, it is easy to verify that this is only relevant for the first-order term. Higher order terms decay faster than $1/\omega$ at infinity (ω here denotes the frequency to be integrated over) and, therefore, the choice of the half-plane is not important. Finally, we notice that it is sufficient to consider only the lesser self-energy. The greater self-energy component required to describe properties of the states above the Fermi level is obtained from symmetry considerations.

Our analytic approach covers the case of the Fig. 16(a) diagram where all partitions are included. Other diagrams in this figure contain only a subset of the partitions of the MBPT diagrams from which they originate. The corresponding analytic expressions can be easily extracted from the general result by analyzing the frequency dependence. The overall ω dependence can readily be obtained on paper by integrating δ functions in lesser and greater correlators. Despite the omission of several partitions the final result is bulky and requires an additional simplification using $\mathcal{A}(k) + \mathcal{B}(k) = 1$.

The results of frequency integration are

$$\Sigma_A^<(z, \zeta) = 2i\pi \int \frac{d^3 y_2}{(2\pi)^3} B_3 C_2 \delta(\zeta - \epsilon_3 + \Omega_2), \quad (49a)$$

$$\begin{aligned} \Sigma_B^<(z, \zeta) &= 2i\pi \iint \frac{d^3 y_1}{(2\pi)^3} \frac{d^3 y_2}{(2\pi)^3} B_3 C_1 C_2 \\ &\times \left[\frac{\mathcal{H}_2(\epsilon_3, \Omega_1) - \mathcal{H}_1(\epsilon_3 - \Omega_2, \Omega_1)}{\epsilon_2 - \epsilon_1 - \Omega_2} \right] \\ &\times \delta(\zeta - \epsilon_3 + \Omega_2), \end{aligned} \quad (49b)$$

$$\begin{aligned} \Sigma_C^<(z, \zeta) &= 2i\pi \iint \frac{d^3 y_3}{(2\pi)^3} \frac{d^3 y_2}{(2\pi)^3} B_3 C_2 C_3 \\ &\times \left[\frac{\mathcal{H}_4(\epsilon_3, \Omega_3) - \mathcal{H}_5(\epsilon_3 - \Omega_2, \Omega_3)}{\epsilon_4 - \epsilon_5 - \Omega_2} \right] \\ &\times \delta(\zeta - \epsilon_3 + \Omega_2), \end{aligned} \quad (49c)$$

$$\begin{aligned} \Sigma_D^<(z, \zeta) &= 2i\pi \iiint \frac{d^3 y_1}{(2\pi)^3} \frac{d^3 y_2}{(2\pi)^3} \frac{d^3 y_3}{(2\pi)^3} B_3 C_1 C_2 C_3 \\ &\times \left[\frac{\mathcal{H}_2(\epsilon_3, \Omega_1) - \mathcal{H}_1(\epsilon_3 - \Omega_2, \Omega_1)}{\epsilon_2 - \epsilon_1 - \Omega_2} \right] \\ &\times \left[\frac{\mathcal{H}_4(\epsilon_3, \Omega_3) - \mathcal{H}_5(\epsilon_3 - \Omega_2, \Omega_3)}{\epsilon_4 - \epsilon_5 - \Omega_2} \right] \\ &\times \delta(\zeta - \epsilon_3 + \Omega_2), \end{aligned} \quad (49d)$$

where we define

$$\mathcal{H}_i(a, \Omega) = \frac{A_i}{a - \Omega - \epsilon_i} + \frac{B_i}{a + \Omega - \epsilon_i}.$$

In these equations we adopt the following notations: $A_i \equiv \mathcal{A}(x_i)$, $B_i \equiv \mathcal{B}(x_i)$, $C_i \equiv \frac{1}{2}v(y_i)w(y_i)$. The quantities ϵ_i and Ω_i are energies labeled by the momenta, as shown in Fig. 16, and have a meaning of electron and plasmon dispersions, respectively. The momenta y_i are associated with plasmonic excitations. Equation (49) possesses some symmetries: Eqs. (49b) and (49c) are identical upon simultaneous permutations of the (1,5)(2,4) fermionic and (1,3) bosonic indices. The two brackets in Eq. (49d) transform analogously. For the numerical momentum integration of Eq. (49) it is useful to rescale the variables as follows: $k = k_F \tilde{k}$, $\epsilon_k = \epsilon_F \tilde{k}^2$, $v(q) \equiv \frac{4\pi}{q^2} = \frac{4\pi}{k_F^2} \frac{1}{\tilde{q}^2}$, $\Sigma = \epsilon_F \tilde{\Sigma}$. This leads to the following density-dependent prefactors:

$$c_i = \left[\left(\frac{k_F}{2\pi} \right)^3 \frac{1}{\epsilon_F^2} \left(\frac{1}{2} \frac{4\pi}{k_F^2} \epsilon_F \right) \right]^i = \left(\frac{\alpha r_s}{2\pi^2} \right)^i, \quad (50)$$

where $i = 1, 2, 3$ denotes the diagram's order.

From the particle-hole symmetry we can obtain the greater self-energy ($\Sigma^>$). For this it is sufficient to replace B_i with A_i and vice versa, and to change the sign of each Ω_i .

Upon a close inspection it is evident that the four terms in Eq. (49) can be combined together as follows:

$$\begin{aligned} \Sigma_{2,\text{PSD}}^< &= 2i\pi \int \frac{d^3 y_2}{(2\pi)^3} B_3 C_2 \\ &\times \left[1 + \int \frac{d^3 y_1}{(2\pi)^3} C_1 \frac{\mathcal{H}_2(\epsilon_3, \Omega_1) - \mathcal{H}_1(\epsilon_3 - \Omega_2, \Omega_1)}{\epsilon_2 - \epsilon_1 - \Omega_2} \right]^2 \\ &\times \delta(\zeta - \epsilon_3 + \Omega_2). \end{aligned} \quad (51)$$

The first-order integrand [cf. Eq. (49a)] is multiplied by a full square. Since we know that the GW self-energy fulfills the PSD property the same holds for the sum of the four terms in Fig. 16. This analytic conclusion is numerically confirmed.

In order to make Eqs. (49) suitable for Monte Carlo integration the following has to be done: (i) integrate in spherical coordinates with zenith direction along the \mathbf{z} vector, (ii) one angular integration is trivially done (2π) because the system is isotropic, and (iii) map integration variables to the interval $[0, 1]$. The speed and quality of a pseudorandom number

generator is very important for the present calculations. We use the Mersenne twister 19937 generator as implemented in the GSL library combined with a highly efficient jump ahead method [59] due to Haramoto *et al.* [58] for parallelization. The method is roughly three times faster than the standard FORTRAN implementation. We used roughly 10^{12} Monte Carlo realizations to get the full frequency dependence for each momentum value. Real self-energy parts were computed using the Hilbert transform:

$$\Sigma^R(k, \omega) = \Sigma_x(k) + \int \frac{d\omega'}{2\pi} \frac{\Gamma(k, \omega')}{\omega - \omega' + i\eta}, \quad (52)$$

where $\Sigma_x(k)$ is the frequency independent exchange self-energy and $\Gamma(k, \omega) = i[\Sigma_c^>(k, \omega) - \Sigma_c^<(k, \omega)] = i[\Sigma_c^R(k, \omega) - \Sigma_c^A(k, \omega)]$ is the rate operator.

Each term of Eq. (49) was separately computed as shown in Figs. 17 and 18 for two values of k . The first-order self-energy is well understood. One of its marked features is the existence of logarithmic singularities at $\omega = \epsilon_k \pm \Omega(0)$ [57]. These singularities have never been observed in an experiment and are believed to be washed out by higher order contributions. Although our calculations do not preclude this conclusion we found that our selection of second-order terms makes the singularities even more pronounced.

The real part of the retarded self-energy of Eq. (51) is displayed in Fig. 19. We observe that the real part of the first order and the complete self-energy cross the y axis at almost the same point which is equal to $\mu/\epsilon_F - 1$. This implies that the higher order corrections do not change the chemical potential appreciably. As expected, the rate operator is everywhere positive despite a large negative contribution of the second-order term. We notice an almost complete cancellation of different order terms beyond the singularities, i.e., $\omega > \epsilon_k + \Omega(0)$ for particle ($k > k_F$) and $\omega < \epsilon_k - \Omega(0)$ for hole ($k < k_F$) states. High accuracy of the Monte Carlo

FIG. 17. (Color online) The rate operator $\frac{1}{2}\Gamma(k, \omega) = -\text{Im}\Sigma_c^R(k, \omega)$ of the homogeneous electron gas at the density of $r_s = 4$ and $k = k_F$ (the energy ω is measured with respect to μ). Different line styles denote contributions of different orders: full, dotted, and dashed lines stand for first, second, and third order, respectively. Thick solid line denotes the sum of all contributions.

FIG. 18. (Color online) The rate operator $\frac{1}{2}\Gamma(k, \omega) = -\text{Im}\Sigma_c^R(k, \omega)$ as in Fig. 17 for a different momentum $k = 1.2k_F$ (the energy ω is measured with respect to μ). The inset magnifies the region of the logarithmic singularity. Notice the almost complete cancellation of $\Sigma_c^>(k, \omega)$ for $\omega > \epsilon_k + \Omega(0)$.

integration was required to get the cancellations properly. This is especially important at metallic densities where different orders have comparable contributions. Due to the density scaling [see Eq. (50)] the first-order self-energy becomes

FIG. 19. (Color online) The real part of the retarded self-energy $\text{Re}\Sigma^R(k, \omega)$, see Eq. (52), and the rate operator $\frac{1}{2}\Gamma(k, \omega) = -\text{Im}\Sigma_c^R(k, \omega)$ of the homogeneous electron gas at the density of $r_s = 4$ and $k = k_F$ (the energy ω is measured with respect to μ). Shaded dashed curves denote the first-order calculation. Full lines denote contribution from diagrams shown in Fig. 16 plus the first-order contribution from the particle-hole excitations. The horizontal line bounding the shaded area in the graph of $\text{Re}\Sigma^R$ crosses the y axis at the value of the exchange self-energy $\Sigma_x(k_F)/\epsilon_F = -\frac{2\alpha}{\pi}r_s \approx -1.327$.

dominant at large densities ($r_s \rightarrow 0$), while the third order is largest in the correlated low density regime ($r_s \rightarrow \infty$).

The selection of diagrams of Fig. 16 and computed in this work in the plasmon pole approximation describes scattering processes accompanied by the emission or absorption of *one* plasmon. Correspondingly, the scattering operator has pronounced (more narrow in comparison with the first-order result) peaks at $\omega = \epsilon_k \pm \Omega(0)$. But how important are the remaining contributions? The simplest first-order term, absent in the plasmon pole approximation, but included in the results of Fig. 19, involves generation of a single particle-hole pair. Due to less restrictions on the available phase space for scattering it is important for $\omega \rightarrow \infty$ and also determines the lifetime of quasiparticles in the vicinity of the Fermi energy. It also gives rise to secondary peaks in Fig. 19. These, however, are not related to scattering mechanisms involving generation of two plasmons. Inclusion of such processes is important for the interpretation of multiple satellites in the spectral function. To lowest order they result from the partition of the second-order self-energy diagram included in Fig. 15, but omitted in Fig. 16. Respective calculations are on the way and will be the subject of a forthcoming publication.

VI. CONCLUSIONS

Approximations of MBPT to the self-energy can lead to unphysical density of states, with a negative spectral weight in some frequency region. This undesired feature entails unphysical results on the system properties and makes self-consistent calculations impossible due to a progressive deterioration of the analytic properties of the Green's function. In 1985 Almladh proposed a diagrammatic perturbation theory of the photoemission current [60], and in a subsequent paper [19] he elaborated on the theory and gave a prescription on how to combine diagrams of different order to get a physically sensible result: the positive-definite photoemission current. These ideas are precursors for our theory. Using the Green's function of the Keldysh formalism we developed a method to construct manifestly PSD spectral functions. The method becomes particularly lucid when expressed in diagrammatic language as it amounts to apply a few simple drawing rules. Most importantly, the only quantity needed to evaluate these

diagrams is the spectral function (available in most MBPT codes).

We derive a Lehmann-like representation of the exact self-energy and show that it is given by the sum of squares of irreducible correlators. We then elucidate the connection between the diagrammatic expansion of the irreducible correlators and MBPT. Any lesser/greater self-energy diagram can be partitioned into two halves with internal time vertices on opposite branches of the Keldysh contour. Thus by simply drawing diagrams and assigning a sign to the internal vertices we are able to extend to a minimal set of diagrams any MBPT approximation and to generate PSD spectral functions. Some important MBPT approximations, such as the *GW* or *T*-matrix approximations, do not require any corrections. Our theory applies equally well to diagrammatic expansions with noninteracting and with self-consistent Green's functions because PSD self-energies do preserve the correct analytic structure.

In standard MBPT approximations the straightforward inclusion of vertex corrections inevitably ruin the PSD property and, hence, our additional diagrams must be included. Remarkably, these diagrams are of higher order. For instance, the inclusion of the *full first-order vertex* leads to diagrams of the fourth order in the screened interaction. Required computational power to numerically evaluate them is immense. Fortunately, excluding some partitions allows us to construct an approximation containing diagrams of maximally third order. They are feasible for numerics as our calculations for the 3D HEG demonstrate.

Even though we only presented in detail the formalism for the spectral function, the same ideas apply to the spectrum of the density response function. This extension, however, goes beyond the scope of the present work and will be presented elsewhere.

- [35] The minimal number of additional diagrams should actually be obtained by finding the smallest set of the form $\bigcup_{\alpha} \tilde{I}_N^{(\alpha)} \times \tilde{I}_N^{(\alpha)} \supset \mathcal{I}_N$. We opted for a simplified presentation to convey more efficiently the essential ideas of the PSD theory.
