Recent works on hard spheres in the limit of infinite dimensions revealed that glass states, envisioned as metabasins in configuration space, can break up in a multitude of separate basins at low enough temperature or high enough pressure, leading to the emergence of new kinds of soft-modes and unusual properties. In this paper we study by perturbative renormalization group techniques the critical properties of this transition, which has been discovered in disordered mean-field models in the 1980s. We find that the upper-critical dimension *du*, above which mean-field results hold, is strictly larger than six and apparently nonuniversal, i.e., system dependent. Below *du*, we do not find any perturbative attractive fixed point (except for a tiny region of the one-step replica symmetry breaking parameter), thus showing that the transition in three dimensions either is governed by a nonperturbative fixed point unrelated to the Gaussian mean-field one or becomes first order or does not exist. We also discuss possible relationships with the behavior of spin glasses in a field.

The properties of glasses at low temperatures are the subject of extensive experimental, numerical, and analytical investigations. In order to understand them, one has to study the properties of the amorphous solids in which liquids freeze at the glass transition. Hence, a crucial preliminary step is arguably understanding glass-formation. One of the most prominent theoretical approaches to do that is the random first-order transition (RFOT) theory introduced by Kirkpatrick, Thirumalai, and Wolynes [\[1–4\]](#page-3-0). It has its roots in the mean-field theory of disordered models, but as it has become clear in recent years, it goes well beyond that. RFOT theory applies to all systems characterized by a certain kind of (free-)energy landscape, such that below a given temperature T_d an exponential number (in the system size) of metastable states emerge. By lowering the temperature, their thermodynamics become ruled by the competition between two kinds of contributions: one (free-energetic) that favors states with lower internal free energy because their corresponding Boltzmann weight is larger, and the other (entropic) that favors states having high internal free energy because they are more numerous. At the so-called Kauzmann temperature, T_K , the entropic contribution vanishes and the system freezes in one low-lying glass state. RFOT theory advocates that this is precisely what happens for super-cooled liquids approaching the glass transition, where T_d corresponds to the so-called mode coupling crossover and T_K to the ideal glass transition. A major result of the past 30 years was to show that this is indeed the case within mean-field theory [\[5\]](#page-3-0). Actually, the range of systems displaying such an energy landscape—at the mean-field level—is remarkably broad: it encompasses physical systems such as super-cooled liquids, colloids, proteins [\[6,7\]](#page-3-0), and models central in other fields like random *K* satisfiability [\[8\]](#page-3-0). Whether this remains true beyond the mean-field approximation is still a matter of debate, although there are by now remarkable numerical and experimental evidences [\[6,9\]](#page-3-0).

For a long time the properties of low-temperature glasses remained a separate research subject from the much more studied problem of glass transition with the notable exception of Ref. [\[10\]](#page-3-0). Recently, however, there has been an increasing research effort aimed at understanding amorphous solids'

unusual features and their relationship with the glass transition [\[11\]](#page-3-0). This was to great extent motivated by the study of jamming [\[12,13\]](#page-3-0). In this context, a new twist of RFOT theory is the suggestion that glass states, envisioned as metabasins in configuration space, can break up in a multitude of separate basins at low enough temperature or high enough pressure, leading to the emergence of new kinds of soft modes and unusual properties [\[14\]](#page-3-0). This transition, called Gardner transition $[15,16]$, was actually found a long time ago for several mean-field models characterized by a RFOT. In these systems at a temperature, T_K , there is a glass phase transition at which, technically, a one-step replica symmetry breaking (1RSB) phase emerges and at a lower temperature, T_G , there is a Gardner transition toward a full replica symmetry breaking (FRSB) phase; see, for example, the case of the Ising *p*-spin-disordered models [\[17,18\]](#page-3-0). As pointed out in Refs. $[19,20]$ (see also Ref. $[21]$) this transition from a valley in configuration space to a multitude of separated basins takes place also for nonequilibrium glass states. In consequence, it is not limited to the (unreachable) equilibrium regime below T_K but is also relevant for common nonequilibrium protocols such as quenches or crunches during which the system gets trapped in a metastable state. For a very long time the study of the Gardner transition remained bounded to abstract mean-field models. From the point of view of the physics of glasses, it was just a pure intellectual curiosity. Recent works on the solution of glassy hard spheres in infinite dimensions highlighted its relevance for amorphous materials [\[14,22–24\]](#page-3-0). In fact, the FRSB phase appearing below T_G is marginally stable and its soft-modes are deeply related to the unusual features displayed by jammed packings [\[13,25](#page-3-0)[–31\]](#page-4-0). Remarkably, the FRSB mean-field theory predicts values for the critical exponents of the jamming transition that are in perfect agreement with the ones observed in numerical simulations in two and three dimensions. Moreover, the Gardner transition is not limited to glasses and jammed packings but it likely emerges in the low-temperature regimes of many other disordered systems. In consequence, understanding how critical finite-dimensional fluctuations affect the Gardner transition found within meanfield theory is no more an abstract and academic question. It has become a open and very relevant issue. The aim of this

work is addressing it using *perturbative* renormalization group techniques.

Before starting our analysis there are two important points worth clarifying. The first question that comes to mind when one applies mean-field results to estimate critical exponents in three-dimensional systems concerns the role of finitedimensional fluctuations. In this respect, it is important to stress that the exponents of the jamming transition found within mean-field theory are related to the soft-modes of the FRSB phase [\[13,25](#page-3-0)[–31\]](#page-4-0). In consequence, they are related to the properties of the low-temperature, high-pressure phases. They are not exponents related to a phase transition. There are therefore two separate issues: one is how the Gardner transition and its critical properties change from infinite dimension down to three, and the other is how the soft modes of the symmetry broken phase change from infinite dimension down to three. An instructive example is provided by the ferromagnetic Heisenberg model: its critical properties at the ferromagnetic phase transition change below four dimensions with respect to the mean-field ones; however, the properties of the soft-Goldstone modes remain the same, as shown by analyzing the corresponding nonlinear σ model [\[32\]](#page-4-0). What we do in this work is to address the first issue; i.e., we focus on the critical properties of the Gardner transition. We shall just touch upon the second one in the conclusion.

The other point we want to address is the relationship between the FRSB physics found for hard spheres in infinite dimensions and the one of spin-glasses in a field. In both cases one finds a FRSB phase without any residual symmetry present. Thus, reasoning only in terms of phases and type of symmetry breaking one would conclude that spin-glasses in a field and low-temperature, high-pressure glasses are in the same universality class both for the transition, Gardner versus spin-glass, and the properties of the FRSB phase. This would be also what one would conclude from the works by Moore and collaborators $[33-35]$, in which the glass transition was argued to be related to the spin-glass transition in a field (see also Ref. [\[36\]](#page-4-0)). As we shall show, however, the situation is more intricate and needs further analysis.

The starting point of our derivation is the effective replica field theory, which describes the critical fluctuations at the Gardner transition. At T_G there is a phase transition from a 1RSB to a FRSB phase. Hence, the action of the theory can be formulated in terms of a fluctuating space-dependent overlap field $Q_{ab}(r) = \phi_{ab}(r) + Q$, where Q is the 1RSB value of the solution of the saddle-point equations. The replica indices *a,b* run from 1 to *m*, and an analytic continuation for *m* to real values is always assumed. In our calculation *m* is the 1RSB breaking point and must be considered fixed to the value reached at T_G [\[18](#page-3-0)[,37\]](#page-4-0). There are no extra $n/m \rightarrow 0$ replicas since we focus on systems without quenched disorder [\[38\]](#page-4-0). Other values of *m*, different from $m(T_G)$, can be used to select nonequilibrium metastable states within mean-field theory [\[39\]](#page-4-0). Whether our analysis for generic values of *m* can be applied to metastable states will be discussed in the conclusion. In order to construct the most general action for $\phi_{ab}(r)$ we recall that there is no other symmetry that has to be taken into account besides replica permutation. As a consequence, one has to consider all quadratic and cubic terms allowed by replica symmetry. By analyzing the quadratic terms of the expansion of the action one recognizes that the replica field theory has a mass matrix that can be easily diagonalized [\[40\]](#page-4-0). Three distinct eigenvalues are found: the replicon, the longitudinal, and the anomalous one. The mean-field analysis shows that the Gardner transition corresponds to the vanishing of the replicon eigenvalue, whereas the others remain massive [\[16\]](#page-3-0). This means that only the replicon modes are critical and the others can be safely integrated out. Thus, in order to obtain the action of the critical modes we only take into account the contribution from the critical replicon modes to the fluctuating overlap field. This is a standard procedure and it has been already followed in the case of the Edwards-Anderson (EA) model in a field [\[41\]](#page-4-0). As expected, the results of the fixed points of the renormalization group equations are the same if the noncritical modes are also taken into account [\[42\]](#page-4-0). The action that one obtains reads [\[33,41,42\]](#page-4-0)

$$
\mathcal{L} = \int dx \left(\frac{1}{2} \sum_{a,b=1}^{m} \{ [\nabla \phi_{ab}(x)]^2 + r[\phi_{ab}(x)]^2 \} - \left\{ \frac{1}{6} g_1 \text{Tr} \phi^3(x) + \frac{1}{12} g_2 \sum_{a,b} [\phi_{ab}(x)]^3 \right\} \right). \tag{1}
$$

The field $\phi_{ab}(\mathbf{p})$ is symmetric $(\phi_{ab} = \phi_{ba})$ and has the following properties:

$$
\phi_{aa}(x) = 0
$$
\n
$$
\sum_{b(\neq a)} \phi_{ab}(x) = \sum_{a(\neq b)} \phi_{ab}(x) = 0,
$$
\n(2)

which characterize the replicon eigenspace. In the limit $m \to 0$ this replica field theory describes the behavior of the EA model in a field. To study the Gardner transition we instead have to keep *m* finite. The perturbative renormalization group equations for such a theory were obtained in Refs. [\[41,42\]](#page-4-0) by performing the ε expansion around $d = 6$, which corresponds to the upper critical dimension of the theory (at least perturbatively; more on this later on). The equations that describe the RG flow read [\[42\]](#page-4-0)

$$
\frac{dr}{dl} = \left(2 - \frac{1}{3}\eta\right)r - \left[g_1^2 \frac{m^4 - 8m^3 + 19m^2 - 4m - 16}{(m-1)(m-2)^2}\right] \n+ g_1 g_2 \frac{2(3m^2 - 15m + 16)}{(m-1)(m-2)^2} \n+ g_2^2 \frac{m^3 - 9m^2 + 26m - 22}{2(m-1)(m-2)^2}\right]I_2
$$
\n
$$
\frac{dg_1}{dl} = \frac{1}{2}(\varepsilon - \eta)g_1 + \left[A_1 g_1^3 + A_2 g_1^2 g_2 + A_3 g_1 g_2^2 + A_4 g_2^3\right]I_3
$$
\n
$$
\frac{dg_2}{dl} = \frac{1}{2}(\varepsilon - \eta)g_2 - \left[B_1 g_1^3 + B_2 g_1^2 g_2 + B_3 g_1 g_2^2 + B_4 g_2^3\right]I_3
$$
\n
$$
\eta = \left(H_1 g_1^2 + H_2 g_1 g_2 + H_3 g_2^2\right) \frac{1+r}{(1+r)^4},
$$

where $I_2 = (1+r)^{-2}$, $I_3 = (1+r)^{-3}$, $\varepsilon = 6 - d$, *d* is the spatial dimension, and η the usual critical exponent related to the anomalous dimension of the field. The expression of the coefficients *A*s*, B*s, and *H*s can be found in the Supplemental Material [\[43\]](#page-4-0). Starting from these equations we can write down

GARDNER TRANSITION IN FINITE DIMENSIONS PHYSICAL REVIEW B **91**, 100202(R) (2015)

an equation for $\lambda = g_2/g_1$ at criticality, i.e., for $r = 0$:

$$
\frac{d\lambda}{dl} = -g_1^2[K_1 + K_2\lambda + K_3\lambda^2 + K_4\lambda^2 + K_5\lambda^4]
$$

\n
$$
K_1 = B_1 \quad K_5 = A_4 \quad K_2 = B_2 + A_1
$$

\n
$$
K_4 = B_4 + A_3 \quad K_3 = B_3 + A_2
$$
 (3)

Equation (3) is dimension independent and thus it is particularly useful to discuss the RG fixed points (FP). The fixed points equation for *λ* reads

$$
K_1 + K_2 \lambda + K_3 \lambda^2 + K_4 \lambda^2 + K_5 \lambda^4 = 0,
$$
 (4)

where we consider $g_1 \neq 0$ since, as we verified, there are no RG-FPs characterized by $g_1 = 0$ except the Gaussian one for which $g_1 = g_2 = 0$. We find that that for $m < m^* \simeq 0.894$, Eq. (4) has two real solutions, $\lambda_1(m)$ and $\lambda_2(m)$. For $m \ge m^*$ other two real solutions $\lambda_3(m)$ and $\lambda_4(m)$ appear. Note that for each value of *λ* there are two RG-FPs related by the transformation $(g_1, g_2) \rightarrow (-g_1, -g_2)$. In the following we consider separately the *d >* 6 and *d <* 6 cases. For the former case we find that *λ*4(*m*) leads always to purely imaginary FPs and, hence, can be disregarded, whereas $\lambda_3(m)$ gives a real value for g_1 and g_2 for $m \geq m \approx 0.905$ ($> m[*]$) only. Thus, depending whether $m \in$ $[0,\tilde{m}]$ or $m \in [\tilde{m},1]$ one finds four or six FPs (none of them stable). They all belong to the border of the basin of attraction of the Gaussian fixed point (G-FP); see Fig. 1. Increasing the value of *m* the basin of attraction stretches along the diagonal direction and becomes very large, or possibly infinite, for *m* close to \tilde{m} . Its size shrinks to zero when $d \downarrow 6$, as found in Ref. $[44]$ in the case $m = 0$. This is the prelude of what happens crossing *d* = 6, where the G-FP becomes unstable. For *d <* 6 the only physical (i.e., real) FPs are given by $\lambda_3(m)$ and $\lambda_4(m)$ for $m \in [m^*, \tilde{m}]$ and by $\lambda_4(m)$ for $m \in [m^*, 1]$. We never find

FIG. 1. (Color online) Basins of attraction of the Gaussian fixed point for $d > 6$ in the quadrant $g_1 > 0$, $g_2 > 0$. The (blue) dots denote the non-Gaussian fixed points. The (red) continuous and (blue) dotted lines correspond, respectively, to the basin of attraction for $m = 0.1 \in$ $[0,\tilde{m}]$ and $m = 0.95 \in [\tilde{m},1]$. We denote with arrows the stability of the FPs and the corresponding eigendirections (for some FPs these are almost collinear and not well distinguishable). The square denotes the stable Gaussian FP.

FIG. 2. (Color online) The RG fixed points in the quadrant g_1 > 0 and $g_2 > 0$ for $d < 6$ and $m \in [m^*, \tilde{m}]$. We find an attractive fixed point and a partially repulsive fixed point on the border of its basin of attraction (continuous red line). For both fixed points, the eigenvectors directions of the linearized RG flow are almost collinear. For $m \in$ $[\tilde{m}, 1]$ only the unstable fixed point survives.

an attractive FPs except in the tiny regime $m \in [m^*, \tilde{m}]$. See Fig. 2 for a summary of the *d <* 6 case.

We now discuss the main consequences of the perturbative RG results found above. The situation is very different from the one corresponding to standard field theories, e.g., the ϕ^4 field theory, because the basin of attraction of the G-FP shrinks to zero approaching $d = 6$ and we do not find any attractive FP below (we neglect for the moment the case $m \in [m^*, \tilde{m}])$. Since the bare values of the coupling constants g_1 and g_2 are not arbitrarily small for a realistic system, the corresponding RG flow is bound to escape from the G-FP *strictly* before $d = 6$ [\[45\]](#page-4-0). This has two consequences: first, the upper critical dimension of the theory, *du*, above which mean-field results hold is strictly larger than six and, second, it is not universal since it depends on where the initial condition lies with respect to the basin of attraction of the G-FP. For $d < d_u$, the system flows to strong coupling, i.e., to a regime that we cannot access perturbatively. Different physical situations can correspond to this behavior. The transition can be destroyed or can become first order for $d < d_u$ [\[46,47\]](#page-4-0). Another appealing possibility is that it remains critical but the critical behavior is dominated by a nonperturbative fixed point. For the spin-glass transition in a field or without time-reversal symmetry, which corresponds to the case $m = 0$, the latter scenario is supported both by numerical simulations [\[48–53\]](#page-4-0) and real space RG analyses [\[54\]](#page-4-0) at least in high enough dimensions (the behavior in three dimension is still controversial). Note that although our results are overall very similar to the ones of spin-glasses in a field [\[41,44\]](#page-4-0), the detailed behavior of the RG flow in the perturbative regime is different [\[55\]](#page-4-0). This, together with the fact for spin-glasses that the critical fluctuating field has a number of components $m(m - 3)/2$ with $m \to 0$ while in the case of the Gardner transition the number of replicas *m* is fixed and positive, suggests that the universality classes should be distinct. On the other hand, if the theories at different *m* have different critical behaviors, then the critical properties of the Gardner transition are system-dependent, i.e., not universal at all (a quite weird physical situation), since the value of the breaking point *m* at the transition is system-dependent. Nonperturbative RG treatments and numerical simulations are needed to clarify these issues.

The regime $m \in [m^*, \tilde{m}]$ that we neglected before is very peculiar since one does find an attractive FP below six dimensions but with a basin of attraction that shrinks to zero when *d* ↑ 6. This leads to a rather baroque RG phenomenology. Since the interval $[m^*, \tilde{m}]$ is not only very tiny but also very close to one, it corresponds to systems (if any) extremely fine tuned. For this reason, we shall not address it further in this work.

One of the main motivations to study the fate of the Gardner transition in finite dimensions is the recent discovery of the FRSB phase of hard spheres in high dimensions and its relevance for the properties of amorphous solids. As already discussed, within mean-field computations or in the limit of infinite dimensions, one can tune the value of *m* to select certain metastable states, e.g., corresponding to packings with a given volume fraction. The problem in applying our results to this case is that the procedure of selecting metastable states tuning *m* is not well defined beyond mean-field theory. The 1RSB solution that is used in the mean-field computations is known to be unstable because of nonperturative effects [\[56\]](#page-4-0), which simply correspond to the fact that the corresponding states are *meta*stable in any finite dimension. One way out of this problem is constraining the particles to only move around the positions they have in a given packing, as in the model

introduced in Ref. [\[34\]](#page-4-0). It is interesting to notice that this procedure explicitly introduces quenched disorder. Although we did not attempt to study this case by RG, we conjecture that a relationship with spin glasses in a field could emerge since the disorder select a given metabasin transforming the Gardner transition we analyzed into a transition from a RS phase (describing the metabasin at high temperature and low pressure) to a FRSB phase (describing the multivalley structure inside the metabasin), similar to what happens for the EA model in a field. Results supporting this view were presented in Refs. [\[34,35\]](#page-4-0). This is certainly an issue worth investigating more both analytically and numerically. Establishing a direct relationship between the behavior of spin-glasses in a field and low-temperature, high-pressure glasses would be extremely important and useful, as argued in Refs. [\[34,35\]](#page-4-0). Our *perturbative* RG results cannot lead to any conclusive result on this.What they make clear, however, is that the Gardner transition in three dimensions either does not exist or it has a different nature from the mean-field one; namely, it can become nonperturbative in the RG sense or first order. Numerical simulations and nonperturbative RG treatments are crucially needed in order to find out which one among these three possibilities is realized.

- [37] The value of the breaking-point parameter is chosen as the value that makes stationary the free energy, hence it is a microscopic nonuniversal quantity.
- [38] When there is quenched disorder the total number of replicas is $n \to 0$. In this case our procedure of focusing on *m* replicas corresponds to taking into account fluctuations within metabasins and neglecting all the others.

- [45] The only way to avoid this conclusion and find $d_u = 6$ is that there exists a bottleneck-effect for the nonperturbative RG flow,

i.e., that (1) there is a finite nonperturbative region in the space of coupling constants that flows under RG toward the arbitrary small (when $d \rightarrow 6^+$) basin of attraction in the g_1, g_2 plane; and that (2) all physical initial conditions belong to this region. We have no reason to believe that these two rather exceptional conditions hold (especially the second one).
