(Received 13 January 2016; revised manuscript received 1 July 2016; published 25 July 2016)

We investigate the magneto-optical properties of excitons bound to single stacking faults in high-purity GaAs. We find that the two-dimensional stacking fault potential binds an exciton composed of an electron and a heavy hole, and we confirm a vanishing in-plane hole *g*-factor, consistent with the atomic-scale symmetry of the system. The unprecedented homogeneity of the stacking-fault potential leads to ultranarrow photoluminescence emission lines (with a full width at half-maximum  $\leq 80 \mu$ eV) and reveals a large magnetic nonreciprocity effect that originates from the magneto-Stark effect for mobile excitons. These measurements unambiguously determine the direction and magnitude of the giant electric dipole moment ( $\gtrsim e \times 10$  nm) of the stacking-fault exciton, making stacking faults a promising new platform to study interacting excitonic gases.

## **I. INTRODUCTION**

The stacking fault (SF), a planar, atomically thin defect, is one of the most common extended defects in zinc-blende, wurtzite, and diamond semiconductors. A fundamental understanding of the SF potential is important for determining how the defect affects semiconductor device performance [\[1,2\]](#page-3-0), engineering heterostructures based on crystal phase [\[3–5\]](#page-3-0), and providing a new two-dimensional (2D) platform for fundamental physics [\[6,7\]](#page-3-0). Here we report on excitons bound to large-area, single SFs in high-purity GaAs, a unique system in which SFs are easily isolated with far-field optical techniques. The atomic smoothness of the potential and the extreme perfection of the surrounding semiconductor result in ultrahigh optical homogeneity ( $\lesssim$ 80 μeV). This enables optical resolution of the SF exciton fine structure and thus direct measurement of the giant built-in dipole moment  $(\geq e \times 10$  nm) via the magneto-Stark effect. These results indicate that the extremely homogeneous SF potential may be promising for studies of many-body excitonic physics, including coherent phenomena  $[8-10]$ , spin currents  $[11]$ , superfluidity [\[12\]](#page-4-0), long-range order [\[13–17\]](#page-4-0), and large optical nonlinearities [\[18–20\]](#page-4-0).

### **II. STACKING FAULT PHOTOLUMINESCENCE**

Figure  $1(a)$  shows a spectrally resolved confocal scan of SF structures in a GaAs epilayer, excited with an above-band-gap laser (1*.*53 eV, 1.5 K) [\[21\]](#page-4-0). The image is colored red, green, or blue according to three characteristic emission bands shown in Fig. [1\(e\).](#page-1-0) The narrowband photoluminescence (PL) at 1.493 and 1.496 eV originates from excitons, electron-hole pairs, bound to the 2D SF potential [\[22,23\]](#page-4-0). The sample consists of a 10 *μ*m GaAs layer on 100 nm AlAs on a 5 nm*/*5 nm AlAs*/*GaAs (10×) superlattice grown directly on a semi-insulating (100) GaAs substrate. Stacking fault structures nucleate near the substrate-epilayer interface during epitaxial growth [\[21,24,25\]](#page-4-0).

The physical origin of the potential can be understood from the atomic structure of the SF defect: the lattice-plane ordering in the [111] direction of zinc-blende is modified by subtracting a layer [intrinsic SF; see Fig. [1\(c\)\]](#page-1-0) or adding a layer (extrinsic SF). The intrinsic SF can be viewed as a monolayer of wurtzite (AB AB stacking) surrounded by zinc-blende (ABC ABC stacking) [\[3](#page-3-0)[,26\]](#page-4-0). Due to the band offset [\[27–29\]](#page-4-0) and spontaneous polarization at the stacking fault [\[30\]](#page-4-0), electrons and/or holes are attracted to the SF plane. While useful for physical motivation, this bulk phase change model must be taken with caution when applied to atomically thin SFs, which can deviate from simple theory [\[31\]](#page-4-0). Here, however, we find that single SFs in bulk GaAs bind excitons, confirming that the potential is attractive for at least one carrier.

In the confocal scan in Fig.  $1(a)$ , most of the SF defects appear as single triangles, which we identify as a pair of nearby SFs [\[32,33\]](#page-4-0). Because the binding energy of excitons to a pair of SFs depends on the distance between the SFs [\[34\]](#page-4-0), the PL emission energy from excitons bound to these structures has a high variability of 10 meV between structures. Strikingly, this inhomogeneity disappears when four SFs grow in an inverted pyramid structure consisting of four well-isolated {111} SF planes [Fig.  $1(b)$ ], which we refer to as up, down, left, and right [\[35\]](#page-4-0). The full width at half-maximum (FWHM) of the SF PL line in our sample is  $(77 \pm 19) \mu$ eV at zero magnetic field [\[21\]](#page-4-0), somewhat narrower than excitonic lines associated with stacking faults in previous work [\[22,36\]](#page-4-0). In comparison, the narrowest reported linewidth for a GaAs/AlGaAs quantum well is 130  $\mu$ eV [\[37\]](#page-4-0), while PL linewidths from analogous zinc-blende/wurtzite quantum disks in nanowires range from 0.6–10 meV [\[29,38](#page-4-0)[–40\]](#page-5-0). This unprecedented homogeneity allows us to resolve the SF–bound-exciton fine structure.

## **III. NATURE OF THE HOLE IN THE SF EXCITON**

Experimentally, we determine that the SF exciton is composed of an electron and a heavy hole using polarizationresolved PL, consistent with the atomic-scale symmetry of the system [\[21\]](#page-4-0). For linearly polarized light incident from above (along the [001] axis), the largest overlap between the light polarization and the in-SF-plane heavy-hole dipole occurs

FIG. 1. (a) Confocal scan of SF structures. The image is formed by coloring emission in different wavelength bands as red, blue, or green, as depicted in (e). Excitation at 1.53 eV, 100 *μ*W, and 1.9 K excite and collect *H* polarization [see (b)]. (b) Diagram of SF pyramid. The up, down, left, and right SFs are labeled, along with the *H* and *V* polarizations. (c) Comparison of perfect zinc-blende and stacking fault crystal structure. (d) Detail of SF pyramid structure. Excitation at 1.53 eV, 100 *μ*W, 1.7 K. (e) Low-power PL spectra at colored dots in (d). Polarizations: blue, excite and collect *H*; green and red, excite and collect *V* . Broadband luminescence is observed from the SF edges (red); 1.53 eV, 2 *μ*W, and 1.7 K. (f) PL from down SF [blue dot in (d)]. Polarizations: dark blue, excite and collect *H*; light blue, excite and collect *V* .

when exciting and collecting along the *H* direction for the down SF [Fig. 1(d)], in agreement with our experimental data [Fig.  $1(f)$ ]. On the other hand, the main dipole moment for the light-hole exciton is along the SF normal, which would give rise to a maximum signal at *V* polarization, contrary to what is observed. Further, we also note that no hole Zeeman splitting is observed for in-plane magnetic fields *B* up to 7 T (Fig. 2). This observation is fully consistent with our symmetry analysis, which finds that *B*-linear splitting for in-plane fields is forbidden for heavy holes but allowed for light holes [\[21\]](#page-4-0). The substantial separation of the heavy- and light-hole states prevents their magnetic-field-induced mixing, in line with experiments on GaAs nanowires [\[21,](#page-4-0)[41,42\]](#page-5-0).

### **IV. NONRECIPROCAL PHOTOLUMINESCENCE**

PL from SFs shows a remarkable nonreciprocity with in-plane applied magnetic field: Figure  $2(a)$  shows that the

FIG. 2. (a) Spectra from up and down SFs as a function of inplane magnetic field. The spectra show a nonreciprocity with applied magnetic field. Excite at 1.65 eV, 0.5 *μ*W, 1.6 K, excite and collect *H*. The inset shows the geometry of the stacking fault pyramid and applied magnetic field. (b) Spectra from left and right SFs as a function of partially out-of-plane magnetic field. The spectra are similar at positive and negative fields. Excitation at 1.65 eV, 0.5  $\mu$ W, 1.6 K, excite and collect V.

PL detected in linear polarization from the up SF occurs at a different energy depending on whether the magnetic field is parallel (positive) or antiparallel (negative) to the  $\overline{1}10$ ] axis. Interestingly, the down SF demonstrates the opposite behavior. Such an asymmetric behavior of the PL is surprising because in general, time-reversal symmetry makes **B** and −**B** equivalent. (Our sample is nonmagnetic, and we use linearly polarized light to avoid dynamic polarization of nuclear spins.) The observed nonreciprocal behavior of the PL spectrum with respect to inversion  $\mathbf{B} \rightarrow -\mathbf{B}$  is only possible if the PL arises from moving excitons. In this case, time reversal changes the direction of both the magnetic field and the exciton wave vector **K**.

Based on the  $C_{3v}$  point symmetry of the SF and timereversal invariance, the effective Hamiltonian for an exciton moving in the presence of an in-SF-plane magnetic field **B** is

$$
\mathcal{H}_{KB} = \frac{g_e}{2} \mu_B (\sigma_x B_x + \sigma_y B_y) + \beta B^2 + \beta' [\mathbf{K} \times \mathbf{B}]_z, \quad (1)
$$

where  $g_e$  is the electron *g*-factor,  $\mu_B$  is the Bohr magneton, *σx,y* are the electron spin Pauli matrices, *β* is a parameter describing the excitonic diamagnetic shift, and  $\beta'$  is a constant responsible for the nonreciprocal effect [\[21](#page-4-0)[,43–48\]](#page-5-0). In Eq. (1) we only retain first- and second-order terms in **B** and use a frame of axes related to the SF plane:  $z \parallel [111]$  is the SF normal,  $x \parallel [11\overline{2}]$ , and  $y \parallel [\overline{1}10]$ . Each symmetry-derived term in Eq. (1) manifests itself in the energetic shift of the SF PL lines with magnetic field (Fig. 2). The first term is the electron Zeeman effect and gives rise to the doublets visible at  $\pm$ 7 T, since an electron with a particular spin projection can recombine with the corresponding hole. The second term is the exciton diamagnetic shift, arising from the magnetic-fieldinduced shrinking of the exciton wave function [\[49\]](#page-5-0). The last term is the magneto-Stark effect, which, as we show below, quantitatively explains the nonreciprocal PL spectra.

The experimental geometry, Fig.  $1(b)$ , is such that only light emitted normal to the sample surface is collected. For <span id="page-2-0"></span>GIANT PERMANENT DIPOLE MOMENT OF TWO- . . . PHYSICAL REVIEW B **94**, 041201(R) (2016)

![](_page_2_Figure_3.jpeg)

FIG. 3. (a) Because of the conservation of in-plane momentum during exciton recombination, the angle of light emission depends on the exciton wave vector. Collecting different angles probes different exciton momenta. The SF has a built-in potential that creates a zero-field dipole moment for the SF exciton. In the exciton frame of reference, the in-plane magnetic field becomes an out-of-plane electric field, leading to the magneto-Stark effect. (b) Spectra of up and down SFs as a function of *θ* and in-plane magnetic field *B<sub>y</sub>*. (c) Light from the up SF originates from excitons with larger  $K_x$  than light from the down SF (for  $\theta > 0$ ). (d) and (e) Spectra of up and down SF at positive and negative  $B_y$ for  $\theta = 0^\circ$  and 43°. At  $\theta = 0^\circ$ ,  $\Delta E_{up}$  and  $\Delta E_{down}$  have the same magnitude, while for  $\theta = 43^\circ$ , the magnitude of  $\Delta E_{up}$  is larger than that of  $\Delta E_{\text{down}}$ . (f) and (g) Splitting  $\Delta E_{\text{up}/\text{down}}$  as a function of magnetic field. Data are obtained from Voigt fits to spectra similar to those shown in (d) and (e). Solid lines are a fit to  $\Delta E = aB$  for the first three data points. (h) The ratio of  $B = 0$  slopes, Eq. [\(6\)](#page-3-0), depends only on geometrical constraints. The theory (solid line) has no adjustable parameters. Data for other angles in Ref. [\[21\]](#page-4-0).

a high-quality 2D potential, in-plane exciton momentum is transferred to the photon during recombination, as depicted in Fig.  $3(a)$ . This conservation of momentum implies

$$
K_x = \frac{\omega n}{c} \sin \theta'', \tag{2}
$$

where  $\theta''$  is the angle between the SF normal and the emitted photon momentum inside the semiconductor [Fig.  $3(a)$ ],  $\omega$  is the photon frequency,  $n$  is the refractive index, and  $c$  is the speed of light. Thus, the collected SF PL arises only from excitons with a specific center-of-mass momentum. [Experimentally, the  $NA = 0.7$  objective lens collects luminescence from a range of angles. In our system, light is collected from exciton momenta within 7% of  $\hbar K_x$  in Eq. (2).] The last term in Eq. [\(1\)](#page-1-0) provides, for a fixed  $K_x$  [Eq. (2)], an odd in  $B_y$ contribution to the overall PL energy shift, giving rise to a magnetic nonreciprocity effect. It is worth noting that the up and down SFs are related by a mirror reflection in the (110) plane, and such a reflection is accompanied by  $B_y \rightarrow -B_y$ , resulting in the opposite behavior of up and down PL spectra observed in Fig.  $2(a)$ .

### **V. MAGNETO-STARK EFFECT**

The physical origin of the nonreciprocal PL is the magneto-Stark effect, i.e., the interaction of a moving exciton's electric dipole moment with a magnetic field [\[50,51\]](#page-5-0). The effect can be understood with a relativistic argument: motion with velocity  $\mathbf{v} = (\hbar K_x/M)\hat{\mathbf{x}}$  through a magnetic field  $\mathbf{B} = B_y\hat{\mathbf{y}}$  gives rise to an electric field  $\mathbf{E}_{\text{eff}} = \hbar K_x B_y / (Mc)\hat{\mathbf{z}}$  in the moving frame of reference, where *M* is the exciton mass in translational motion and *c* is the speed of light. Since the  $\hat{\mathbf{z}}$  || [111] and −**z**ˆ directions are not equivalent for the SF, the SF-bound exciton has a nonzero dipole moment  $\mathbf{p} = ed_{he}\hat{\mathbf{z}}$ , where  $e = |e|$ is the elementary charge and *dhe* is the average separation between the hole and electron along the *z* axis. The Stark effect  $H_s = -\mathbf{p} \cdot \mathbf{E}_{\text{eff}}$  in the exciton's reference frame thus becomes the magneto-Stark effect:

$$
\mathcal{H}_{\rm S} = -\frac{e\hbar}{Mc} d_{he} K_x B_y, \qquad (3)
$$

in agreement with Eq. [\(1\)](#page-1-0) with  $\beta' = -e\hbar d_{he}/(Mc)$ ; see Ref. [\[21,](#page-4-0)[49\]](#page-5-0) for a formal derivation.

Physically, the dipole moment of a SF bound exciton is a consequence of symmetry breaking and spontaneous polarization similar to that in zinc-blende/wurtzite heterostructures [\[23](#page-4-0)[,52\]](#page-5-0). The hole in the exciton is presumably localized in the SF plane while the electron is weakly bound via the Coulomb interaction. The spontaneous polarization shifts the electron cloud to one side of the SF, resulting in a giant excitonic dipole moment.

Equations  $(1)$ – $(3)$  predict that the asymmetric energy shift of the exciton PL is linearly related to the in-plane wave vector **K**. Since the angle of light collection determines the exciton momentum  $[Eq. (2)]$ , we test the applicability of the model by recording spectra of the up and down SFs as a function of the collection angle  $\theta$  and magnetic field  $B_y$  [Fig. 3(b)]. The collection angle is related to the emission angle from the up/down SF by  $\sin \theta = n \sin \theta' = \pm n \sin(\theta'' - \theta_{\rm SF})$ , where  $\theta_{\rm SF}$  is the angle the SF normal  $\hat{\mathbf{z}}$  || [111] makes with [001] [Fig. 3(c)].

In this experiment, we modified the collection angle by mounting the sample at different angles. Since the sample was removed from the cryostat to change the angle, different SF pyramids were used at different angles. This does not introduce artifacts because of the extreme similarity of different SFs, which have a standard deviation of line-center energies of only 57  $\mu$ eV, less than the linewidth. Spectra were acquired with  $B_y$ ranging from −6*.*5 to 6.5 T on the up and down SFs. We fit the spectra to one or a sum of two Voigt function(s) depending on whether the electron Zeeman splitting is resolved. The singlet or doublet line center is denoted  $E_{\text{up}/\text{down}}(B_y)$ . The part of the exciton energy odd with magnetic field is found by computing

$$
\Delta E_{\text{up}/\text{down}}(B_y) = E_{\text{up}/\text{down}}(B_y) - E_{\text{up}/\text{down}}(-B_y). \tag{4}
$$

It follows from Eq.  $(3)$  that the asymmetric shift is

$$
\Delta E_{\text{up}/\text{down}}(B_y) = \mp 2n\hbar\omega \frac{ed_{he}}{Mc} \sin(\theta_{SF} \pm \theta')B_y. \tag{5}
$$

Thus the proportionality constant of  $\Delta E_{\text{up}/\text{down}}$  versus  $B_y$ provides a measurement of the SF exciton's built-in dipole moment. The experimental values and first-order theory for  $\Delta E$  are shown in Figs. [3\(f\)](#page-2-0) and [3\(g\).](#page-2-0) Further, the ratio

$$
r(\theta) = \frac{|\Delta E_{\text{up}}| - |\Delta E_{\text{down}}|}{\frac{1}{2}(|\Delta E_{\text{up}}| + |\Delta E_{\text{down}}|)}
$$
(6)

depends (to first order in  $B_y$ ) only on the experimental geometry and the index of refraction:  $r(\theta)$  vanishes for collection angle  $\theta = 0$  and increases as a function of  $\theta$ [Fig.  $3(h)$ ]. We obtain good agreement between  $r(\theta)$  calculated experimentally from the  $B = 0$  slope of  $\Delta E$  without any fit parameters [Fig. [3\(h\)\]](#page-2-0).

Further, by fitting  $\Delta E_{\text{up}/\text{down}}(B_y)$  with a  $B_y$ -linear function, we can estimate the dipole moment of the exciton  $p = ed_{he} = e \times (10^{+20}_{-1})$  nm. The main uncertainties result from the accuracy of the  $B_y$ -linear fit and the value of the in-(111)-plane heavy-hole mass, which depends on the details of the SF potential  $[21,53,54]$  $[21,53,54]$ . The exciton mass can be roughly estimated as  $0.17m<sub>o</sub>$ , the sum of the bulk-GaAs in-(111)-plane heavy-hole mass and the isotropic electron mass, where  $m<sub>o</sub>$  is the free-electron mass. In addition, we note that the magneto-Stark induced splitting saturates at high fields [Figs.  $3(f)$  and  $3(g)$ ], possibly due to a decreased exciton dipole moment from the magnetic-field-induced shrinking of the exciton wave function. Future work will investigate exciton confinement potentials consistent with the observed dipole

## <span id="page-3-0"></span>TODD KARIN *et al.* PHYSICAL REVIEW B **94**, 041201(R) (2016)

moment, diamagnetic shift, and saturation of the magneto-Stark effect. A microscopic understanding of the confinement potential may enable predictions for the binding potential and excitonic dipole moment for SFs in other semiconductors.

# **VI. CONCLUSION**

We have shown that SFs in GaAs are an almost perfect 2D potential that binds heavy-hole excitons. These excitons freely propagate in the SF plane, a conclusion confirmed via the magneto-Stark effect. Further, an asymmetry of the SF potential induces a giant dipole moment of the SF-bound exciton. Such excitons could be useful for studying the many-body physics of interacting dipoles. In conventional excitonic systems, typical electron-hole separations are on the order of several nm  $[6,55]$  $[6,55]$ , whereas the SF-bound exciton has a gigantic electron-hole separation of 10 nm and the possibility to modify this value with an applied field. In addition, the ultranarrow linewidths in the SF system will allow the small energy shifts present in many-body interactions to be observed. As a rough estimate, the interaction energy of two such dipoles will exceed the SF FWHM of 77 *μ*eV when the exciton density is greater than 230  $\mu$ m<sup>-2</sup>. Using a wave-function size of approximately 10 nm, the critical density for exciton overlap in the 2D potential is 10 000  $\mu$ m<sup>-2</sup>. Therefore, the SF-bound exciton system could show sizable dipole-dipole interactions and may demonstrate coherent phenomena at reasonable exciton densities [\[24,25](#page-4-0)[,53\]](#page-5-0).
