(Received 19 February 2016; revised manuscript received 20 September 2016; published 9 December 2016)

By means of first-principles calculations, we have systematically investigated how the magnetodynamic properties Gilbert damping, magnetization, and exchange stiffness are affected when permalloy (Py) (Fe₀¹⁹Ni₀⁸¹) is doped with 4*d* or 5*d* transition metal impurities. We find that the trends in the Gilbert damping can be understood from relatively few basic parameters such as the density of states at the Fermi level, the spin-orbit coupling, and the impurity concentration. The temperature dependence of the Gilbert damping is found to be very weak which we relate to the lack of intraband transitions in alloys. Doping with 4*d* elements has no major impact on the studied Gilbert damping, apart from diluting the host. However, the 5*d* elements have a profound effect on the damping and allow it to be tuned over a large interval while maintaining the magnetization and exchange stiffness. As regards the spin stiffness, doping with early transition metals results in considerable softening, whereas late transition metals have a minor impact. Our result agree well with earlier calculations where available. In comparison to experiments, the computed Gilbert damping appears slightly underestimated, whereas the spin stiffness shows a general good agreement.

I. INTRODUCTION

Spintronics and magnonic applications have attracted a great extent of attention due to the potential of creating devices with reduced energy consumption and improved performance compared to traditional semiconductor devices $[1-3]$. An important ingredient for understanding and improving the performance of these devices is a good knowledge of the magnetic properties. In this study, we focus on the saturation magnetization M_s , the exchange stiffness A , and the Gilbert damping α [\[4\]](#page-6-0). The latter is determining the energy dissipation rate of which a magnetic system returns to its equilibrium state from an excited state, e.g., after the system has been subjected to external stimuli such as an electrical current which alters its magnetic state. The three parameters, M_s , *A*, and α , describe the magnetodynamical properties of the system of interest. Ultimately one would like to have complete independent control and tunability of these properties. In this study, the magnetodynamical properties of permalloy (Py) doped with transition-metal impurities are systematically investigated within a coherent computational framework.

The capability of tuning the damping with additional doping elements for a material with such a technological importance as Py is important for the development of possible new devices in spintronics and magnonics. The understanding of how transition metals or rare-earth dopants can affect the properties of Py has been the focus of a number of recent experimental studies [\[5–9\]](#page-6-0). In principle, a large variety of elements in the Periodic Table can be used as dopant but in order to narrow down the present study, we here solely concentrated on transition metals belonging to the 4*d* and 5*d* series. Typically in the experimental studies, the ferromagnetic resonance $[10]$ (FMR) technique is employed and α and M_s are extracted from the linewidth of the uniform precession mode, while *A* is extracted from the first perpendicular standing spin-wave mode $[11,12]$. On the theory side, calculations of Gilbert damping from first-principles density-functional theory methods have only recently become possible due to the complexity of such calculations. Two main approaches have emerged: the breathing Fermi surface model [\[13,14\]](#page-6-0) and the torque correlation models [\[15,16\]](#page-6-0). Common to both approaches is that spin-orbit coupling along with the density of states at the Fermi level are the main driving forces behind the damping. The breathing Fermi surface model only takes into account intraband transitions while torque correlation model also includes interband transitions. The torque correlation model in its original form contains a free parameter, namely the scattering relaxation time. Brataas *et al.* [\[17\]](#page-6-0) later lifted this restriction by employing scattering theory and linear response theory. The resulting formalism provides a firm foundation of calculating *α* quantitatively from first-principles methods and allows further investigations of the source of damping. Gilbert damping in pure Py as well as doping with selected elements have been calculated in the past [\[9,18–20\]](#page-6-0); however, no systematic study of the magnetodynamic properties within the same computational framework has been conducted which the present paper aims to address.

The paper is outlined as follows: in Sec. II we present the formalism and details of the calculations, in Sec. [III](#page-1-0) we present the results of our study, and in Sec. [IV](#page-6-0) we summarize our findings and provide an outlook.

II. THEORY

A. Crystal structure of permalloy and treatment of disorder in the first-principles calculations

Pure permalloy (Py), an alloy consisting of iron (Fe) and nickel (Ni) with composition Fe_{0.19}Ni_{0.81}, crystallizes in the

^{*}fanpan@kth.se

face-centered-cubic (fcc) crystal structure, where Fe and Ni atoms are randomly distributed. Additional doping with 4*d* and 5*d* impurities (M) substitutes Fe (or Ni) so that it becomes a three-component alloy with composition $Py_{1-x}M_x$, where *x* is the concentration of the dopant.

All first-principles calculations in this study were performed using the spin-polarized relativistic (SPR) Korringa-Kohn-Rostoker (KKR) [\[21\]](#page-6-0) Green's function (GF) approach as implemented in the SPR-KKR software [\[22\]](#page-6-0). The generalized gradient approximation (GGA) [\[23\]](#page-6-0) was used in the parametrization of the exchange correlation potential and both the core and valence electrons were solved using the fully relativistic Dirac equation. The broken symmetry associated with the chemical substitution in the system was treated using the coherent potential approximation (CPA) [\[24,25\]](#page-6-0).

B. Calculation of magnetodynamical properties of alloys: Gilbert damping within linear response theory and spin stiffness

The formalism for calculating Gilbert damping from first principles, used in the present work, has been derived in Refs. [\[17,19,20\]](#page-6-0). Within the adiabatic approximation the damping can be related as the dissipation rate of the magnetic energy which in turn can be associated to the Landau-Lifshitz-Gilbert (LLG) equation [\[4\]](#page-6-0). The dimensionless Gilbert damping parameter α has the generalized form of a tensor and was originally derived from a Kubo-Greenwood-like transport equation [\[26,27\]](#page-6-0). The final expression for the Gilbert damping parameter in the present framework becomes

$$
\alpha_{\mu\nu} = -\frac{\hbar \gamma}{\pi M_s} \text{Trace} \bigg(\frac{\partial \hat{H}}{\partial u_{\mu}} \text{Im} G^+(E_F) \frac{\partial \hat{H}}{\partial u_{\nu}} \text{Im} G^+(E_F) \bigg)_{c}, \quad (1)
$$

where $\langle \ldots \rangle_c$ denotes a configurational average and γ the gyromagnetic ratio, $\partial \hat{H}/\partial u$ the torque operator, and $G^+(E_F)$ a Green's function at the Fermi energy E_F . For the cubic systems treated in this study, the tensorial form of the damping with no loss of generality can be replaced by a scalar damping parameter.

Thermal effects from the atomic displacements and spin fluctuations were included using the alloy-analogy model [\[28\]](#page-6-0) within CPA.

The spin-wave stiffness *D* is defined as the curvature of the spin-wave dispersion spectrum at small wave vectors $[\omega(\mathbf{q}) \approx$ $Dq²$. *D* in turn is directly related to the exchange interactions in the Heisenberg model which are obtained using the LKAG formalism [\[29,30\]](#page-6-0) such that

$$
D = \frac{2}{3} \sum_{ij} \frac{J_{ij} R_{ij}^2}{\sqrt{m_i m_j}},
$$
 (2)

where J_{ij} is the interatomic exchange parameter between the *i*th and *j*th magnetic moment, R_{ij} the distance connecting the atomic sites with index i and j , and m_i (m_j) the magnetic moment at site i (j). It is worth noting that Eq. (2) only holds for cubic systems as treated here; for lower symmetries this relation needs modifications. The exchange couplings in metallic systems are typically long ranged and could have oscillations of ferromagnetic and antiferromagnetic character, such as present in RKKY type interactions. Due to the oscillations in exchange interactions, care is needed to guarantee a numerical convergence of the series in Eq. (2). This was achieved following the methodology as outlined in Refs. [\[31,32\]](#page-6-0).

C. Calculation of finite temperature magnetic properties

Once the exchange interactions of the Heisenberg model have been calculated, the properties at finite temperature were obtained from Metropolis [\[33\]](#page-6-0) Monte Carlo simulations as implemented in the UppASD software package [\[34,35\]](#page-6-0). After having the temperature-dependent magnetization, the micromagnetic exchange stiffness *A* is expressed in terms of [\[36](#page-6-0)[–39\]](#page-7-0)

$$
A(T) = \frac{DM(T)}{2g\mu_B},\tag{3}
$$

where μ_B is the Bohr magneton, *g* is the Landé *g* factor, and $M(T)$ is the magnetization at temperature T .

D. Details of the calculations

For each concentration of the different impurities in Py, the lattice parameter was optimized by varying the volume and finding the energy minimum. The *k*-point mesh for the selfconsistent calculations and exchange interactions was set to $22³$ giving around 800 k points in the irreducible wedge of the Brillouin zone (IBZ). The Gilbert damping calculation requires a very fine mesh to resolve all the Fermi surface features and therefore a significantly denser *k*-point mesh of 2283 (∼1*.*⁰ [×] 106 *^k* points in IBZ) was employed in these calculations to ensure numerical convergence. Moreover, vertex corrections [\[40\]](#page-7-0) were included in the damping calculations since it has been revealed to be important in previous studies [\[20\]](#page-6-0) for obtaining quantitative results.

III. RESULTS

A. Equilibrium volumes and induced magnetic moments

Figure 1 shows the calculated equilibrium volume of doped Py for two different concentrations (10% and 15%) of impurities from the 4*d* and 5*d* series of the Periodic Table.

FIG. 1. Calculated equilibrium volumes of Py-M, where M stands for a 4*d* (left) or 5*d* (right) transition metal. Values for 10% and 15% doping concentrations are shown. Reference value of pure Py is displayed with a dashed line.

FIG. 2. (Upper) Total magnetic moment (spin and orbital) for different impurities and concentrations. Reference value for pure Py marked with a dashed line. (Lower) Local impurity magnetic moment for $Py_{0.95}M_{0.05}$.

First of all, it is noted that the volume increases with the concentration, and the volume within a series (4*d* or 5*d*) has a parabolic shape with minimum in the middle of the series. This is expected since the bonding states are consecutively filled and maximized in the middle of the series and thus the bonding strength reaches a maximum. Moving further through the series, antibonding states start to fill, giving rise to weaker bonding and larger equilibrium volumes. This is also consistent with the atomic volumes within the two series [\[41\]](#page-7-0).

The local moments of the host atoms are only weakly dependent on the type of impurity atom present. Moreover, the magnetic moments are dominated by the spin moment μ_S , while the orbital moments μ_L are much smaller. As an example, in pure Py without additional doping, the spin (orbital) moments of Fe is calculated to $\approx 2.64(0.05)\mu_B$ and for Ni $\approx 0.64(0.05)\mu_B$, respectively. This adds up to an average spin (orbital) moment of $\approx 1.04(0.05)\mu_B$ by taking into account the concentration of Fe and Ni in Py. The total moment is analyzed in more detail in Fig. 2 (upper panel). As mentioned above, one would like to achieve tunable and independent control of the saturation magnetization. Reducing the magnetization reduces the radiative extrinsic damping but could at the same time affect the other properties in an unwanted manner. In many situations, one strives for keeping the value of the total moment (saturation magnetization) at least similar to pure Py, even for the doped systems. It is immediately clear from Fig. 2 that doping elements late in the series are the most preferable in that respect, for instance, Rh and Pd in the 4*d* series and Ir, Pt, and Au in the 5*d* series, which is expected since the electronic configuration of these impurities are closely matched with the host.

In Fig. 2 (lower panel) we show the local impurity magnetic moments for 5% impurities in Py. In the beginning of the 4*d* (5*d*) series, the impurity atoms have an antiferromagnetic coupling, reflected in the negative moments relatively to the host (Fe and Ni) atoms, whereas they are ferromagnetically

FIG. 3. Bloch spectral function *A*(*E,***k**) of Py (upper panel) and Py doped with 20% Pt impurities (lower panel). The Fermi level is indicated with a horizontal black line at zero energy.

coupled (i.e., positive moments) among the latter elements in the series. The antiferromagnetic coupling may not be preferred from an engineering point of view since it will tend to soften the magnetic properties and maybe even cause more complicated noncollinear magnetic configurations to occur.

B. Band structure

The lack of translational symmetry in Py and doped-Py random alloys complicates the calculations using normal bandstructure methods due to the need for large supercells. However, employing CPA restores the translational symmetry and, more importantly, the band structure of disordered systems can be analyzed through the Bloch spectral function (BSF) *A*(*E,***k**), which can be seen as a wave vector **k**-dependent density of states (DOS) function. For ordered systems the BSF is a δ -like function at energy $E(\mathbf{k})$, while for disordered systems each peak has an associated broadening with a linewidth proportional to the amount of disorder scattering. In the upper panel of Fig. 3 the calculated BSF for pure Py is displayed. Despite being a disordered system, the electron bands are rather sharp below the Fermi level, while in the vicinity of the Fermi level the bands become much more diffuse indicating that most of the disorder scattering takes place around these energies.

When Py is doped with 20% Pt impurities, the positions of the electron bands do not change much as shown by the BSF in the lower panel of Fig. 3. The most striking change is the large increase of the disorder scattering compared to Py causing diffuse electron bands throughout a wide energy window in the Brillouin zone. However, exactly at the Fermi level the difference between the doped and undoped system is

FIG. 4. (Upper) Calculated Gilbert damping parameter for Py+M in different concentrations of 4*d* and 5*d* transition metal M at low temperatures $(T = 10 \text{ K})$. Experimental results from Ref. [\[5\]](#page-6-0) measured at room temperature are displayed by solid squares and dashed lines indicate the reference value for pure Py. (Lower) Total (blue) and impurity (black) density of states at the Fermi level E_F for 10% impurities in Py.

not very pronounced and these states are the most important for the determination of the Gilbert damping, as seen from Eq. (1) .

C. Gilbert damping: Effect of doping

The calculated Gilbert damping of the doped Py systems for different concentrations of impurities is shown in Fig. 4 (upper panel). The 4*d* impurities only marginally influence the damping, while the 5*d* impurities dramatically change the damping. The first observation is that we obtain a very good agreement with the previous study [\[19\]](#page-6-0) for the 5*d* series with 10% impurities; this is however expected, since we have used the same methodology. Secondly, the most dramatic effect on damping upon doping is for the case of Py doped with 20% Os impurities in which the damping increases with approximately 800% compared to pure Py, as previously reported in Ref. [\[20\]](#page-6-0). In the present study we have systematically varied the impurity elements and concentrations over a large interval for identifying the trends of Gilbert damping. Compared to experiments [\[5\]](#page-6-0), the calculations consistently find smaller Gilbert damping than what are reported in experiments, and for the 4*d* series the calculations do not capture some of the experimental trends, in particular the peak for Ru. However, it is worth remembering that calculations only show the intrinsic part of the damping, while experiments may still have some additional portion of extrinsic damping left such as eddy current damping and radiation damping, since it is difficult to fully separate the different contributions. Moreover, in calculations a completely random distribution of atoms without short-range order effects is assumed, while there may be sample inhomogeneities such as clustering in the real samples.

In order to give a rough estimate of the error bar of the calculated damping, we repeated the calculations for a few different volumes and different choices of exchange correlation potentials. The values did not change significantly $(\pm 10\%)$. In particular, the use of local spin density approximation (LDA) instead of GGA result in slightly larger damping, but the overall trend is very similar.

According to most theoretical models, the two main physical properties that determine the damping are the density of states (DOS) at the Fermi level and the strength of the spin-orbit coupling. In the following, we first investigate separately how these properties affect the damping and later the combination of the two. In the lower panel of Fig. 4, the total DOS and the impurity-DOS are displayed for 10% impurity concentration of 4*d* and 5*d* series transition metals. In both the 4*d* and 5*d* series the impurity-DOS exhibits a maximum in the middle of the series. However, the value of the DOS are similar for the 4*d* and 5*d* series and therefore cannot solely explain the large difference in damping found between the two series. For the 4*d* series, the calculated damping is not directly proportional to the DOS, while there is a significant correlation between the DOS and damping in the 5*d* series. The qualitative discrepancy between theory and experiment for the 4*d* series is a bit surprising, most significantly the experimental peak for Ru that is missing in calculations. Unfortunately, we have not been able to pinpoint the origin of the disagreement, which is surprising, in particular, since the results for 5*d* series show good agreement. We have not found any other calculated values of 4*d* impurities in Py in the literature to compare with.

In order to analyze the separate influence of spin-orbit coupling on the damping, we show in the upper panel of Fig. [5](#page-4-0) the spin-orbit parameter $ξ \propto (1/r)dV(r)/dr$, where $V(r)$ is the radial potential, of the impurity d states. The calculations include all relativistic effects by solving the Dirac equation but here we have specifically extracted the main contribution from the spin-orbit coupling. As expected, the spin-orbit parameter increases with atomic number *Z*, and is therefore considerably larger in the 5*d* series compared to the 4*d* series. This is the most likely explanation why the damping is found to be larger in the 5*d* series than in the 4*d* series. Within a single element in either the 4*d* or 5*d* series, the damping is quadratically dependent on the relative strength of the spin-orbit strength [\[20\]](#page-6-0). The calculated values of the spin-orbit parameter are in good agreement with previous calculations [\[42,43\]](#page-7-0) and reaches large values of 0.6–0.9 eV for the late 5*d* elements Ir, Pt, and Au, while all values are below 0.3 eV for the 4*d* series. If the damping across elements would only be proportional to the spin-orbit coupling, then the damping would monotonously increase with atomic number and since this is not what happens, we conclude that there is a delicate balance between spin-orbit coupling and DOS that determines the damping which is further highlighted through a qualitative analysis of the involved scattering processes.

In the torque correlation model, the dominant contribution to damping is through the scattering [\[44,45\]](#page-7-0) and takes the

FIG. 5. Upper: the spin-orbit parameter of *d* electrons of the impurity atoms. Lower: qualitative comparison between our calculations and the torque correlation (TC) model for the damping with 10% impurity concentration.

following form:

$$
\alpha = \frac{1}{\gamma M_s} \left(\frac{\gamma}{2}\right)^2 n(E_F) \xi^2 (g-2)^2 / \tau, \tag{4}
$$

where τ is the relaxation time between scattering events, and *g* the Landé *g* factor, for small orbital contributions, can be related as [\[46\]](#page-7-0) $g = 2(1 + \mu_L/\mu_s)$. We assume that τ is the same for all impurities, which is clearly an approximation but calculating τ is beyond the scope of the present study. By normalizing the damping from Eq. (4) such that the value for Os (10% concentration) coincides with the first-principles calculations, we obtain a qualitative comparison between the model and calculations, as illustrated in the lower panel of Fig. 5. It confirms the trend in which the 5*d* series leads to a larger damping than the 4*d* series and captures qualitatively the main features. However, the peak value of the damping within the 5*d* series in the TC model occurs for Ir, while calculations give Os as in experiment. Another model developed for lowdimensional magnetic systems such as adatoms and clusters suggests that the damping is proportional to the product of majority and minority density of states at the Fermi level [\[47\]](#page-7-0). It produces a parabolic trend but with maximum at incorrect position and fails to capture the increased damping of the 5*d* elements.

To further analyze the role of impurity atoms on the damping we also performed calculations where instead of impurities we added vacancies in the system, i.e., void atoms. The results are shown in Fig. 6 where damping as a function of concentration of Ag (4*d*), Os (5*d*), and vacancies are compared to each other along with Os results from experimental [\[5\]](#page-6-0)

FIG. 6. Calculated Gilbert damping as a function of Os, Ag and vacancy (Vac) concentration in Py. Open red circle: calculation from Ref. [\[19\]](#page-6-0); solid red circle: calculation from Ref. [\[20\]](#page-6-0); red solid square: experimental data from Ref. [\[5\]](#page-6-0).

and previous calculations. Surprisingly, vacancies have more or less the same effect as Ag, with the damping practically constant as the vacancy concentration is increased. Since Ag has a zero moment, small spin-orbit coupling, and small density of states at the Fermi level, the net effect of Ag from a damping (or scattering point of view) is mainly diluting the host, i.e., an effect similar to what one would expect from void atoms. In contrast to Ag, Os being a 5*d* metal has a strong dependence on the concentration which is previously analyzed in terms of density of states, and meanwhile has a strong spin-orbit coupling effect to the damping parameter. Our results from Os are slightly lower than the previous reported values [\[19,20\]](#page-6-0), despite using same software. However, the most likely reason for the small discrepancy is the use of different exchange-correlation potentials in the two cases.

D. Gilbert damping: Effect of temperature

In the previous section we studied how the damping depends on the electronic structure and spin-orbit coupling at low temperatures. However, with increasing temperature additional scattering mechanisms contribute to the damping, most importantly phonon and magnon scattering. The phonon scattering is indirectly taken into account by including a number of independent atomic displacements bringing the atoms out from their equilibrium positions. The magnon scattering is indirectly included by reducing the magnetic moment for a few configurations and then averaging over all atomic and magnetic configurations within CPA. It should be noted that the present methodology using the alloy-analogy model [\[28\]](#page-6-0) has limitations for pure systems at very low temperatures where the damping diverges, but we are far from that situation in this study since all systems have intrinsic chemical disorder. Nevertheless, the limitations for pure systems can be lifted by a more advanced treatment using the explicit calculation of the dynamical susceptibility [\[48\]](#page-7-0).

FIG. 7. Gilbert damping parameter including temperature effects from both atomic displacements and spin fluctuations (upper panel). The effect of spin fluctuations on the Gilbert damping (lower panel); see text in details.

The temperature dependence of the damping for a few selected systems is displayed in Fig. 7, where both atomic displacements and spin fluctuations are taken into account. From the 4*d* (5*d*) series, we choose to show results for Mo and Rh (W and Pt), where Mo (W) has a small antiferromagnetic moment and Rh (Pt) a sizable ferromagnetic moment; see Fig. [2.](#page-2-0) All systems display an overall weak temperature dependence of the damping which increases only marginally with temperature, as shown in upper panel of Fig. 7. In order to separate the temperature contributions from atomic displacements and spin fluctuations, we show the ratio between the total damping and damping where only atomic displacements are taken into account in the lower panel of Fig. 7. The two systems with sizable moments (Rh and Pt), clearly have a dominant contribution from spin fluctuations when the moments are reduced upon increased scattering due to temperature. On the contrary, in the two systems with (small) antiferromagnetic moments (Mo and W), the effect of the spin fluctuations on the damping is negligible and atomic displacements are solely responsible. The weak temperature dependence found in these doped Py systems is somewhat surprising since, in pure metals like Fe and Ni, a strong temperature dependence has been both measured and calculated [\[20\]](#page-6-0); however, data for other random alloy systems is scarce.

The temperature dependence of the damping from the band structure is often attributed to interband and intraband transitions which is demonstrated from the torque-correlation model. Intraband transitions have a conductivitylike dependence on temperature, while interband shows a resistivitylike dependence. The weak overall dependence found in the

FIG. 8. Spin-wave stiffness *D* of Py-M in the ground state (top) and exchange stiffness constant *A* at room temperature $T = 300 \text{ K}$ (bottom) as a function of doping concentration. The horizontal dashed and solid lines show the reference values of pure Py from calculation and experiments, respectively. The scattered dots indicate the experimental data for $Py+15\%M$ (Ag/Pt/Au) from Ref. [\[9\]](#page-6-0).

systems in Fig. 7 suggests a lack of intraband transitions but a more detailed analysis of the band structure and thermal disorder is left for a future study.

E. Spin-wave stiffness and exchange stiffness

In the previous sections, we investigated saturation magnetization and damping and we now turn to the exchange stiffness. The calculated spin-wave stiffness D at $T = 0$ K, from Eq. [\(2\)](#page-1-0), is displayed in the upper panel of Fig. 8. *D* can be directly measured from neutron scattering experiments but, as far as we are aware, no such data exist. For the late elements in the 4*d* and 5*d* series, the spin-wave stiffness is maximized and has values rather similar to pure Py, however with a reduction of approximately 20%. In micromagnetic modeling, it is common to use the exchange stiffness *A* instead of *D*. *A* is proportional to *D*, as follows from Eq. [\(3\)](#page-1-0), and the sole temperature dependence of *A* therefore comes from the magnetization. In the lower panel of Fig. 8, we show the calculated room temperature $(T = 300 \text{ K})$ values of *A*, together with values for pure Py and available experimental data. In the beginning of the 4*d* (5*d*) series, the exchange stiffness becomes small upon increasing concentration of impurities and the systems are magnetically very soft. This follows from the fact that magnetization is small because the systems are close to their ordering temperature. Contrary, for

the late elements in the 4*d* (5*d*) series, the magnetization has a large finite value even at room temperature and therefore the exchange stiffness also has a large value, however reduced by approximately 15% compared to pure Py.

IV. SUMMARY AND CONCLUSIONS

A systematic study of the intrinsic magnetic properties of transition-metal doped Py has been presented. It is found that the Gilbert damping depends strongly on the spin-orbit coupling of the impurity atoms and does also show a weak dependence on the density of states that determines disorder scattering. The strong spin-orbit coupling effect makes the 5*d* elements much more effective ingredients for changing the Gilbert damping and more sensitive to the concentration than the 4*d* elements. As a result, the damping is increased by an order of magnitude compared to undoped Py. Overall, the damping features are qualitatively rather well explained by the torque correlation model, yet it misses some quantitative predictive power that only first-principles results provide. Moreover, it is found that the damping overall has a weak temperature dependence even though it is slightly enhanced with temperature due to increased scattering caused by atomic displacements and spin fluctuations. Elements in the beginning of the 4*d* or 5*d* series are found to strongly influence the magnetization and exchange stiffness due to the antiferromagnetic coupling between impurity and host atoms. In contrast, elements in the end of the 4*d* or 5*d* series keep the magnetization and exchange stiffness rather similar to undoped Py. More specifically, doping with the 5*d* elements Os, Ir, and Pt are found to be excellent candidates for influencing the magnetodynamical properties of Py.

Recently, there has been an increasing attention to finding metallic materials with small intrinsic damping, for instance half metallic Heusler materials and FeCo alloys [32[,49\]](#page-7-0). Controlling and varying the magnetodynamical properties in these systems through doping or by other means, like defects, are very relevant and left for a future study.
