(Received 1 April 2017; published 28 June 2017)

Understanding the nature of two-level tunneling defects is important for minimizing their disruptive effects in various nanodevices. By exploiting the resonant coupling of these defects to a superconducting qubit, one can probe and coherently manipulate them individually. In this work, we utilize a phase qubit to induce Rabi oscillations of single tunneling defects and measure their dephasing rates as a function of the defect's asymmetry energy, which is tuned by an applied strain. The dephasing rates scale quadratically with the external strain and are inversely proportional to the Rabi frequency. These results are analyzed and explained within a model of interacting defects, in which pure dephasing of coherent high-frequency (gigahertz) defects is caused by interaction with incoherent low-frequency thermally excited defects. Our analysis sets an upper bound for the relaxation rates of thermally excited defects interacting strongly with strain fields.

DOI: [10.1103/PhysRevB.95.241409](https://doi.org/10.1103/PhysRevB.95.241409)

Since the early 1970's, various experiments over a wide range of amorphous solids revealed a universality in their thermal, acoustic, and dielectric properties below $1 K[1–3]$ $1 K[1–3]$. In an attempt to account for this universal behavior, the existence of two-level tunneling systems (TLSs) as a generic property in amorphous systems was postulated [\[4,5\]](#page-4-0). This phenomenological standard tunneling model (STM) is capable of explaining many of the universal low-temperature properties of the amorphous state of matter [\[6\]](#page-4-0). However, despite extensive efforts, the exact nature of the TLSs is still unknown.

With the recent progress in fabrication, manipulation, and measurement of quantum devices, it became crucial to understand the microscopic nature of the environment responsible for decoherence. There exists abundant experimental evidence that TLS-baths form a ubiquitous source of noise in various devices such as superconducting microwave resonators [\[7\]](#page-4-0), single-electron transistors [\[8\]](#page-4-0), and nanomechanical resonators [\[9\]](#page-4-0). In superconducting qubits, TLSs residing in the amorphous tunnel barrier of Josephson junctions were found to constitute a major source of decoherence [\[10,11\]](#page-4-0). Via their electric dipole moment, TLSs couple to the ac microwave fields in the circuit [\[12\]](#page-4-0). Whereas this coupling is deleterious from the point of view of qubit operation, it opens up the possibility to use superconducting qubits as tools for detection, manipulation, and characterization of individual TLSs. The transfer of a quantum state from a superconducting phase qubit to a resonant TLS was first demonstrated in Ref. [\[13\]](#page-4-0). This method was used to probe the coherence times of individual TLSs [\[13,14\]](#page-4-0). Furthermore, in Ref. [\[15\]](#page-4-0), it was shown that there exists an effective qubit-mediated coupling between TLSs and an externally applied electromagnetic ac field. This effective coupling was utilized to directly control the quantum state of individual TLSs by coherent resonant microwave driving [\[16\]](#page-4-0).

Previously [\[17\]](#page-4-0), we measured the Ramsey (free induction decay) and spin-echo pure dephasing rates of individual TLSs in a phase qubit as a function of their asymmetry energy, which was tuned by an applied strain via a piezoactuator [\[18\]](#page-4-0). Since the mutual longitudinal coupling between TLSs is proportional to the product of their asymmetry energies, strain-tuning allows one to gradually increase the longitudinal coupling of a single probed TLS to other TLSs and study its dephasing rates as a function of this coupling. This yields information about the spectrum of the environment to which a TLS couples, and provides a test to distinguish between different TLS models [\[19\]](#page-4-0). The experimental data on Ramsey dephasing indicate that the main low-frequency noise is quasistatic and can be attributed to slow thermal TLSs (with energy splitting smaller than the temperature), which flip between their energy eigenstates with maximum rates $\Gamma_{1,\text{max}} \approx 10 \, (\text{ms})^{-1}$ [\[17,19\]](#page-4-0), much smaller than the dephasing rates of the probed TLS which are of the order of $\Gamma_{\text{Ramsey}} \approx 1 (\mu s)^{-1}$. For such an environment, the echo protocol should be very efficient. Surprisingly, the experiment shows that the echo dephasing rates are not negligible, revealing the existence of an additional noise source with a flat power spectral density. It was suggested that this white noise may arise due to fast relaxing TLSs that interact much more strongly with strain fields compared to the weakly interacting TLSs of the STM [\[19,20\]](#page-4-0), or due to quasiparticle excitations [\[17,21,22\]](#page-4-0).

Here we study experimentally and theoretically the decoherence of Rabi oscillations of individual TLSs as a function of their strain-tuned asymmetry energy. At resonance with the driving field, the Rabi decay rate consists of three contributions from noise at different frequencies [\[24\]](#page-4-0). The first contribution results from noise at frequency equal to the energy splitting of the probed TLS ($\approx 2\pi \times 7$ GHz), and arises from degrees of freedom other than thermal TLSs, such as phonons or microwave photons. The other two contributions are due to noise at the Rabi frequency of the probed TLS (several megahertz) and low-frequency quasistatic noise similar to the one responsible for the Ramsey dephasing discussed in Refs. [\[17,19\]](#page-4-0). The last two contributions result from a transverse noise in the rotating frame, the origin of which is suggested to be thermal TLSs. Due to its transverse nature, this noise leads to a quadratic strain dependence of the Rabi dephasing rate near the symmetry point of the probed TLS, making the dephasing rates smaller than those in a Ramsey experiment.

We begin with a model of a high-frequency (gigahertz) single TLS driven by a microwave field at frequency ω_d and interacting with a thermal bath. In the basis of local states of the TLS, the Hamiltonian of the system is [\[23\]](#page-4-0)

$$
\hat{\mathcal{H}} = \frac{1}{2} (\varepsilon \hat{\tau}_z + \Delta \hat{\tau}_x) - \Omega_R^0 \cos (\omega_d t) \hat{\tau}_z + \frac{1}{2} \hat{\tau}_z \hat{O} + \hat{\mathcal{H}}_b. \quad (1)
$$

The first term describes the TLS, characterized by the asymmetry and tunneling energies, ε and Δ , with $\hat{\tau}_x$ and $\hat{\tau}_z$ being the Pauli matrices. The second term describes its coupling to the driving field with $\Omega_R^0 = pE_z$ being the maximum Rabi frequency, where *p* is the electric dipole moment of the TLS and E_z is the component of the electric field along its dipole moment. The third term is the coupling of the TLS to the bath observable \hat{O} . Motivated by the experimental data below, we write $\hat{O} = \hat{X} + \hat{Y}$, separating the environmental degrees of freedom which couple to the TLS into those fluctuating at frequencies below \sim megahertz (\hat{X}) and those fluctuating at frequencies of the order of the energy splitting of the TLS, $E = \sqrt{\varepsilon^2 + \Delta^2} \approx 2\pi \times 7$ GHz (\hat{Y}).

In the eigenbasis of the TLS, Eq. (1) reads

$$
\hat{\mathcal{H}} = \frac{E}{2}\hat{\sigma}_z - \Omega_R^0 \cos{(\omega_d t)}(\hat{\sigma}_z \cos{\theta} - \hat{\sigma}_x \sin{\theta}) \n+ \frac{1}{2}(\hat{\sigma}_z \cos{\theta} - \hat{\sigma}_x \sin{\theta})(\hat{X} + \hat{Y}) + \hat{\mathcal{H}}_b, \qquad (2)
$$

where $\hat{\sigma}_x$ and $\hat{\sigma}_z$ are the Pauli matrices in the eigenbasis of the TLS, $\cos \theta = \varepsilon / E$ and $\sin \theta = \Delta / E$. All these are straindependent via $\varepsilon(\epsilon)$, where ϵ is the strain at the position of the TLS. Taking into account the characteristic frequencies of \hat{X} and \hat{Y} , the relevant terms are [\[24\]](#page-4-0)

$$
\hat{\mathcal{H}} = \frac{E}{2}\hat{\sigma}_z + \Omega_{\mathbb{R}}\cos{(\omega_d t)}\hat{\sigma}_x + \frac{1}{2}(\cos{\theta}\,\hat{\sigma}_z\hat{X} - \sin{\theta}\,\hat{\sigma}_x\hat{Y}) \n+ \hat{\mathcal{H}}_b,
$$
\n(3)

where $\Omega_R = \Omega_R^0 \sin \theta$ is the Rabi frequency.

We are interested in the decay of Rabi oscillations, Γ_{D} , which is the equivalent of Γ_2 in the rotating frame. At resonance, $\omega_d = E$, the contribution of the high-frequency part *Y* to Γ_{D} is known to be $\frac{3}{4}\Gamma_1$ [\[24\]](#page-4-0), where $\Gamma_1 = \frac{1}{2}\sin^2\theta S_Y(\omega = E)$ is the relaxation rate in the laboratory frame, with $S_Y(\omega)$ being the noise spectral density of \hat{Y} . We now discuss the contribution of \hat{X} to Γ_{D} . To this end, we consider the Hamiltonian

$$
\hat{\mathcal{H}} = \frac{E}{2}\hat{\sigma}_z + \Omega_{\rm R} \cos{(\omega_d t)}\hat{\sigma}_x + \frac{\cos{\theta}}{2}\hat{\sigma}_z \hat{X} + \hat{\mathcal{H}}_{\rm b}.
$$
 (4)

We move to the rotating frame by applying the unitary transformation $\hat{U}_R = e^{i\omega_d t \hat{\sigma}_z/2}$. Using the rotating wave approximation and assuming resonant driving ($\omega_d = E$), the transformed Hamiltonian $\hat{\mathcal{H}}_R = \hat{U}_R \hat{\mathcal{H}} \hat{U}_R^{\dagger} + i \frac{d\hat{U}_R}{dt} \hat{U}_R^{\dagger}$ is

$$
\hat{\mathcal{H}}_R = \frac{\Omega_\mathrm{R}}{2} \hat{\sigma}_x + \frac{\cos \theta}{2} \hat{\sigma}_z \hat{X} + \hat{\mathcal{H}}_b. \tag{5}
$$

We observe that in the rotating frame and at resonance, the noise is purely transverse. This transverse noise gives rise to relaxation in the rotating frame of reference [\[24\]](#page-4-0), for which the golden rule yields

$$
\Gamma_{\nu} = \frac{1}{2} \cos^2 \theta \, S_X(\omega = \Omega_R), \tag{6}
$$

where $S_X(\omega)$ is the noise spectral density of \hat{X} . As usual, this results in a contribution of $\Gamma_{\nu}/2$ to Γ_{D} .

In an echo experiment, the same noise \hat{X} is longitudinal and the dephasing rate is

$$
\Gamma_{\text{Echo}} = \frac{1}{2} \cos^2 \theta \ S_X(\omega \approx \Gamma_{\text{Echo}}). \tag{7}
$$

Equation (7) coincides with the golden rule result if $S_X(\omega)$ is flat on a scale of Γ_{Echo} around zero frequency. Otherwise, it provides self-consistently an order of magnitude estimate for the dephasing time. Both Eqs. (6) and (7) are determined by the spectral density $S_X(\omega)$ at frequencies $\lesssim 1$ MHz (see the experimental data below).

Based on the Ramsey dephasing observed and discussed in Refs. $[17, 19]$, \hat{X} contains contributions from many slow fluctuators (thermal TLSs). Using standard estimations within the STM, one expects the relaxation rates Γ_1 of thermal TLSs (at $T = 35$ mK) to be smaller than 10 (ms)⁻¹ [\[17,19\]](#page-4-0). Consequently, these fluctuators are in the regime $\Gamma_1 \ll \Omega_R$, Γ_{Echo} and thus give rise to quasistatic noise, for which \hat{X} is constant during each run of the experiment but fluctuates between different runs. These fluctuators will not contribute to Γ_{ν} and $\Gamma_{\rm Echo}$. However, their second-order contribution to pure dephasing may be important.

The noise due to these fluctuators can be treated classically, $\hat{X} \rightarrow X(t) = \sum_j v_j \alpha_j(t)$, where each fluctuator is represented by a random telegraph process (RTP) $\alpha_j(t)$ which randomly switches between the states $\alpha_j = \pm 1$ with flipping rate $\gamma_{1,j}$ [\[25\]](#page-4-0), and interacts with the probed TLS with a coupling strength v_i . As shown in Refs. [\[17,19\]](#page-4-0), the interaction between the probed TLS and its closest thermal TLS, v_T , is of the order of a few megahertz. Therefore close to the symmetry point $\varepsilon = 0$ (thus $\cos \theta \ll 1$), one may assume *X* $\cos \theta \ll \Omega_R$. P point $\varepsilon = 0$ (thus cos *θ* \ll 1), one may assume *x* cos *θ* \ll sz_R.
We therefore expand $\sqrt{\Omega_R^2 + X^2 \cos^2 \theta} \approx \Omega_R + \frac{X^2 \cos^2 \theta}{2\Omega_R} =$ $\Omega_R + \frac{\cos^2 \theta}{2\Omega_R} \sum_j v_j^2 + \frac{\cos^2 \theta}{2\Omega_R} \sum_{i \neq j} v_i v_j \alpha_i(t) \alpha_j(t)$. The last term shows that the second-order contribution to the Rabi dephasing is due to products of RTPs. Since a product of two RTPs with flipping rates γ_1 and γ_2 is also a RTP with flipping rate $\gamma_1 + \gamma_2$, the second-order contribution to the Rabi dephasing is essentially similar to the Ramsey dephasing [\[17,19\]](#page-4-0). The decay law due to this low-frequency noise is $f_{\text{Rabi}}(t) =$ $(1/2^N)\sum_{\{\xi_k\}} \exp\left[i t \frac{\cos^2\theta}{2\Omega_k}\sum_{i\neq j} v_i v_j \xi_i \xi_j\right]$, where *N* is the number of thermal TLSs and the sum is over all the configurations of the variables $\xi_k = \pm 1$. Similarly to the Ramsey dephasing, it is expected to be dominated by the few closest fluctuators, and the typical decay rate is [\[26\]](#page-4-0)

$$
\Gamma_{\varphi}^{(2)} \approx \frac{v_T^2}{\Omega_R} \cos^2 \theta \,. \tag{8}
$$

The Rabi decay rate is the sum of the three contributions discussed above,

$$
\Gamma_{\rm D} = \frac{3\Gamma_1}{4} + \frac{\Gamma_{\nu}}{2} + \Gamma_{\varphi}^{(2)}.
$$
 (9)

We now discuss the experimental results for this decay rate. The distinct strain dependence of the first and the other RABI NOISE SPECTROSCOPY OF INDIVIDUAL TWO- . . . PHYSICAL REVIEW B **95**, 241409(R) (2017)

FIG. 1. Results obtained on four different TLSs. (Top) TLS swap spectroscopy, showing the resonance frequencies of TLSs by a reduction *δP* of the qubit population probability (dark traces in color-coded data). Superimposed dots are obtained from microwave spectroscopy, with the static TLS parameters resulting from hyperbolic fits. (Middle) Observed Rabi frequency $f_R = \Omega_R/2\pi$ for the probed TLSs driven at their resonance frequencies at fixed microwave power. (Bottom) TLS relaxation and pure dephasing rates as indicated in the legend, with quadratic fits to the Rabi oscillations and echo dephasing rates. The horizontal axes are calibrated to the asymmetry energy *ε/h* of the probed TLS.

two terms of Eq. [\(9\)](#page-1-0) allows us to separate the effect of the noise at the two spectral ranges discussed above (i.e., below ∼ megahertz and at gigahertz frequencies).

The TLSs studied here are contained in the amorphous AlO*^x* tunnel barrier of a 1 μ m²-sized Josephson junction, embedded in a superconducting loop, thus forming a SQUID whose discrete energy levels are used as logical qubit states between which transitions are driven via resonant microwave pulses. The sample was fabricated in the group of J. M. Martinis and is described in detail in Ref. [\[27\]](#page-4-0). We apply mechanical strain to the qubit chip by means of a piezoactuator [\[18\]](#page-4-0) to tune the asymmetry energy *ε* of the TLSs while their resonance frequencies are tracked with the qubit (top row of Fig. 1) [\[28\]](#page-4-0). At each strain value, standard microwave pulse sequences are applied [\[17\]](#page-4-0) to measure the energy relaxation rate Γ_1 and the dephasing rates of Rabi oscillations and echo signals, Γ_{Rabi} and Γ_{Echo} , of the probed TLS (bottom row of Fig. 1). Here, slightly negative rate values stem from uncertainties in the independently measured energy relaxation rates which are subtracted from the dephasing rates.

In the middle row of Fig. 1, we present the frequency of Rabi oscillations for a fixed microwave driving power. Peaks and dips, which appear symmetrically with respect to $\varepsilon = 0$, mainly originate from the frequency dependence of the transmitted microwave power due to cable resonances. When these fluctuations are smoothened out, the Rabi frequency tends to increase with *ε*. This is because the TLS is driven via a transition that involves a virtual state of the qubit, such that the effective driving strength depends on the detuning between the TLS and the qubit [\[16\]](#page-4-0), where the latter was tuned to the fixed frequency of 8.8 GHz during all measurements. This increase is partly compensated by the factor $\sin \theta = \Delta/E$ appearing in the definition of the Rabi frequency.

The strain dependence of Γ_1 and Γ_{Echo} was discussed in Ref. [\[17\]](#page-4-0). Here we focus on the Rabi dephasing rate. Due to limitations in the applicable microwave power, the Rabi frequency is at maximum of order 5 MHz, such that only a few oscillations can be observed during the coherence time of the TLS [see Fig. $2(a)$]. Together with the measurement uncertainties it therefore becomes practically impossible to determine the exact functional form of the decay envelope. We thus extract an effective decay rate Γ_D from a fit to an exponentially damped sinusoid.

At the symmetry point $\varepsilon = 0 (\cos \theta = 0)$, one expects $\Gamma_{\text{D}} = \frac{3}{2} \Gamma$, so that the Babi decay rate is independent of the Babi $\frac{3}{4}\Gamma_1$, so that the Rabi decay rate is independent of the Rabi frequency. The experimental observation is in good agreement with this prediction, as shown in the inset of Fig. [2\(b\).](#page-3-0) To analyze the effect of the noise at frequencies $\omega \le \Omega_R$, one has to subtract this contribution of fluctuations at gigahertz frequencies from Γ_{D} . In the bottom row of Fig. 1, we show the Rabi dephasing rate $\Gamma_{\text{Rabi}} \equiv \Gamma_{\text{D}} - \frac{3}{4} \Gamma_{\text{1}}$. For all investigated TLSs, Γ_{Rabi} vanishes at the symmetry point and increases quadratically with *ε*. This quadratic strain dependence is also predicted by the above model, which shows that both Γ_v and $\Gamma_{\varphi}^{(2)}$ scale as $\cos^2 \theta = (\varepsilon/E)^2 \approx (\varepsilon/\Delta)^2$ [Eqs. [\(6\)](#page-1-0) and [\(8\)](#page-1-0)]. Table [I](#page-3-0) summarizes the measured tunneling energies , the deformation potentials *∂ε/∂V* where *V* is the applied piezovoltage, and the relaxation times T_1 measured at $\varepsilon = 0$. The strength of Rabi and echo dephasing rates is obtained from quadratic fits to $\Gamma_i = A_i(\varepsilon/E)^2$, where $i = \{\text{Rabi}, \text{Echo}\}.$

FIG. 2. (a) Rabi oscillations observed in TLS 2 at $\varepsilon/h =$ −0*.*921 GHz and at different drive powers (individual curves offset by 0.15 each for clarity). Rabi frequency $f_R = \Omega_R/2\pi$ and effective decay time $T_D \equiv \Gamma_D^{-1}$ quoted in the legend are extracted from fits to exponentially damped sinusoids (solid lines). (b) Log-log plot of the pure dephasing rate $\Gamma_{\text{Rabi}} \equiv \Gamma_{\text{D}} - \frac{3}{4} \Gamma_1$ as a function of the Rabi frequency. Solid lines are fits to $\Gamma_{\text{Rabi}} = A/\Omega_{\text{R}}$. (Inset) At the symmetry point of the TLS, $\varepsilon = 0$, the Rabi decay is only limited by energy relaxation such that $\Gamma_{\text{D}} = \frac{3}{4} \Gamma_{1}$.

We now compare the values extracted for A_{Rabi} and A_{Echo} with the expressions derived from the above model,

$$
A_{\text{Rabi}} = \frac{\Gamma_{\text{Rabi}}}{\cos^2 \theta} = \frac{\Gamma_\nu / 2 + \Gamma_\varphi^{(2)}}{\cos^2 \theta} = \frac{S_X(\Omega_\text{R})}{4} + \frac{v_T^2}{\Omega_\text{R}},\quad(10)
$$

$$
A_{\rm Echo} = \frac{\Gamma_{\rm Echo}}{\cos^2 \theta} = \frac{S_X(\Gamma_{\rm Echo})}{2}.
$$
 (11)

Further information on A_{Rabi} comes from the inverse dependence of the Rabi dephasing rate on the Rabi frequency, $\Gamma_{\text{Rabi}} = A / \Omega_{\text{R}}$, observed at fixed ε and displayed in Fig. 2(b)

TABLE I. Parameters of the four TLSs investigated here.

SHLOMI MATITYAHU *et al.* PHYSICAL REVIEW B **95**, 241409(R) (2017)

for TLS 2, with fit parameters *A* listed in the legend. Comparing this observation with Eq. (10) , we identify two possibilities: (I) the first term of Eq. (10) dominates, in which case $S_X(\Omega_R) \propto \Omega_R^{-1}$ (1/*f* noise), and (II) the second contribution dominates. In the first case $\Gamma_{\text{Echo}} \gg \Gamma_{\text{Rabi}}$ because $\Gamma_{\rm Echo} \ll \Omega_{\rm Rabi}$, which is inconsistent with the experimental observations. Thus we adopt the second scenario. Indeed, with v_T estimated by several megahertz $[17,19]$, the contribution v_T^2 / Ω_R due to thermal standard TLSs gives the correct order of magnitude for *A*Rabi, and therefore this scenario seems plausible. Moreover, according to our previous results [\[17\]](#page-4-0), the strain dependence and the ratio between the Ramsey and the echo dephasing rates are inconsistent with a 1*/f* spectrum at frequencies around $\Gamma_{\rm Echo}$, but rather suggest a flat spectrum. It is therefore improbable that $S_X(\Omega_R) \propto \Omega_R^{-1}$, leading to the conclusion that $S_X(\Omega_R) \ll v_T^2/\Omega_R$.

What could then be learned from comparing A_{Rabi} with *A*Echo? Based on our previous results in Ref. [\[17\]](#page-4-0), we try to associate the two contributions to Γ_{Rabi} with the two types of TLSs discussed in Refs. [\[19,20\]](#page-4-0). In Refs. [\[17,19\]](#page-4-0), we attributed the Ramsey dephasing to an ensemble of slow (quasi-static) thermal TLSs (denoted as *τ* -TLSs), with parameters consistent with the STM, for which the echo protocol should be more efficient than observed. This discrepancy was explained by the existence of a few fluctuators, with relaxation rates greater than $\Gamma_{\text{Echo}} \sim 1 \ \mu s^{-1}$ (denoted as *S*-TLSs). In contrast to the standard fluctuators, these fast fluctuators contribute to $S_X(\omega)$ at megahertz frequencies. The existence of fast relaxing TLSs interacting strongly with strain fields was recently suggested as a generic property in disordered solids [\[20\]](#page-4-0), and the distribution of their asymmetry energies was analyzed [\[29,30\]](#page-4-0). However, the distribution of their tunneling energies, and hence their relaxation rates, is unknown.

Let us assume the existence of a single fast fluctuator with relaxation rate γ_1 and coupling constant to the probed TLS $v_{S\tau}$, for which $S_X(\omega) = 2v_{S\tau}^2 \gamma_1/(\omega^2 + \gamma_1^2)$. If the second contribution to *A*Rabi is dominant, the observation that *A*Rabi and *A*_{Echo} are comparable (see Fig. [1](#page-2-0) and Table I) implies that $S_X(\Gamma_{\text{Echo}}) \gg S_X(\Omega_R)$. Since $\Omega_R \gg \Gamma_{\text{Echo}}$, one obtains the condition $\Omega_R > \gamma_1$, which sets an upper bound of ~ 10 μs^{-1} for γ_1 of the fast relaxing fluctuator. We thus conclude that the relaxation rates of the fast relaxing fluctuators are in the range $1 (\mu s)^{-1} \lesssim \gamma_1 \lesssim 10 \ \mu s^{-1}.$

In summary, we have measured the decay of Rabi oscillations as a function of the asymmetry energy of individual TLSs, which is controlled by applying an external strain. We employ a theoretical model based on interacting TLSs and find agreement with the experimentally observed magnitude of the Rabi dephasing rate and its dependence on the applied strain and on the Rabi frequency. In conjunction with measurements of energy relaxation, Ramsey and echo dephasing [\[17,19\]](#page-4-0), Rabi noise spectroscopy provides information about the spectrum of the environment to which TLSs couple, within three different spectral ranges. This allows one to distinguish between contributions from distinct environmental degrees of freedom. Such information is important for minimizing noise due to TLSs in nanodevices, for exploiting TLSs as useful degrees of freedom, and for a basic understanding of amorphous systems at low temperatures. Particularly, our analysis reveals that besides the usual environment of phonons

RABI NOISE SPECTROSCOPY OF INDIVIDUAL TWO- . . . PHYSICAL REVIEW B **95**, 241409(R) (2017)

and standard TLSs obeying the STM, the probed TLSs also couple to fast relaxing fluctuators with relaxation rates $1 (\mu s)^{-1} \lesssim \gamma_1 \lesssim 10 \ \mu s^{-1}.$
