(Received 26 February 2008; published 11 August 2008)

The matrix coherent-state approach of the interacting boson model with configuration mixing is used to study the geometry of the platinum isotopes. With a parameter set determined in previous studies, it is found that the absolute minimum of the potential for the Pt isotopes evolves from spherical to oblate and finally to prolate shapes when the neutron number decreases from $N = 126$ (semi-magic) to $N = 104$ (mid-shell). Shape coexistence is found in the isotopes $^{182,184,186,188}\text{Pt}$. A phase diagram is constructed that shows the coexistence region as a function of the number of bosons and the strength of the mixing parameter.

I. INTRODUCTION

The phenomenon of shape coexistence in nuclei has been studied for decades and still is an active topic of research. Conversion electron coincidence, recoil and recoil-decay tagging techniques, heavy-ion-induced fusion-evaporation reactions, and the study of the fine-structure of α decay have, for example, allowed the identification of three low-lying 0^+ states in ^{186}Pb [1], each interpreted in terms of a distinct shape, originating from multiple particle-hole excitations across the $Z = 82$ proton shell gap. Coexisting shapes have also been proposed to influence the yrast states in ^{174}Pt [2] where mixing between different nuclear configurations results in the observation of a single mixed yrast band. Investigations in $^{176-182}\text{Pt}$ have suggested that the two lowest-lying 0^+ of these isotopes are formed from the mixing of two intrinsic states of different deformation [3].

Calculations within a deformed mean-field approximation have indicated the possibility to find close-lying oblate and prolate minima next to the spherical ground-state configuration of ^{186}Pb [4]. In general, these studies have focused on the properties of static potential energy surfaces (PESs) and only recently it has become possible to implement the generator coordinate method with symmetry restoration which yields spectroscopic properties of nuclei, albeit with considerable numerical effort (for an example in the neutron-deficient Pb isotopes, see Ref. [5]). Shell-model studies [6] of the coexistence phenomenon are even more numerically challenging because of the large spaces involved. The Interacting Boson Model (IBM) [7,8], on the other hand, assumes a truncated shell-model Hilbert space composed of correlated like-nucleon pairs coupled to angular momentum $L = 0$ and 2, which are subsequently approximated as bosons, and employs an appropriate Hamiltonian in this space. This simplified analysis makes possible a calculation consistent with both the spectroscopic properties and the geometry of an isotope series. In particular, for the Pt isotopes a transitional Hamiltonian can

be proposed that covers the range from U(5) vibrational to SU(3) rotational nuclei.

The use of coherent states allows one to derive a PES starting from an algebraic IBM Hamiltonian, which can in turn be used to determine the equilibrium configurations of the system and their corresponding shapes in terms of the β and γ variables. In case there are close-lying configurations that can mix, the appropriate algebraic framework was first proposed by Duval and Barrett [9]. Their approach leads to coexisting minima that can be associated with the presence of intruder excitations [10,11], in particular at or near shell closures. The origin of these intruder states can be traced back to many-particle many-hole (p-h) excitations across shell gaps [12]. Duval and Barrett [9] suggested the possibility of including the simplest intruder 2p-2h configuration by adding two extra bosons to the IBM and allowing this configuration to mix with the regular (ground state) one with N bosons. In the Pb isotopes, where a coexistence of spherical, oblate, and prolate shapes seems to occur (in particular in ^{186}Pb), three configurations are required of a regular, a 2p-2h, and a 4p-4h type. The configuration-mixing IBM has allowed a simultaneous description of the whole series of Pb isotopes with a single Hamiltonian [13]. To analyze the geometry of such Hamiltonians, a matrix coherent-state method was introduced [14,15] that allows a consistent description of shape coexistence phenomena, as well as an analysis of the phase diagrams and the transitional behavior of IBM Hamiltonians [16,17].

In this article we use the matrix coherent-state method to study the evolution of the shape and the phenomenon of coexistence in the Pt isotopes and we present the phase diagrams associated with the chain. The article is organized as follows. In Sec. II the model Hamiltonian and the matrix formulation of the problem are introduced. The results for the shape potentials and phase diagrams in the $^{182-198}\text{Pt}$ isotopes are presented in Secs. III and IV. A brief summary and conclusions are given in Sec. V.

II. THE MODEL HAMILTONIAN

The Hamiltonian of the configuration-mixing IBM is

$$\hat{H} = \hat{H}_{0p-0h} + \hat{H}_{2p-2h} + \hat{H}_{\text{mix}}. \quad (1)$$

This Hamiltonian acts in a Hilbert space that consists of the sum of two symmetric $U(6)$ representations $[N] \oplus [N+2]$, corresponding to the 0p-0h and 2p-2h excitations, respectively. The separate pieces of the Hamiltonian are

$$\hat{H}_i = \epsilon_i \hat{n}_d + \kappa_i \hat{Q}_i \cdot \hat{Q}_i + \kappa'_i \hat{L} \cdot \hat{L}, \quad (2)$$

where \hat{H}_i ($i = 0$ or 2) are the Hamiltonian operators acting in the 0p-0h (regular) and 2p-2h (deformed) subspaces, respectively. Furthermore, the operator \hat{n}_d counts the number of d bosons, \hat{L} is the angular momentum operator, \hat{Q}_i is the standard quadrupole operator of the IBM,

$$\hat{Q}_{i,\mu} = (s^\dagger \tilde{d} + d^\dagger \tilde{s})_\mu^{(2)} + \chi_i (d^\dagger \tilde{d})_\mu^{(2)}, \quad (3)$$

and \hat{H}_{mix} mixes the two configurations,

$$\hat{H}_{\text{mix}} = \omega [(s^\dagger s^\dagger + \tilde{s} \tilde{s})^{(0)} + (d^\dagger d^\dagger + \tilde{d} \tilde{d})^{(0)}]. \quad (4)$$

The parameters ϵ_i , κ_i , and χ_i in Eqs. (2) and (3) pertaining to the 0p-0h ($i = 0$) and 2p-2h ($i = 2$) configurations and the off-set energy Δ between the two configurations have been taken from Ref. [18] without any modification and are shown in Table I. (Note that the value of $\Delta = 1400$ keV quoted in Ref. [18] corresponds to *half* the off-set energy.) These parameters were extracted from a comprehensive fit to excitation energies and $B(E2)$ values in the ^{194}Pt and ^{196}Pt isotopes for the regular N configuration and, based on the concept of I -spin symmetry [19], from the W isotopes for the 2p-2h $N+2$ configuration. The intensity of the mixing is determined by the parameter ω . We have taken for the calculation of PESs the average value $\omega = 50$ keV but for the phase diagram a larger range has been considered to map the complete region.

The algebraic formalism does not provide directly a geometric interpretation in terms of shapes but this can be achieved with the theory of coherent states [20]. A geometric interpretation is obtained by computing the expectation value of the Hamiltonian in the ground coherent state, a procedure that is known as the classical limit [21,22]. Hence a connection was established between the IBM and the Bohr-Mottelson geometrical model [23], giving an intrinsic geometric structure to the former. With the coherent-state formalism the following energy surface is obtained for a general IBM Hamiltonian,

$$E(N, \beta, \gamma) = a_1^{(0)} + \frac{N}{1 + \beta^2} (a_1^{(1)} \beta^2 + a_2^{(1)}) + \frac{N(N-1)}{(1 + \beta^2)^2} \times (a_1^{(2)} \beta^4 + a_2^{(2)} \beta^3 \cos 3\gamma + a_3^{(2)} \beta^2 + a_4^{(2)}), \quad (5)$$

TABLE I. Parameters in the Hamiltonian (2) (in units of keV) taken from Ref. [18].

| | ϵ_i | κ_i | χ_i^a | κ'_i | Δ |
|-----------------|--------------|------------|------------|-------------|----------|
| $i = 0$ (0p-0h) | 540 | -27 | 0.25 | 0 | - |
| $i = 2$ (2p-2h) | 0 | -22 | -0.45 | 10 | 2800 |

^aDimensionless.

where the $a_i^{(k)}$ are fixed in terms of the parameters in the Hamiltonian. For the Hamiltonian (2) the energy surface $E_0(N, \beta, \gamma)$ in the 0p-0h configuration is given by

$$E_i(N, \beta, \gamma) = (\epsilon_i + 6\kappa'_i) \frac{N\beta^2}{1 + \beta^2} + \kappa_i \left[\frac{N}{1 + \beta^2} (5 + (1 + \chi_i^2)\beta^2) + \frac{N(N-1)}{(1 + \beta^2)^2} \times \left(\frac{2}{7} \chi_i^2 \beta^4 - 4\sqrt{\frac{2}{7}} \chi_i \beta^3 \cos 3\gamma + 4\beta^2 \right) \right], \quad (6)$$

with $i = 0$. The classical limit of the Hamiltonian for the 2p-2h configuration has the same form but with $N \rightarrow N+2$ and $i = 2$. The nondiagonal matrix elements $\Omega(\beta)$ are given by the matrix elements of the mixing Hamiltonian (4) between the ground coherent state, leading to

$$\Omega(\beta) = \frac{\sqrt{(N+2)(N+1)}}{1 + \beta^2} \left(\omega + \frac{\omega}{\sqrt{5}} \beta^2 \right). \quad (7)$$

Alternatively, the mixing Hamiltonian can be defined with a scalar product $d \cdot d$ instead of the tensor product as in Eq. (4), leading to a β -independent classical limit of the mixing term. We have followed here the original parametrization of Ref. [18]. The two choices lead to results that are quantitatively different but there are no qualitative differences in the PESs and phase diagrams.

For the platinum isotopes, in particular for $^{182-204}\text{Pt}$, a single set of parameters describes their PESs for N ranging from 2 to 13 bosons (two proton boson holes and the neutron boson holes counting from the closed shell $N = 126$ to midshell at $N = 104$). The 0p-0h configuration corresponds to N bosons whereas the 2p-2h excitations require two extra bosons [9]. This leads to a 2×2 potential energy matrix [14,15]:

$$E(\beta, \gamma) = \begin{pmatrix} E_0(N, \beta, \gamma) & \Omega(\beta) \\ \Omega(\beta) & E_2(N+2, \beta, \gamma) + \Delta \end{pmatrix}, \quad (8)$$

where Δ corresponds to the single-particle energy expended in raising two protons from the lower (50–82) to the upper (82–126) shell, corrected for the gain in energy due to pairing. After numerical diagonalization of this matrix we obtain the eigenpotentials. In fact, two eigenpotentials are obtained in this way. The lowest of the two corresponds to the ground state of the mixed system and is presented in the next section for the various nuclei. The second eigenpotential corresponds to an excited configuration. For example, if the nucleus is predominantly spherical in its ground state, the second eigenpotential will give the energy of the configuration, which is predominantly 2p-2h.

III. POTENTIAL ENERGY SURFACES

In this section we present the PESs for several platinum isotopes from $A = 182$ to 204; the phase diagram for the entire chain is presented in the next section. Beginning with the heavier isotopes, we show in Fig. 1 the energy surface corresponding to the lowest eigenpotential for the semi-magic

FIG. 1. (Color online) Potential energy for ^{204}Pt . The upper part shows the lowest eigenpotential of the matrix $E(\beta, \gamma)$ in Eq. (8). The lower part shows the potential for $\gamma = 0^\circ$ as a function of β for the regular (solid line) and 2p-2h (dot-dashed line) configurations.

nucleus ^{204}Pt . The PES is almost identical to that of the regular configuration and exhibits a completely spherical shape. The 2p-2h configuration has a prolate minimum, but being more than 2.5 MeV higher in energy, it has a negligible contribution to the mixed (eigen)surface. The large energy difference between these configurations that is found in ^{204}Pt decreases when moving toward the mid-shell isotopes. We also observe that the PES minima associated with the 0p-0h and 2p-2h configurations become deeper when moving toward the lighter isotopes as well as closer in energy. This can be seen in Fig. 2, which displays the PES associated with ^{196}Pt . The figure shows two apparent minima in the 2p-2h configuration, but in the β - γ plot of Fig. 3 it is seen that only one (namely, the one

FIG. 2. Potential energy for $\gamma = 0^\circ$ as a function of β for ^{196}Pt for the regular (dot-dashed line) and 2p-2h (dashed line) configurations and for the lowest (solid line) and highest (dotted line) mixed configurations.

FIG. 3. (Color online) Potential energy surface in the β - γ plane for the 2p-2h configuration in ^{196}Pt .

with $\gamma = 0^\circ$) is a real minimum while the other extremum, with $\beta < 0$, is in fact a saddle point. This analysis shows that each configuration contributes with one minimum and that, if the surfaces are close in energy, their mixing can generate a single surface exhibiting more than one minimum, in principle allowing the phenomenon of coexistence.

The ^{194}Pt isotope, corresponding to seven bosons, has an almost spherical minimum but shows a tendency to be flat, as can be seen in Fig. 4. The 2p-2h potential exhibits two extrema in the $\gamma = 0^\circ$ projection but as in ^{196}Pt the one corresponding to oblate deformation is a saddle point. The $^{190-194}\text{Pt}$ isotopes have a PES flatter than those of nuclei closer to semi-magic ^{204}Pt , leading to a region of shapes with apparent γ instability. This feature is reminiscent of the E(5) “critical point symmetry” recently proposed to describe critical behavior [24,25].

In this region and going toward the lighter isotopes, we find that the flat potential displays a small depression, making them slightly oblate. The nucleus ^{192}Pt is a good example of this feature, as seen in Fig. 5. The absolute oblate minimum at $\gamma = 60^\circ$, in the upper part of the figure, at $\beta = 0.344$ is only 32 keV below the second minimum associated with a spherical shape (lower part of the figure). This very flat potential of the 0p-0h configuration combined with the one corresponding to 2p-2h, lowered in energy due to pairing, makes the resultant PES nearly γ unstable. Figure 6 makes the near- γ -instability evident in case a stronger mixing is taken, $\omega = 200$ keV. Near- γ -instability is also found in ^{186}Pt (11 bosons), where the

FIG. 4. Potential energy for $\gamma = 0^\circ$ as a function of β for ^{194}Pt . Lines are as in Fig. 2.

FIG. 5. (Color online) Potential energy for ^{192}Pt . The upper part shows the lowest eigenpotential of the matrix $E(\beta, \gamma)$ in Eq. (8). The lower part shows the potential for $\gamma = 0^\circ$ as a function of β . Lines are as in Fig. 2.

potential has a minimum at $\beta = 0.617$ (see Fig. 7). The phase diagram presented in the next section shows that there is indeed a large region in the ω - N space that corresponds to near- γ -instability.

The PES for ^{188}Pt is shown in Fig. 8. We see that in this case the absolute minimum corresponds to an oblate shape. The nucleus ^{188}Pt has a potential that is deeper and not as flat as the one for heavier isotopes. The oblate deformation arises from the regular configuration while the 2p-2h configuration is almost 200 keV higher in energy. The mixing makes that difference smaller but still the lowest eigenvalue corresponds to an oblate shape.

In isotopes lighter than ^{188}Pt the PES shows two coexisting minima. In ^{186}Pt the absolute minimum with oblate

FIG. 6. (Color online) Potential energy in the β - γ plane for ^{190}Pt with a strong mixing $\omega = 200$ keV.

FIG. 7. (Color online) Potential energy plot in the β - γ plane for ^{186}Pt with a strong mixing $\omega = 200$ keV.

deformation is nearly 100 keV deeper than the prolate one, while in ^{184}Pt the absolute minimum is prolate, being 100 keV deeper than the oblate one. The isotope ^{182}Pt has a potential with a prolate absolute prolate and a second oblate minimum that is 400 keV higher in energy. We show Fig. 9 as a representative example of this kind of coexistence, displaying the PES of ^{182}Pt . Level curves clearly show both minima and the projection in $\gamma = 0^\circ$ displays the difference in energy between them.

The predominance of a spherical shape in isotopes heavier than ^{190}Pt seems clear from the PES. The geometrical analysis exhibits the way in which shape coexistence, present in 182 – ^{188}Pt , disappears as the number of neutrons increases. Isotopes heavier than ^{190}Pt have a very flat potential, which

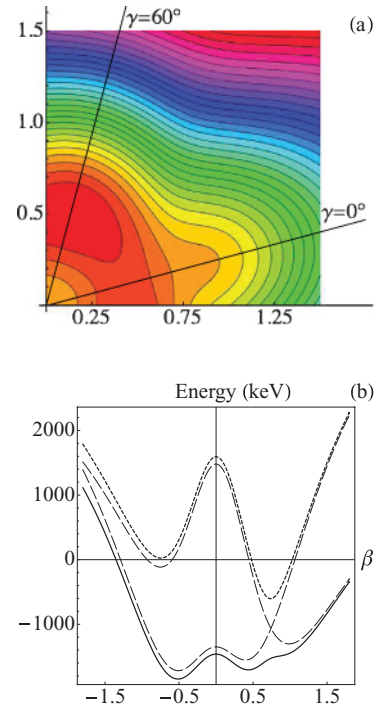

FIG. 8. (Color online) Potential energy for ^{188}Pt . The upper part shows the lowest eigenpotential of the matrix $E(\beta, \gamma)$ in Eq. (8). The lower part shows the potential for $\gamma = 0^\circ$ as a function of β . Lines are as in Fig. 2.

is characteristic of this region, as was first demonstrated by Davidson *et al.* [3], Stuchbery *et al.* [26], and Bengtsson *et al.* [27].

A more detailed analysis of the shape coexistence region and the different phases for the Pt chain is presented in the next section.

IV. PHASE DIAGRAM

The phase diagram for the Pt isotopes is shown in Fig. 10. We plot the strength of the mixing parameter ω of Eq. (4) on the vertical axis against the boson number N on the horizontal axis. These are considered as control parameters with the boson number, for the sake of clarity, taken as continuous. In the application to the Pt isotopes of Ref. [18] the mixing parameter ω was set to values between 0 and 50 keV. To map a larger region, this parameter is varied between 0 and 400 keV in the present work.

In the left-most region of Fig. 10 the absolute minimum is spherical and the PES is completely dominated by the 0p-0h configuration. By increasing the number of bosons, this configuration turns oblate while the 2p-2h configuration goes down in energy. If the difference in energy between the two configurations is small, a region of shape coexistence results, first with the 0p-0h configuration lowest (oblate-prolate coexistence) and for bigger N with a dominant 2p-2h configuration (prolate-oblate coexistence). Isotopes with a single prolate minimum are only possible for big mixing values ($\omega > 200$ keV). Around the (Maxwell) line separating the

FIG. 10. The phase diagram for the lowest eigenpotential of Eq. (8) with the boson number N on the x axis and the mixing parameter ω on the y axis. All other parameters are taken from the Pt isotopes. The inset figures illustrate the character of the potential in the different regions in the diagram that are separated by critical lines. The red dots correspond to the Pt isotopes.

oblate-prolate and prolate-oblate coexistence regions, the two minima have almost the same energy. This corresponds to a γ -instability zone.

In a very recent article [17] it has been shown that in the IBM with configuration mixing there are large regions of shape coexistence. That work was carried out for mixing between the exact U(5) limit ($\kappa = 0$) and the exact SO(6) or SU(3) limits (i.e., $\epsilon = 0$ and either $\chi = 0$ or $\chi = \sqrt{7}/2$). As a result coexistence of spherical and deformed shapes was found. In the present study we have not taken these schematic parameters but rather used realistic values as obtained from a fit to the overall properties of the Pt isotopes. In particular, because in this parametrization the 0p-0h configuration turns slightly oblate for large N while the 2p-2h configuration is prolate deformed, oblate-prolate coexistence becomes possible and is indeed found for realistic values of the mixing parameter ω . The possibility of oblate-prolate coexistence (and its associated γ instability) was considered by Hellemans [28] in the context of a schematic model of $\text{SU}_-(3)\text{-SU}_+(3)$ mixing, and the present results are an excellent example of this study.

V. CONCLUSIONS

In this article we have shown that the matrix coherent-state method applied to the IBM with configuration mixing yields results that are in close agreement with mean-field calculations, describing at the same time the known spectroscopic properties of the Pt isotopes. We have presented results for shape phase transitions in the chain of Pt isotopes from $A = 182$ to 204. Large values of the mixing parameter can produce a PES with near- γ -instability, despite of the fact that no SO(6) Hamiltonian is used explicitly. We expect that the measurement of intensities of two-nucleon transfer (one-boson transfer) reactions between the Pt isotopes should produce a strong signature for criticality, indicating the presence of shape

coexistence and giving direct information on the actual mixing of configurations [29].
