(Received 11 April 2016; published 2 June 2016)

In an experiment with the RIKEN projectile fragment separator called BigRIPS at the RIKEN Nishina Center, the fragmentation of a 78 Kr beam allowed the observation of new neutron-deficient isotopes at the proton drip line. Clean identification spectra could be produced and 63 Se, 67 Kr, and 68 Kr were identified for the first time. In addition, 59 Ge was also observed. Three of these isotopes, 59 Ge, 63 Se, and 67 Kr, are potential candidates for ground-state two-proton radioactivity. In addition, the isotopes ${}^{58}Ge$, ${}^{62}Se$, and ${}^{66}Kr$ were also sought but without success. The present experiment also allowed the determination of production cross sections for some of the most exotic isotopes. These measurements confirm the trend already observed that the empirical parametrization of fragmentation cross sections, EPAX, significantly overestimates experimental cross sections in this mass region.

DOI: [10.1103/PhysRevC.93.061301](http://dx.doi.org/10.1103/PhysRevC.93.061301)

Introduction. Experiments on nuclei at the limits of nuclear stability allow the testing of nuclear models under extreme conditions. Thus concepts well established close to the line of nuclear stability can be checked for their ability to describe nuclear structure over the whole chart of isotopes. Very often it is found that these concepts have to be modified and new concepts developed.

When moving close to the limits of stability, the mass difference between neighboring nuclei increases. Therefore new decay channels open and exotic radioactivities appear. For example, close to stability $\beta-\gamma$ decay is the most common decay mode for radioactive nuclei. When approaching the limits of stability the available energy for the decay, the Q value, increases and the particle emission threshold, e.g., the proton separation energy, decreases and β-delayed particle emission becomes a more important decay channel. Close to the proton drip line, β -delayed one-, two-, and three-proton emissions have all been observed [\[1–3\]](#page-4-0).

After crossing the proton drip line (proton separation energy $S_p < 0$, the direct emission of protons becomes the dominant decay channel. While one-proton $(1p)$ radioactivity is today an established decay channel used in many studies of nuclear structure beyond the limits of nuclear stability [\[1\]](#page-4-0), two-proton $(2p)$ radioactivity is the most recently discovered radioactivity and only a few cases are known at present [\[4\]](#page-4-0). Two-proton radioactivity with half-lives of the order of milliseconds was first observed in the region of iron-nickel-zinc with the $2p$ emitters ⁴⁵Fe, ⁴⁸Ni, and ⁵⁴Zn [\[4\]](#page-4-0). Just above this region, ⁵⁹Ge, 63 Se, and 67 Kr were predicted to be possible new 2p emitters (see, e.g., $[5]$).

Additional interest in studying proton-rich nuclei arises from the fact that these nuclei often lie on the path of astrophysical nucleosynthesis processes [\[6\]](#page-4-0). The rp-process, a sequence of proton captures and β decays, produces many of these proton-rich nuclei close to the proton drip line and a precise knowledge of the properties of these nuclei, i.e., their masses, half-lives, and decay properties, is essential for the correct modeling of these processes.

In the region of interest of the present experiment between zinc and krypton ($Z = 30-36$), the limits of stability of all odd-Z (proton number) elements are believed to be known [\[7,8\]](#page-4-0). However, due to the pairing energy, the even- Z elements can bind isotopes with even fewer neutrons and thus the two-proton drip line lies even farther away from the valley of stability than the one-proton drip line for odd-Z elements. The drip line for zinc has clearly been crossed with the observation of two-proton radioactivity for 54 Zn [\[9,10\]](#page-4-0). In an experiment at the National Superconducting Cyclotron Laboratory (NSCL) of Michigan State University $[11]$, ⁶⁰Ge and 64Se were observed for the first time with three and four events, respectively. The last new isotope in this region, reported after the completion of the present experiment, is 59 Ge, which was also produced at NSCL with four counts [\[12\]](#page-4-0). Finally for krypton, the last known isotope prior to the present experimental effort was ⁶⁹Kr observed at the LISE3 facility of the Grand Accelerateur National d'Ions Lourds (GANIL) [\[7\]](#page-4-0).

In an experiment at the RIKEN projectile fragment separator called BigRIPS of the RIKEN Nishina Center, we produced many proton-rich nuclei with unprecedented intensity, some of them for the first time. In the following, we will describe the experimental details, give the results concerning the production of new isotopes and their production cross sections, and put these results into a general context.

Experimental details. In a recent experiment at the Radioactive Ion Beam Factory (RIBF) of the RIKEN Nishina Center, BigRIPS [\[13,14\]](#page-4-0) was used to fragment a primary 78 Kr beam at 345 MeV/A with an intensity of up to 250 pnA. The primary beam impinged on ⁹Be targets with thicknesses of 5 mm (settings on 51 Ni, 65 Br, and 64 Se) and 7 mm (setting on 62 Se). The fragments produced in these targets were separated according to their magnetic rigidity in the first dipole of BigRIPS and their energy loss in a first degrader (focal plane F1, aluminum, 2 mm), before being analyzed again according to their magnetic rigidity by the second magnet of BigRIPS. A second achromatic degrader (focal plane F5, aluminum, 2 mm)

B. BLANK *et al.* PHYSICAL REVIEW C **93**, 061301(R) (2016)

allowed us to enhance the selectivity of BigRIPS. The second half of BigRIPS was used to measure the time of flight of the isotopes transmitted, their positions at different focal planes, and their energy loss. For this purpose, a series of parallel-plate avalanche counters, plastic scintillators, and multisampling ionization chambers was used [\[13,14\]](#page-4-0). The BigRIPS separator allowed us to separate the isotopes of interest from the bulk of the less exotic nuclei produced and to detect and identify the most exotic species by means of the ΔE -TOF- $B\rho$ method.

However, scattered beam particles, double hits occurring mainly in detectors at the beginning of BigRIPS, incomplete events, and other problems may yield erroneous identification parameters. Therefore, in the off-line analysis cuts were placed on signals from various beam-line detectors to remove these events (see $[15]$ for details). After these cuts, clean identification spectra could be produced.

The nuclei thus selected were transmitted to the zero-degree spectrometer at the end of which a setup for decay spectroscopy was installed comprising the double-sided silicon strip detector setupWAS3ABi [\[16\]](#page-4-0) for implantation and detection of charged particles emitted during the decay of implanted isotopes and the EURICA germanium detector array [\[17\]](#page-4-0). Measurements performed with this setup will be reported elsewhere.

Results and discussion. In the present analysis, we used data from four different settings of BigRIPS : (i) A setting optimized on 51 Ni to produce well-known β -delayed proton emitters for detector calibration. The run at this setting lasted for 12 h with an effective data-taking time of 10.5 h. (ii) A setting on the unbound isotope ⁶⁵Br, which lies between two of the isotopes sought, namely, 63 Se and 67 Kr. The runs at this setting lasted about 156 h with an effective counting time of 115 h. (iii) A setting on 64 Se for 52 h with an effective data-taking time of about 50 h. (iv) A setting on 62 Se to search for 58 Ge and 62 Se for 52 h with an effective data-taking time of 48 h.

Figure $1(a)$ presents the identification plot of nuclides at the exit of BigRIPS at its focal plane F7 for the second setting, while Fig. $1(b)$ is from the last setting. The new isotopes 63 Se, 67 Kr, and 68 Kr are indicated. The total number of counts for

FIG. 1. Identification plot of the charge Z of the nuclides as a function of their ratio A/Q . (a) Isotopes produced in the setting optimized on ⁶⁵Br. The isotopes of interest are highlighted by a surrounding ellipse and indicated with their names. ⁶³Se, ⁶⁷Kr, and ⁶⁸Kr are observed for the first time in the present work. (b) Identification plot for the setting on 62 Se with the isotopes of interest indicated. The absence of 58 Ge, 62 Se, and 66 Kr is evident in (a), whereas the results from the setting presented in (b) allow one to conclude that 58 Ge and 62 Se are unbound and therefore unobserved (see text for details).

NEW NEUTRON-DEFICIENT ISOTOPES FROM 78Kr . . . PHYSICAL REVIEW C **93**, 061301(R) (2016)

these isotopes, summed over all settings, were 348, 82, and 479 counts, respectively. In addition, we produced 1221 nuclei of 59Ge in the various settings, a factor of 300 more than in a recent MSU experiment [\[12\]](#page-4-0). These numbers are the sums from different settings with greatly different transmissions for the different isotopes. Therefore, these numbers should not be compared directly.

The latest Atomic Mass Evaluation (AME2012) [\[18\]](#page-4-0) predicts 59Ge to be two-proton unbound with a two-proton separation energy (S_{2p}) of $-1.66(36)$ MeV. Brown *et al.* [\[5\]](#page-4-0) give a value of $-1.16(14)$ MeV. We use a simple diproton barrier penetration model which usually yields half-lives that are too short, because it does not take into account correlations between the two protons and a proton-proton resonance energy. However, it gives a first guess for barrier penetration half-lives. Using the first value yields a barrier-penetration half-life of 10 μ s with upper and lower limits of 39 ms and 26 ns, respectively, a rather large half-life range which includes the flight time through BigRIPS of about 410 ns. The separation energy of Brown *et al.* gives a half-life range between 0.04 and 420 s with a central value of 2.6 s. Such a long half-life for barrier penetration would clearly indicate that this isotope decays by β decay rather than by 2p emission.

In the case of 63 Se, AME2012 does not give any mass value and thus no separation energy. Brown *et al.* predict a value of [−]1.51(14) MeV yielding a half-life range between 0.3 ms and 0.24 s with 6.9 ms for the central value of the separation energy, which could be compatible with *2p* radioactivity.

Finally, for 67 Kr AME2012 again does not give any value, whereas Brown *et al.* predict $S_{2p} = -1.76(14)$ MeV. This value allows us to determine a barrier-penetration half-life between 62 μ s and 17 ms with a central value of 0.83 ms. Evidently, this nucleus seems to be the most promising candidate for $2p$ radioactivity. 68 Kr is predicted to have an S_{2p} value of $-0.62(14)$ MeV [\[5\]](#page-4-0), too small for a possible 2p emission.

The rates observed in the present experiment make it possible to study the decay of these nuclei. In particular, it will be interesting to see whether 59 Ge, 63 Se, and 67 Kr are indeed $2p$ emitters. The analysis of the decay of these isotopes as well as many others produced in this experiment with high statistics is ongoing and the results will be published elsewhere.

The present experiment allowed us to determine the production cross sections for nuclei transmitted close to the central beam line. We limit the data to these nuclei because they have calculated ion optical transmissions between 20% for the lighter, less exotic nuclei (see Fig. 2) and 90% for fragments closer to the projectile. These relatively high transmission values ensure that the uncertainties due to the momentum distribution of the fragments and the separator transmission are minimal. For the determination of the fragmentation cross sections we used only the setting for ${}^{65}Br$ and the calibration run optimized for 51 Ni. For the settings on 62 Se and 64 Se, the slits of BigRIPS were significantly narrower, thus introducing much larger errors for the isotope transmission.

The cross sections were determined by means of the number of nuclides detected N_{iso} , the primary beam intensity N_{beam} , the transmission through BigRIPS of the different isotopes

FIG. 2. Comparison of experimental cross sections and predic-tions from the EPAX3 parametrization [\[20\]](#page-4-0) for $T_z = -5/2$ and -2 nuclei. Details of the data selected for this figure are given in the text and in Table [I.](#page-3-0) Stolz *et al.*, 2005: [\[11\]](#page-4-0), Ciemny *et al.*, 2015: [\[12\]](#page-4-0).

 T_{iso} , and the target thickness d_{tar} according to the following formula:

$$
\sigma = \frac{N_{\rm iso}}{N_{\rm beam}} \frac{A}{d_{\rm tar} N_A} \frac{1}{T_{\rm iso}},
$$

with N_A being Avogadro's constant and A the molar weight of the target. The isotopes of interest were counted with the BigRIPS standard detection setup (statistical errors only), while the beam intensity was measured with scattered beam particles by means of scintillation detectors in the vicinity of the production target. This measurement was calibrated at two instances during the beam time. The difference between these two calibrations (of the order of 10%) was used as the uncertainty in the beam intensity. The isotopes produced in the target have a certain probability to be destroyed in a secondary reaction in the production target itself or in the degraders (we neglect here possible interactions in the detectors the thicknesses of which are much smaller than for the targets and the two degraders). Although the total reaction probabilities determined with the formula of Kox *et al.* [\[19\]](#page-4-0) vary a little from one nucleus to the other, we use an average secondary reaction probability of 14% for all nuclei and correct the counting rates for these secondary reactions. We consider that this correction, already small compared to other corrections, has a negligible uncertainty. A dead time of the order of 8% deduced from the ratio of the number of BigRIPS triggers and those accepted by the data acquisition and determined on a run-by-run basis was also taken into account.

Transmissions were calculated with the LISE++ simulation tool [\[21\]](#page-4-0) and the LIESCHEN code [\[22\]](#page-4-0) developed in the framework of the simulation of the fragment separator (FRS) [\[23\]](#page-4-0) at GSI. The two codes differ in their degree of sophistication, with the LISE++ code being more elaborate with, e.g., the momentum distributions including an exponential tail [\[24\]](#page-4-0). However, both codes give results which differ on average by only 12% for the nuclei in Fig. 2, with the LIESCHEN code yielding somewhat lower transmission values. The largest

TABLE I. Experimental fragmentation cross sections are compared to EPAX3 [\[20\]](#page-4-0). For the data presented in this table, the cross sections are based on ion optical transmissions between 20% and 90% for the settings used to produce these nuclei. The data for $\frac{39}{11}$ to $⁵¹Ni$ stem from the setting on $⁵¹Ni$, whereas the other data are from</sup></sup> the setting on ${}^{65}Br$.

Nucleus	Expt. cross section (mb)	EPAX3 cross section (mb)
39 Ti	$6.8^{+7.3}_{-6.8}\times10^{-10}$	1.3×10^{-7}
40 Ti	$2.6^{+1.5}_{-1.5} \times 10^{-8}$	2.7×10^{-6}
^{43}Cr	$2.4^{+1.4}_{-1.4}\times10^{-9}$	5.5×10^{-8}
^{44}Cr	$2.3^{+1.3}_{-1.3}\times10^{-7}$	1.1×10^{-6}
46 Mn	$3.3^{+2.2}_{-2.2} \times 10^{-7}$	7.4×10^{-7}
^{47}Fe	$7.2^{+3.9}_{-3.9}\times10^{-9}$	2.2×10^{-8}
^{48}Fe	$4.0^{+3.6}_{-3.6}\times10^{-7}$	4.7×10^{-7}
51 Ni	$1.9_{-1.2}^{+1.2} \times 10^{-9}$	8.5×10^{-9}
59 Ge	$4.8^{+1.0}_{-1.0}\times10^{-11}$	1.6×10^{-9}
60 Ge	$1.3^{+0.7}_{-0.7}\times10^{-9}$	4.1×10^{-8}
${}^{63}Se$	$1.3^{+0.3}_{-0.3} \times 10^{-11}$	8.7×10^{-10}
64 Se	$3.8^{+2.4}_{-2.4} \times 10^{-10}$	2.4×10^{-8}
67 Kr	$3.0^{+0.8}_{-0.8} \times 10^{-12}$	4.3×10^{-10}
68 Kr	$3.3^{+2.1}_{-2.1}\times10^{-11}$	1.1×10^{-8}

discrepancy in the transmissions from the two codes was 25%. For the cross-section calculations, we used the results from the more sophisticated $LISE++code$. For the uncertainty, we used the difference of the two codes and a smooth additional error that takes into account the general fact that the transmissions are more uncertain if they are small. To do so, we employed a smooth function yielding a relative uncertainty of 10% for a transmission of 90% and reaching 40% of uncertainty for a transmission of 20%. This is a somewhat arbitrary function, but we believe that it reflects correctly the fact that the uncertainties increase significantly with the decrease of the transmission. The target thickness was measured by means of the $B\rho$ of the primary beam with and without the targets. The B ρ measurement precision is of the order of 10⁻³ which leads to an uncertainty in the target thickness of 50 μ m.

Figure [2](#page-2-0) presents these cross sections and compares them with the predictions of EPAX3, an empirical parametrization of fragmentation cross sections [\[20\]](#page-4-0). The numerical values are given in Table I. Clearly, EPAX3 overestimates the experimental cross sections by a large factor.

The present experimental cross section for ⁵⁹Ge is about a factor of 3 larger than the value determined in Ref. [\[12\]](#page-4-0) of $1.7^{+1.4}_{-1.0} \times 10^{-11}$ mb. We believe that these differences are most likely due to the difficulty in correctly calculating the transmission with models. In order to get reliable transmissions, much more settings have to be run to scan the full transmissions experimentally.

We believe that the cross sections determined for the lightest nuclei (in particular 39 Ti to 44 Cr) should be treated with some caution. An important input for the transmission calculations with the simulation codes is the momentum distribution of the fragments and it is not clear whether the momentum parametrization used in these codes [\[24\]](#page-4-0) is also valid for

B. BLANK *et al.* PHYSICAL REVIEW C **93**, 061301(R) (2016)

isotopes this far away from the projectile. If the momentum distributions for these isotopes were larger than expected, the transmissions would be reduced and larger cross sections would be determined. So, maybe it is timely to measure the cross sections for 78Kr fragmentation in a specially designed experiment where the full momentum distributions of the nuclides of interest are scanned.

The finding that EPAX in its different versions [\[20,25,26\]](#page-4-0), which differ slightly for neutron-deficient nuclei, overestimates production cross sections in this region of the chart of nuclei is not new (see, e.g., $[11, 12, 27]$). However, it is indeed astonishing that EPAX reproduces experimental cross sections for $92Mo$ [\[28\]](#page-4-0) and $58Ni$ [\[29\]](#page-4-0) fragmentation, while in between these two nuclei, EPAX does not work for 70 Ge [\[27\]](#page-4-0) and 78 Kr fragmentation ([\[11,12\]](#page-4-0) and present work). A possible explanation could be that this is linked to nuclear structure effects with ⁹²Mo lying on the $N = 50$ shell closure and ⁵⁸Ni having $Z = 28$, whereas the other two lie between the N, $Z = 28$ and N, $Z = 50$ shells. However, according to our knowledge such an effect has not yet been observed elsewhere.

The search for 58 Ge, 62 Se, and 66 Kr in the settings on 65 Br and 62Se was unsuccessful. No event could be identified for any of these nuclei (see Fig. [1\)](#page-1-0). From the numbers of counts for the neighboring nuclei observed in the two settings, the transmissions calculated with the two codes $LISE++ [21]$ $LISE++ [21]$ and LIESCHEN [\[22\]](#page-4-0) and trends for production cross sections [on average there is a loss of a factor of 22(9) going from one even- N isotope to its more exotic odd- N neighbor as determined from our experimental data for even-Z elements, and a loss factor of 3.7(17) between two even-Z isotopes with the same isospin projection, e.g., between 59 Ge and 63 Se], we determine the following expected numbers of counts: (i) 1.2(12), 1.6(10), and 0.6(3), for ⁵⁸Ge, ⁶²Se, and ⁶⁶Kr using the observed numbers of counts for the neighboring nuclei with one more neutron in the setting for ${}^{65}Br$; (ii) 4.8(30) and 20(12) for 62 Se and 58 Ge in the setting for 62 Se from the number of counts observed for 59Ge. These numbers are based on the assumption that the isotopes live longer than the flight time through the separator and also include a loss factor of 2 due to the fact that the even- N isotopes of even- Z elements have roughly a factor of 2 lower production cross sections than their odd-N neighbors [\[27,29\]](#page-4-0).

These low numbers do not allow us to draw definite conclusions about the lifetimes of these nuclei from their nonobservation, except most likely for ⁵⁸Ge where a lifetime limit of about 100 ns can be deduced from the flight time through BigRIPS. However, even for the other nuclei, it is unlikely that they have lifetimes comparable to or longer than the flight time through BigRIPS.

This is corroborated by model predictions. Brown *et al.* [\[5\]](#page-4-0) predict 2^p separation energies of [−]2.38(14) MeV and $-2.76(14)$ MeV for ⁵⁸Ge and ⁶²Se, respectively. Unfortunately, no value is given for 66 Kr. With the simple 2p barrier penetration model used above, we obtain half-lives between 0.07 and 1.5 ns for ⁵⁸Ge with a central value of 0.3 ns and between 0.02 and 0.3 ns for 62 Se with a value of 0.07 ns for the central value of the separation energy. For the case of 66 Kr, we used the Garvey-Kelson method [\[30\]](#page-4-0) to determine the 2p separation energy and found $S_{2p} = -3.0$ MeV yielding a barrier penetration half-life of 0.05 ns.

All these values are more than two orders of magnitude shorter than the flight time through BigRIPS of typically 410 ns for the most exotic nuclei. Thus the nonobservation of 58 Ge, 62 Se, and 66 Kr is in line with expectations from mass predictions.

Under the assumption of one count observed, the calculated transmissions and their error bars, as well as the beam intensity and its uncertainty in the two settings, we can determine one- σ cross-section limits of 1.8×10^{-13} mb for ⁶⁶Kr, 8.1×10^{-14} mb for ⁶²Se, and 7.6×10^{-14} mb for ⁵⁸Ge.

Conclusions. In the present work, we fragmented a highintensity primary 78 Kr beam and separated the fragments of interest with the RIKEN separator BigRIPS. The experiment allowed us to discover the new isotopes 63 Se, 67 Kr, and 68 Kr. In addition, ⁵⁹Ge was observed with high rates. ⁵⁹Ge, ⁶³Se, and 67 Kr are predicted to have two-proton separation energies of the order of -1 to -2 MeV and are thus potential two-proton emitters, with ⁶⁷Kr being the best candidate. As these nuclei are $2p$ unbound by a significant separation energy, they are beyond the drip line and are expected to be the most neutron-deficient isotopes of their elements that can be observed. This appears to be confirmed by the nonobservation of 58 Ge, 62 Se, and 66 Kr.

The fragmentation cross sections determined for the observed nuclei confirm again that EPAX overpredicts the cross

sections at the limits of stability in this region. This clearly calls for an experiment designed to measure cross sections in this region systematically in order to try to understand this discrepancy.

Acknowledgments. This experiment was carried out under programs NP0702-RIBF4R1-01, NP1112-RIBF82, and NP1112-RIBF93 at the RIBF operated by RIKEN Nishina Center, RIKEN, and CNS, University of Tokyo. We would like to thank the whole RIBF accelerator staff for their support during the experiment and for maintaining excellent beam conditions with record intensities.
