Neutrinoless double-β decay ($0\nu\beta\beta$ decay) is a hypothetical process that can occur if the neutrino is its own antiparticle. The COBRA Collaboration operates a demonstrator to search for these decays at the Laboratori Nazionali del Gran Sasso in Italy using CdZnTe semiconductor detectors. The exposure of 234.7 kg d considered in this analysis was collected between September 2011 and February 2015. The analysis focuses on the decay of the nuclides ^{114}Cd, ^{128}Te, ^{70}Zn, ^{130}Te, and ^{116}Cd. A Bayesian analysis is performed to estimate the signal strength of $0\nu\beta\beta$ decay. No signal is observed for any of these nuclides. Therefore, the following half-life limits at 90% credibility are set: $T_{1/2}^{0\nu} > 1.6\times10^{21}$ yr (^{114}Cd), $T_{1/2}^{0\nu} > 1.9\times10^{21}$ yr (^{128}Te), $T_{1/2}^{0\nu} > 6.8\times10^{18}$ yr (^{70}Zn), $T_{1/2}^{0\nu} > 6.1\times10^{21}$ yr (^{130}Te), and $T_{1/2}^{0\nu} > 1.1\times10^{21}$ yr (^{116}Cd).

I. INTRODUCTION

An open question in neutrino physics is the absolute mass and nature of the neutrino. Is it a Majorana or a Dirac particle, i.e.. is it its own antiparticle or not? These questions can potentially be answered if neutrinoless double-β decay ($0\nu\beta\beta$ decay) is observed.

Double-β decay is a rare second-order weak process that changes the atomic number by 2 units, while leaving the atomic mass constant [1]. It comes in two modes: neutrino-accompanied double-β decay ($2\nu\beta\beta$ decay) results in two charged leptons, and the corresponding neutrinos, $(A,Z) \rightarrow (A,Z+2) + 2e^- + 2\bar{\nu}$. This decay mode has been observed in several isotopes, and half-lives between 7.1×10^{18} yr (^{100}Mo) and 7.7×10^{24} yr (^{128}Te) have been measured [2–4]. Neutrinoless double-β decay [5], which is mediated via an exchange of a virtual neutrino, can only occur if the neutrino is a Majorana particle [6]. This process is forbidden in the standard model of particle physics because it violates the lepton number by 2 units: $(A,Z) \rightarrow (A,Z\pm2) + 2e^\mp$. The half-life of this decay is inversely proportional to the square of the effective Majorana neutrino mass.

$0\nu\beta\beta$ decay has been searched for in several isotopes, but has not been observed, yet. Recent experiments report upper limits on the half-life. The GERDA Collaboration searches for the $0\nu\beta\beta$ decay of ^{76}Ge using high-purity germanium detectors; the currently best limit on the half-life is $T_{1/2}^{0\nu} > 1.9\times10^{25}$ yr at 90% credibility [7]. The KamLAND-Zen and EXO-200 Collaborations have searched for the $0\nu\beta\beta$ decay of ^{136}Xe [8,9]. Both experiments have observed zero events in their region of interest, which results in a half-life lower limit

of $T_{1/2}^{0\nu} > 2.6\times10^{25}$ yr for the KamLAND-Zen Collaboration and $T_{1/2}^{0\nu} > 1.1\times10^{25}$ yr for the EXO-200 Collaboration, both at a 90% confidence level. The CUORE Collaboration set a new limit of $T_{1/2}^{0\nu} > 4\times10^{24}$ yr at 90% credibility for the $0\nu\beta\beta$ decay of ^{130}Te [10]. The Solotvina experiment sets a limit of $T_{1/2}^{0\nu} > 1.7\times10^{23}$ yr for ^{116}Cd [11]. Other experiments have searched for the $0\nu\beta\beta$ decay of ^{114}Cd and ^{70}Zn by using CdWO$_2$ and ZnWO$_2$ scintillator crystals. Both experiments have observed zero events, which results in half-life limits of $T_{1/2}^{0\nu} > 1.1\times10^{21}$ yr for ^{114}Cd and $T_{1/2}^{0\nu} > 3.2\times10^{19}$ yr for ^{70}Zn, both limits are reported at a 90% confidence level [12,13]. For an overview of the current experimental status, see, e.g., Ref. [14].

This paper reports on the search for the $0\nu\beta\beta$ decay of several isotopes using the COBRA demonstrator. The CdZnTe semiconductor crystals deployed in the setup contain nine double-β isotopes with several decay modes. A focus is placed on the five $\beta^-\beta^-$ ground-state-to-ground-state transitions of the isotopes ^{114}Cd, ^{128}Te, ^{70}Zn, ^{130}Te, and ^{116}Cd with Q values between 542 and 2813 keV. Section II introduces the COBRA demonstrator. The data-taking and data-quality criteria are discussed in Sec. III. In Sec. IV, the energy reconstruction and the calibration procedure are explained. The pulse shape analysis is discussed in Sec. V. The event selection for the analysis is discussed in Sec. VI. Section VII explains the methods used for the signal estimation. Section VIII introduces all the systematic uncertainties that are considered in the signal estimation. The results are discussed in Secs. IX and X concludes the article.

II. THE COBRA DEMONSTRATOR

The COBRA demonstrator is located at the Laboratori Nazionali del Gran Sasso (LNGS) of the INFN in L'Aquila, Italy. The setup is described in detail in Ref. [15]. The

---

†thomas.quante@tu-dortmund.de

demonstrator comprises 64 CdZnTe coplanar-grid semiconductor detectors arranged in four layers of 4×4 detectors. Each detector has a size of 1×1×1 cm^3 and a mass of 5.9 g. The detectors are supported by a polyoxymethylene frame installed in a support structure made of electroformed copper. The setup is constantly flushed with evaporated nitrogen to suppress radon-induced background. The detectors are surrounded by 5 cm of electroformed copper, followed by a 5-cm layer of ultralow-activity lead (<3 Bq/kg of ^{210}Pb) and 15 cm of standard lead. A 5-cm borated polyethylene layer is used to reduce the neutron flux inside the setup. A charge-sensitive preamplifier integrates the current pulses and converts the single-ended detector pulses into differential signals to suppress electronic noise during transmission. After linear amplification, the pulse shapes are digitized using 100-MHz flash analog-to-digital converters (FADCs) and written to disk.

III. DATA TAKING AND DATA QUALITY CRITERIA

The data taking of the COBRA demonstrator started in September 2011 after the commissioning of a partial setup that contained only one detector layer. The other three layers were installed successively in 2012 and 2013. The demonstrator was completed in November 2013 with 64 installed detectors. Currently, 61 out of 64 detectors operate under stable conditions. For further information see Ref. [16].

This publication uses data corresponding to an exposure of 234.7 kg d, recorded between September 2011 and February 2015. A set of quality criteria based on the observed noise level of single detectors is applied. A small fraction of data taking runs is discarded because of a failure of the nitrogen flushing. In such cases radon diffused into the setup and the overall background rate increased for the duration of these runs. After the data-quality selection, the dataset corresponds to an exposure of 216.1 kg d.

For the analysis of ^{114}Cd, runs with energy thresholds larger than 421 keV are discarded due to the lowered trigger efficiencies. Therefore, the corresponding exposure is reduced to 212.8 kg d.

IV. ENERGY CALIBRATION AND RESOLUTION

The energy deposited inside a CdZnTe detector is estimated by the pulse heights of signals measured with electrodes on the detector surface. Because the mobility-lifetime product for holes in CdZnTe is 2 orders of magnitude lower than for electrons, the hole contribution to the induced signal depends strongly on the interaction depth. Therefore, CdZnTe detectors are typically designed to have a coplanar-grid configuration, which is a modification of the Frisch grid principle used for semiconductors [17]. This approach is based on two interleaved comb-shaped anodes, a collecting anode (CA) on ground potential and a noncollecting anode (NCA) on a slightly negative potential. The deposited energy is then estimated to be
$$E \propto H_{CA} - \omega H_{NCA}, \qquad (1)$$

FIG. 1. The effective FWHM as a function of the energy determined with calibration measurements (markers). The line energies used are 238 keV (^{212}Pb), 511 keV (annihilation γ radiation), 1275 keV (^{22}Na), and 2614 keV (^{208}Tl). Also shown is the parametrization (red line) including the corresponding uncertainty (yellow band).

where H_{CA} and H_{NCA} are the pulse heights of the two anode signals and ω is a weigthing factor introduced to compensate for electron trapping. This weighting factor is determined and optimized for each detector by calibration measurements. In this configuration, the signal shape is only generated by the electron contribution. Besides the improved energy resolution, the coplanar-grid technique allows for the reconstruction of the interaction depth. An analytical model for the calculation of the interaction depth is discussed, e.g., in Ref. [18].

A ^{22}Na source and a ^{228}Th source are used to determine the energy calibration of each detector. The energy threshold of each detector is set depending on the noise level. The thresholds range from 40 keV up to 550 keV for all regions of interest (ROI) except the ^{114}Cd ROI, where the highest threshold is 421 keV. Higher noise levels are observed after periods of detector maintenance if the detectors have been exposed to light or humidity.

The effective energy resolution of the demonstrator setup is estimated from a combined spectrum of all detectors, each weighted with its corresponding exposure. The γ peaks from measurements with the calibration sources are modeled by double-Gaussian functions from which the full width at half maximum (FWHM) is calculated. The parametrization of the energy resolution as a function of the energy takes into account the charge carrier production and a noise component. The FWHM takes the form

$$\mathrm{FWHM}(E) = \sqrt{aE + b}, \qquad (2)$$

where a is a Poisson component and b is associated with the noise. Figure 1 shows the effective FWHM as a function of the incident energy. It ranges from about 15 keV at an energy of 238 keV up to approximately 30 keV at 2.6 MeV.

A linear function is used to determine the energy calibration of each detector. Figure 2 shows the difference between the
FIG. 2. Difference between the estimated and the true energy for several γ lines (markers) as well as the systematic uncertainty associated with the energy calibration (red dashed line).

peak position and the calculated calibration function of several γ lines.

V. PULSE SHAPE ANALYSIS

The analysis of the pulse shapes is a powerful tool to identify energy deposits on the detector surface caused, e.g., by α and β radiation. Three characteristic quantities are defined in the following, which are used to suppress events that deposit energies close to the electrodes (depth requirement) and lateral surface events (LSE requirement). The pulse shape analysis is performed using MANTICORE [19]. The recorded pulse shapes can be divided into four time intervals: the prepulse baseline, the charge-cloud drift, the charge collection, and the postpulse baseline. The prepulse and postpulse baselines of the difference pulse are used to determine the pulse height of the signal, which is proportional to the deposited energy. During the charge-cloud drift the induced signal is approximately the same on both anodes. The difference signal is therefore approximately zero. Once the charge cloud approaches the anode side the grid bias potential becomes important. The electrons are collected by the CA, leading to a sharp rise of the CA signal and a sharp fall of the NCA signal. The resulting weighted difference signal is a function of the energy and does not depend on the interaction depth. The interaction depth is reconstructed by the ratio of the cathode pulse height and the difference pulse height. The cathode signal itself is reconstructed from the sum of both anode signals.

If the energy is deposited on the lateral surfaces near the CA, the difference signal shows an earlier rise than the bulk signal. This behavior is characterized by the early rise time (ERT) value, which is defined as the time difference between the 3% point and the 50% point of the maximum pulse height. On the NCA near lateral surfaces, the difference pulse shows a small dip below the baseline before the sharp rise of the signal. It is characterized by the dip value, which is defined as the difference of the baseline and the pulse minimum in a window of 30 samples ending at the 50% pulse height point

on the right edge. More information about these quantities is given in Ref. [20].

VI. EVENT SELECTION

Pulse shapes are recorded if at least one detector records an energy deposition above its energy threshold. Before any software requirement is applied, the spectrum between 400/keV and 5 MeV contains 166 668 counts; 104 013 counts remain after requiring the reconstructed interaction depth to be in the interval [0.2,0.97] and thus removing events close to the cathode or the anode side. Requiring the dip and ERT values to be below 53 and 8, respectively, reduces the number of events to 65 176. For the current analysis, no anticoincidence between the detectors is required. This will be studied in the future.

Figure 3 shows the spectrum between 400 keV and 5 MeV after the event selection. Three γ lines are identified. The e^+e^- annihilation line at 511 keV is most likely dominated by ^{22}Na, which is also responsible for the line visible at 1275 keV. A primordial source of radiation is ^{40}K causing a line at 1460 keV. The small peak at 3.5 MeV is most likely caused by α radiation on the cathode side. They are induced by radon remnants that are attracted to the cathode after short failures of the nitrogen flushing. The detectors of the fourth layer have a coated cathode side with a thickness of 30 μm. This is not sufficient to stop all α particles, but instead reduces their kinetic energy.

VII. BACKGROUND MODELING AND SIGNAL ESTIMATION

A Bayesian analysis [21] is performed to estimate the signal strength of potential $0\nu\beta\beta$ decay. For each isotope a ROI is defined as the ± 3 FWHM interval around the Q value. For ^{114}Cd and ^{130}Te the ROI is extended to cover the γ lines, which can contribute to the background. The statistical model is a binned likelihood in the energy distribution describing Poisson fluctuations of the number of events n_i in each bin,

FIG. 3. The energy spectrum of all detectors after the full event selection. Three γ lines are identified: the annihilation line at 511-keV, the 1275-keV line of ^{22}Na, and the 1460-keV line of ^{40}K. The line at 3.5 MeV is most likely caused by α radiation on the cathode side.

i.e.,

$$p(\vec{n}|\vec{v}_s, \vec{v}_b, \vec{v}_{\text{line}}) = \prod_{i=1}^{n} \frac{e^{-\left(v_s^i + v_b^i + v_{\text{line}}^i\right)}\left(v_s^i + v_b^i + v_{\text{line}}^i\right)^{n_i}}{n_i!}, \quad (3)$$

with v_s^i being the expectation of the signal, v_b^i the expectation of the continuous background in each bin ΔE_i, and v_{line}^i the expectation of a line-shaped background, which is only greater than zero if a line is present in the ROI.

Based on previous COBRA data, the background is modeled by an exponential function:

$$v_b^i = \int_{\Delta E_i} \frac{B\lambda}{(e^{-\lambda E_{\min}} - e^{-\lambda E_{\max}})} e^{-\lambda E} dE, \quad (4)$$

where B is the total number of background events in the ROI, $E_{\min/\max}$ are the interval boundaries of the ROI, and λ is the decay parameter of the exponential function. The comparison with a background model using a second-order polynomial results in a difference in the estimated half-life of less than 2%.

Lines from γ radiation and the signal process have intrinsic widths smaller than the energy resolution. The energy resolution varies from detector to detector. Thus, a γ line in the dataset combining all detectors should in principle be described by a superposition of 64 Gaussian peaks. For simplicity such lines are described by double-Gaussian functions that model the energy resolution of the full detector array:

$$v_{\text{line/s}}^i = \int_{\Delta E_i} A\left(\frac{F}{\sqrt{2\pi}\sigma_1} e^{\frac{-(E-E_0)^2}{2\sigma_1^2}} + \frac{1-F}{\sqrt{2\pi}\sigma_2} e^{\frac{-(E-E_0)^2}{2\sigma_2^2}}\right) dE, \quad (5)$$

where $v_{\text{line/s}}^i$ is the expected number of counts for an energy interval ΔE_i, A is the amplitude, F is the fraction of the first Gaussian, E_0 is the peak position, and $\sigma_{1,2}$ are the widths of the Gaussian functions. A can be the total number of signal events, S, or B_{line} the total number of line-shaped background events. Studies show that $\sigma_1 = 2\sigma_2$ is a reasonable choice that describes the full energy peaks well and ensures that the fraction of both Gaussian functions is stable over the whole energy range.

The parameters B, λ, S, and, if applicable, B_{line} are free parameters of the model, for which uniform prior probabilities are assumed. The parameters F, $\sigma_{1,2}$, and E_0 are nuisance parameters, which are used to model the corresponding systematic uncertainties, assuming Gaussian prior probabilities.

The half-life of $0\nu\beta\beta$ decay is calculated from the signal strength as

$$T_{1/2}^{0\nu\beta\beta} = \frac{\ln(2)NX\epsilon}{\hat{s}}, \quad (6)$$

where N is the number of atoms of the evaluated isotope per kilogram detector mass, X is the total exposure, and $\hat{s}$ is the observed signal strength of the $0\nu\beta\beta$ decay. The total efficiency ϵ includes the intrinsic efficiency for the signal process and the efficiencies of the pulse shape analysis requirements. The

systematic uncertainties associated with the efficiency ϵ and the number of atoms N are also modeled using nuisance parameters and assuming Gaussian prior probabilities.

VIII. SYSTEMATIC UNCERTAINTIES

The systematic uncertainties discussed in the following are used as the standard deviations of the Gaussian priors for the corresponding nuisance parameters. These are summarized in Table I.

The uncertainties of the Q values range from 0.01 to 2.1 keV [22]. The systematic uncertainty associated with the energy calibration, and thus on the peak position E_0, is estimated by the largest difference between the calibration function and the means of Gaussian fits of all γ lines. The maximum difference is 1.9 keV.

The total uncertainty associated with the mean of the $0\nu\beta\beta$ decay line is calculated using the uncertainty propagation of the Q value uncertainty and the uncertainty of the energy calibration. The uncertainties of F and σ_1 are estimated via calibration measurements. The fraction $F = 0.52 \pm 0.03$ is constant over the considered energy range. The σ_1 for each ROI is calculated from the resolution function shown in Fig. 1. The values range from 7.2 keV up to 12.8 keV, and the corresponding uncertainties range from 0.09 to 0.15 keV.

All efficiencies are estimated as the ratio of events that fulfill the corresponding selection criteria and the total number of events. The depth requirement efficiency is evaluated with a pulse shape simulation. It is based on a simulation of the electric fields for the coplanar electrode layout that simulates

TABLE I. The first part lists all means and widths that are used as prior information. The second part lists all values that are used to calculate the total uncertainties.

charge propagation including diffusion and electromagnetic repulsion of the charge cloud. To estimate possible systematic deviations from the data, the results of the simulation are compared to an efficiency calculated using the observed ^{113}Cd spectrum with an endpoint of 320 keV. For futher information about the spectrum see Ref. [16]. ^{113}Cd is homogenously distributed inside the detector and gives a good measure of the efficiency losses caused by the depth requirement in an energy range from 180 to 300 keV. The absolute difference between both efficiency measurements is about 0.1. A possible source of these systematic deviations is distortions of the energy reconstruction near the anode grids. The efficiency is calculated for each ROI separately and ranges from 0.74 (^{114}Cd) to 0.78 (^{116}Cd). The associated absolute systematic uncertainty is ±0.1.

The impact of the LSE requirement on the efficiency is estimated with the double escape peak of the ^{208}Tl γ line of the calibration measurements. This is advantageous because the early rise time also depends on the spatial distribution of the energy deposits. This distribution is smaller for the double escape peak and $0\nu\beta\beta$ decay events and it is more confined than events caused by multiple-scattered photons. The efficiency is systematically underestimated even if calculated at the double escape peak because of the underlying background caused by ^{212}Bi. The emitted γ line overlaps strongly with the double escape peak and hence the fraction of the ^{212}Bi line is minimized by using the low-energy side of the peak. Based on measurements with calibration data the efficiency is estimated to be 0.76 ± 0.02.

The intrinsic efficiency is the probability to deposit the whole energy of a $0\nu\beta\beta$ event inside the active volume of one detector and is estimated with Monte Carlo simulations. The values range from 0.62 to 0.96. The absolute uncertainty of the calculated efficiencies is not expected to be larger than 0.002. The simulation is based on GEANT4 9.6, which models the particle propagation and interaction with matter [23]. The energy and angular distributions of the physics processes are predicted by an event generator based on DECAY0 [24]. To estimate detector-specific efficiency losses, causes, e.g., by dead layers, each detector is scanned with a ^{137}Cs point source with a known activity in three different distances. The peak count rates of these three measurements are fitted with $f(r) = a/r^2$. The fit parameter a is proportional to the activity of the source, the solid angle fraction covered by the detector, the emission probability of the γ line, and the efficiency of the detector. For the estimation of the efficiency of the full detector array, the detector with the highest efficiency is assumed to be fully efficient. All other detector efficiencies are calculated in relation to this detector. The average detection efficiency of the detector array is 0.89 ± 0.01.

The total efficiency uncertainty is obtained by error propagation and is shown in Table III. Runs with the highest trigger threshold of 550 keV are excluded for the ^{114}Cd analysis and are well below all other regions of interest. Therefore the trigger efficiency is assumed to be 100%.

One virtual CdZnTe molecule consists of $Cd_{0.9}Zn_{0.1}Te_1$. This composition is consistent with inductively coupled plasma mass spectroscopy measurements, which were done with a CdZnTe sample. However, the fraction of Zn can vary throughout the crystals and therefore a systematic uncertainty of ±2 % points is introduced for the Cd fraction, which corresponds to a variation of ±20% in the Zn fraction.

The detector lifetime is measured by the internal FADC clock. The uncertainty of each clock is of the order of 10 ms/4 h. The mass of each detector is measured before installation with an accuracy of milligrams, which is negligible compared to a single detector mass of approximately 6 g. Therefore, the exposure uncertainty is neglected in this analysis.

IX. RESULTS

The energy spectrum is fitted in several ROI for the isotopes listed in Table II. The table lists the exposure after the run selection, the ROI, the Q values [22], and the interval of the uniform prior used for each isotope. The energy spectra including the best-fit model and the corresponding uncertainty bands are shown in Figs. 4(a) to 4(e).

For each ROI, a signal model, H_1, and a background only model, H_0, are defined. The Bayes factor is defined as

$$K = \frac{P(D|H_1)}{P(D|H_0)}, \qquad (7)$$

where $P(D|H_1)$ is the probability of the data given the signal model and $P(D|H_0)$ is the probability of the data given the H_0 model. Bayes factors below 1 indicate that the signal hypothesis is disfavored against the background-only hypothesis.
All Bayes factors are well below 1, and thus the signal hypothesis is disfavored for each isotope. The absolute values of K are listed in Table III. The observed events in the ROI range from 288 (^{116}Cd) to 18 670 (^{114}Cd). The corresponding background indices range from 2.7 counts/(keV kg yr) (^{116}Cd) up to 213.9 counts/(keV kg yr) (^{114}Cd).

For ^{130}Te the ^{208}Tl line at 2614 keV is included in the analysis to scan for possible contributions of the thorium decay chain.
If the signal hypothesis is rejected, a lower limit on the half-life at 90% credibility is calculated. For ^{114}Cd, the analysis results in a lower limit of $T_{1/2} > 1.6 \times 10^{21}$ yr. The included annihilation line has a signal strength of 1770 counts. For ^{128}Te the analysis yields zero events resulting in a limit of $T_{1/2} > 1.9 \times 10^{21}$ yr. The fit of ^{70}Zn prefers zero events, which results in a limit of $T_{1/2} > 6.8 \times 10^{18}$ yr. The ^{208}Tl line included

The solid black lines corresponding to signal contributions equal the 90% upper limits. The black dashed lines indicate the expected statistical fluctuations of the number of counts in each bin.

TABLE III. Results of the Bayesian signal estimation after folding all systematic uncertainties. The second column shows the natural abundance of atoms per kilogram that is used for the signal estimation; for its uncertainty, see Table I. In the third column the background index b for the different ROI is presented. The fourth column reports the limit at 90% credibility and the last column reports the calculated Bayes factor.

Isotope	$N/10^{23}$ $\left(\frac{\text{atoms}}{\text{kg}}\right)$	b $\left(\frac{\text{counts}}{\text{keV kg yr}}\right)$	$T_{1/2}$ 90% C.L. $(10^{21}$ yr)	K
^{114}Cd	6.59	$213.9^{+1}_{-1.7}$	1.6	0.07
^{128}Te	8.08	$65.5^{+0.5}_{-1.6}$	1.9	0.17
^{70}Zn	0.015	$45.1^{+0.6}_{-1}$	6.8×10^{-3}	0.06
^{130}Te	8.62	$3.6^{+0.1}_{-0.3}$	6.1	0.14
^{116}Cd	1.73	$2.7^{+0.1}_{-0.2}$	1.1	0.27

in the ^{130}Te fit yields zero events, so there is no evidence for any background contribution from the thorium decay chain. The limit for ^{130}Te is $T_{1/2} > 6.1 \times 10^{21}$ yr. In the ^{116}Cd ROI the fit yields zero events for the $0\nu\beta\beta$ decay mode. The resulting limit is $T_{1/2} > 1.1 \times 10^{21}$ yr. Switching to a prior uniform in the effective Majorana neutrino mass increases the limits on the half-life by 30%–40%, depending on the isotope.

Table III reports the abundance per kilogram of detector mass of the analyzed isotope, the total efficiency, the background level in each ROI, and the 90% credibility lower limit on the half-life for each isotope.

X. CONCLUSION

A search for $0\nu\beta\beta$ decay with the COBRA demonstrator setup has been performed using data corresponding to an exposure of 234.7 kg d. No indication for $0\nu\beta\beta$ decay has been found and 90% credibility limits have been set for different isotopes. The COBRA demonstrator continues to collect data. A layer of large segmented CdZnTe detectors will be installed in the near future, which is expected to increase the sensitivity considerably.
