**Background:** Recently, a systematic exploration of two-neutron transfer induced by the (<sup>18</sup>O, <sup>16</sup>O) reaction on different targets has been performed. The high-resolution data have been collected at the MAGNEX magnetic spectrometer of the INFN-LNS Laboratory in Catania and analyzed with the coupled reaction channel (CRC) approach. The simultaneous and sequential transfers of the two neutrons have been considered under the same theoretical framework without the need for adjustable factors in the calculations.

**Purpose:** A detailed analysis of the one-neutron transfer cross sections is important to study the sequential two-neutron transfer. Here, we examine the (<sup>18</sup>O, <sup>17</sup>O) reaction on <sup>16</sup>O, <sup>28</sup>Si, and <sup>64</sup>Ni targets. These even-even nuclei allow for investigation of one-neutron transfer in distinct nuclear shell spaces.

**Method:** The MAGNEX spectrometer was used to measure mass spectra of ejectiles and extract differential cross sections of one-neutron transfer to low-lying states. We adopted the same CRC formalism used in the sequential two-neutron transfer, including relevant channels and using spectroscopic amplitudes obtained from shell-model calculations. We also compare with the one-step distorted-wave Born approximation (DWBA).

**Results:** For the <sup>18</sup>O + <sup>16</sup>O and the <sup>18</sup>O + <sup>28</sup>O systems, we used two interactions in the shell model. The experimental angular distributions are reasonably well reproduced by the CRC calculations. In the  $^{18}O + ^{64}Ni$ system, we considered only one interaction, and the theoretical curve describes the shape and order of magnitude observed in the experimental data.

**Conclusions:** Comparisons between experimental DWBA and CRC angle-integrated cross sections suggest that excitations before or after the transfer of a neutron are relevant in the  $^{18}O + ^{16}O$  and  $^{18}O + ^{64}Ni$  systems.

# **I. INTRODUCTION**

Transfer reactions are very sensitive tools to study correlation between the initial and the final nuclear states of two neighboring nuclei, providing hints for particle configurations of such states. In recent works, we have dedicated our experimental and theoretical efforts to study pairing correlations in heavy-ion-induced transfer reactions. Using the  $(^{18}O, ^{16}O)$ reaction we have measured the two-neutron transfer cross sections leading to states in <sup>14</sup>C [\[1\]](#page-8-0), <sup>15</sup>C [\[2–4\]](#page-8-0), <sup>18</sup>O [\[5,6\]](#page-8-0),  $30$ Si [\[7\]](#page-8-0), and  $66$ Ni [\[8\]](#page-8-0). The combination of direct reaction and nuclear structure calculations have allowed to assess the role of sequential and simultaneous processes in these two-neutron transfer reactions. The sequential transfer corresponds to uncorrelated transfers of the two nucleons, whereas, in the simultaneous process, the particles are transferred as a single entity to the target nucleus. Comparisons between theoretical and experimental cross sections indicate that the simultaneous process is dominant in ground-to-ground two-neutron transfer reactions.

A wider picture of the sequential process in two-neutron transfer can be pursued by measuring the one-neutron transfer reaction to the intermediate nuclear system. A successful description of this reaction channel using the same theoretical approach is an important evaluation for the robustness of the sequential two-neutron transfer calculations.

In the past 50 years, many experimental studies have been performed using the  $(d, p)$  or  $(p, d)$  reactions  $[9, 10]$ . Recently these probes have been used to investigate single-particle configurations far from stability thanks to the use of radioactive beams in inverse kinematics detector setup [\[11,12\]](#page-8-0). Conclusions from these data were mainly established based on the distorted-wave Born approximation (DWBA) grounds using effective nucleon-nucleus (NN) interactions. A high degree of accuracy in the theoretical transfer cross sections is a challenging task and requires the inclusion of deuteron breakup and the nonlocality of the NN interaction. The former can be treated within the continuum discretized (CD) coupled channel [\[13\]](#page-8-0), the Alt-Grassberger-Sandhas method [\[14\]](#page-8-0), or the adiabatic distorted-wave approximation (ADWA) [\[15\]](#page-8-0). The nonlocality can be neglected in favor of a local equivalent potential with energy dependency, although deviations of about 40% compared with local potentials have been <span id="page-1-0"></span>reported in Ref. [\[16\]](#page-8-0). Within the ADWA framework, Tsang *et al.* reanalyzed most of the  $(d, p)$  neutron-transfer reactions using global potentials to describe the elastic-scattering data of deuterons and protons [\[17\]](#page-8-0). The obtained spectroscopic factors are remarkably consistent with large-basis shell-model calculations for *sd*-shell nuclei.

In heavy-ion-induced transfer, the theoretical scenario is also challenging. First, effects of strong absorption are more pronounced, and the angular distributions exhibit a diffractionlike pattern as the bombarding energy increases. Second, second-order mechanisms, such as projectile-target excitation preceding and/or following the transfer of nucleons, must be taken into account properly [\[18\]](#page-8-0). In addition, partial waves that mostly contribute to transfer reactions are limited within a range of optimum *Q* values and angular momentum transfer  $l_{\text{opt}}$  for a given reaction and energy  $[19]$ . The one-neutron transfer reactions induced by heavy ions have been studied recently in Refs. [\[20–22\]](#page-8-0). In particular, in Ref. [\[20\]](#page-8-0), integrated cross sections for one- and two-neutron transfers to  $^{11}$ B,  $^{12}$ C,  $^{13}$ C, and  $^{28}$ Si show that the probability for twoneutron transfer is not a simple composition of two independent one-neutron transfers due to the pairing correlation between the two neutrons. This interpretation is also corroborated by results using the constrained molecular dynamics approach to describe the collision [\[23\]](#page-8-0).

In this paper, we present a systematic analysis of the one-neutron transfer reaction to <sup>16</sup>O, <sup>28</sup>Si, and <sup>64</sup>Ni nuclei induced by the  $(^{18}O, ^{17}O)$  reaction in the context of the coupled reaction channel (CRC) theory using a systematic optical potential. Relevant spectroscopic amplitudes in the CRC are derived from shell-model calculations. This approach provides a detailed description of the one-neutron transfer compared to the constrained molecular dynamics one and is the same adopted in the calculations of the sequential twoneutron transfer in previous works [\[1–8\]](#page-8-0). All experimental data have been collected at the same bombarding energy  $(E_{lab} = 84 \text{ MeV}).$ 

The paper is organized as follows. In Sec. II the experimental details are given. Section  $III$  is devoted to the analysis of the experimental data using different theoretical approaches for the cross-sectional calculations. Results and discussions for each system are presented in Sec. [IV.](#page-3-0) Finally, in Sec. [V,](#page-7-0) a summary and conclusions are given.

### **II. EXPERIMENTAL DETAILS**

The measurements were performed at the *Istituto Nazionale di Fisica Nucleare, Laboratori Nazionali del Sud*, Catania, Italy. The 84-MeV  $^{18}O^{6+}$  beam was delivered by the tandem accelerator. A WO<sub>3</sub> (  $210 \pm 20 \text{-} \mu\text{g/cm}^2$  thickness), <sup>28</sup>Si (140  $\pm$  10- $\mu$ g/cm<sup>2</sup> thickness), and an enriched self-supporting  $^{64}$ Ni foil (110  $\pm$  10- $\mu$ g/cm<sup>2</sup> thickness) were used as targets. The  $^{17}O^{8+}$  reaction ejectiles were momentum analyzed by the MAGNEX magnetic spectrometer [\[24–26\]](#page-8-0) set in full acceptance mode ( $\Omega \approx 50$  msr). The parameters of the ions' trajectories (i.e., vertical and horizontal positions and incident angles) are measured by the focal plane detector, which also allows for particle identification [\[27\]](#page-8-0). Examples of the particle identification are shown in Figs.  $1(a)$  and

FIG. 1. Typical spectra for particle identification performed at the Focal Plane Detector of the MAGNEX spectrometer. The atomic numbers of ejectiles are selected in a  $\Delta E$ -*E* spectrum [see (a)]. The isotopic identification is performed exploring the correlation between horizontal position and residual energy [see (b)]. A graphical selection on oxygen in (a) removes other atomic species and  $^{18,17,16}$ O<sup>8+</sup> [identified in (b)], and a small fraction of  $18,17,16$ O<sup>7+</sup> isotopes are clearly seen in red.

1(b), exploring the  $\Delta E$ -*E* correlation for *Z* identification [Fig.  $1(a)$ ] and the horizontal position to residual energy correlation for mass selection [Fig.  $1(b)$ ]. After a graphical selection of the oxygen species in the  $\Delta E$ -*E* plot [Fig. 1(a)], only the <sup>18*,*17*,*16</sub> $O$ <sup>8+</sup> and a small fraction of <sup>18*,*17*,*16 $O$ <sup>7+</sup> isotopes</sup></sup> are clearly seen in red [Fig.  $1(b)$ ]. Note that this procedure removes interference from other nuclei, such as  ${}^{20}F^{9+}$  at the right of  ${}^{16}O^{8+}$  [in Fig. 1(b)]. The one-neutron transfer reaction channel corresponds to a graphical selection in  ${}^{17}O^{8+}$ .

Trajectory reconstruction of  $17$ O particles is performed solving the equation of motion for each detected particle [\[25\]](#page-8-0) to obtain scattering parameters at the target reference system. Further details of the data reduction technique can be found in Refs. [\[28,29\]](#page-8-0). For the <sup>16</sup>O(<sup>18</sup>O, <sup>17</sup>O)<sup>17</sup>O and the  $^{28}Si(^{18}O,~^{17}O)^{29}Si$  reactions, two angular settings were explored with the spectrometer optical axis centered at 8<sup>°</sup> and 10◦. Due to the large angular acceptance of the spectrometer, these angular settings correspond to a total covered angular range of  $4^\circ < \theta_{lab} < 15^\circ$  with an overlap of  $8^\circ$  between the two angular settings. For the  $^{64}$ Ni( $^{18}$ O,  $^{17}$ O)  $^{65}$ Ni

<span id="page-2-0"></span>

FIG. 2. Excitation energy spectra of (a)  $^{17}O$ , (b)  $^{29}Si$ , and (c)  $^{65}$ Ni residual nuclei. Backgrounds due to contamination in the targets are negligible under the peaks of interest and are not shown in the spectra. The blue lines are set at a one-neutron emission threshold energy for each nucleus. Transfer cross sections have been extracted for the numbered peaks indicated in each spectrum.

reaction, three angular settings were explored with the spectrometer optical axis centered at  $\theta_{\text{lab}} = 12°$ , 18°, and 24°. For this reaction, the total covered angular range is about  $7^\circ < \theta_{\text{lab}} < 29^\circ$ .

The excitation energy spectra, relative to the ground-toground states (g.s.) transition *Q* value for each reaction are shown in Fig. 2. The overall energy resolution is about 250 keV (full width at half maximum). A list of the main peaks identified in Fig. 2 is presented in Table [I.](#page-3-0) A supplementary measurement was performed using a  $50 \pm 5 \cdot \mu$ g/cm<sup>2</sup> self-supporting <sup>12</sup>C target for the estimation of the contribution from carbon backing on the  $WO_3$  target. In this case, contamination was negligible, and it was not shown in the spectrum [Fig.  $2(a)$ ]. Contamination from carbon buildup in the  $^{28}$ Si and  $^{64}$ Ni targets does not interfere with the analyzed peaks.

For the  ${}^{16}O({}^{18}O, {}^{17}O) {}^{17}O$  reaction, the experimental energy resolution allows for a clear identification of the ground and  $1/2^+$  (0.8-MeV) states. The peaks corresponding to these two states are numbered as 1 and 2, respectively, in Fig. 2(a). Since the residual and ejectile particles are the same in the outgoing mass partition, peak 2 may also contain a nonnegligible contribution from excitation of the ejectile, leaving the residual nucleus in the ground state. The third peak [numbered as 3 in Fig. 2(a)] at  $\approx$  1.74 MeV is generated by the simultaneous excitation of the  $1/2^+$  state in both projectile and residual nuclei, i.e.,  ${}^{16}O({}^{18}O, {}^{17}O_{0.87}) {}^{17}O_{0.87}$ .

In the <sup>28</sup>Si(<sup>18</sup>O, <sup>17</sup>O)<sup>29</sup>Si reaction, the ground (5/2<sup>+</sup>) and first excited  $(3/2^+)$  states of <sup>29</sup>Si are identified by numbers

6 and 8, respectively [see Fig. 2(b)]. Peak 7 corresponds to the excitation of the <sup>17</sup>O projectile  $(1/2^+)$  at 0.87 MeV. Other peaks appear at higher excitation energies in the spectrum and correspond to the unresolved states of  $^{29}$ Si and/or  $^{17}$ O.

In the <sup>64</sup>Ni(<sup>18</sup>O, <sup>17</sup>O)<sup>65</sup>Ni reaction, the first peak [label 14 in Fig.  $2(c)$ ] corresponds to three unresolved states of <sup>65</sup>Ni, namely, 5*/*2<sup>−</sup> (g.s.), 1*/*2<sup>−</sup> (0.06 MeV), and 3*/*2<sup>−</sup> (0.31 MeV). The second peak [label 15 in Fig.  $2(c)$ ] corresponds to four unresolved states, namely, 3*/*2<sup>−</sup> (0.69 MeV), 9*/*2<sup>+</sup> (1.02 MeV), 7*/*2<sup>−</sup> (1.14 MeV), and 5*/*2<sup>−</sup> (1.27 MeV).

Angular distributions for the one-neutron transfer cross sections leading to the states indicated in Fig. 2 have been obtained and are shown in the next sections. The angular resolution is 0*.*3◦ for 64Ni and 0*.*5◦ for 16O and 28Si. The error bars in the cross sections correspond to an uncertainty in the solid angle determination and the statistical error. A systematic uncertainty of 10%, coming from the target thickness and beam integration by the Faraday cup, is common to all the angular distribution points, and it is not included in the error bars.

#### **III. THEORETICAL FRAMEWORK**

The CRC approach is adopted for the calculation of the direct reaction cross sections. In this framework, calculations were performed using the FRESCO code  $[30,31]$  with the nuclear São Paulo potential (SPP) [\[32\]](#page-9-0) as the optical potentials in both mass partitions. States considered in each system are indicated in the next subsections. In the entrance partition, a normalization coefficient of 0.6 for the imaginary part of the SPP was used to account for dissipative processes and missing couplings to continuum states [\[33,34\]](#page-9-0). Due to the fact that the mass diffuseness of the  $18$ O projectile does not follow the systematics of the SPP, we used the value of 0.61 fm as indicated in Ref. [\[35\]](#page-9-0). In the outgoing partition, the imaginary part is scaled by a larger factor (0.78). This optical potential describes the angular distribution of elastic and quasielastic cross sections for many systems in a wide energy interval [\[36\]](#page-9-0) and an unexpected rainbowlike pattern in the elastic scattering of the  ${}^{16}O + {}^{27}Al$  system at 100 MeV [\[37\]](#page-9-0) without the need for adjustable parameters. Moreover, this is also the same potential adopted in previous works on the two-neutron transfer reaction to  $^{12,13}$ C,  $^{16}$ O,  $^{28}$ Si, and  $^{64}$ Ni at the same bombarding energy.

The potentials for the calculations of one-neutron wave functions were assumed to have a Woods-Saxon shape with reduced radii and diffuseness values set at 1.2 and 0.6 fm for the nuclear cores, respectively. The depths of these shapes were varied in order to fit the experimental separation energies for one neutron. In recent studies on two-neutron transfer induced by the  $(^{18}O, ^{16}O)$  reaction  $[1-8]$ , this approach has proven to be adequate for lighter nuclei, such as the 12C and <sup>16</sup>O nuclei. In the <sup>64</sup>Ni(<sup>18</sup>O, <sup>16</sup>O)<sup>66</sup>Ni reaction, the sequential two-neutron transfer provides a better agreement with experimental data for the g.s.  $\rightarrow$  2<sup>+</sup> transition using slightly different values for the reduced radii and diffuseness parameters that were obtained with the interacting bosonfermion model [\[38\]](#page-9-0) to describe the wave functions for states in <sup>64</sup>*,*65Ni [\[8\]](#page-8-0). Nevertheless, for the one-neutron transfer, we

<sup>b</sup>The peaks that may also contain projectile excitations along with states of the residual nuclei.

c The peak corresponds to the sum of the projectile and target excitations.

found that this dependence is not as critical as in the sequential two-neutron transfer and we set the same values for the <sup>64</sup>Ni core.

Spectroscopic amplitudes (SAs) were extracted from the shell-model calculations using the NUSHELLX code [\[39\]](#page-9-0). The coupling scheme for the projectile overlaps, used throughout this paper, is shown in Fig. 3. Similar schemes were considered in the previous analyses of sequential two-neutron transfers to <sup>12</sup>C [\[1\]](#page-8-0), <sup>13</sup>C [\[2\]](#page-8-0), <sup>16</sup>O [\[6\]](#page-8-0), and <sup>64</sup>Ni [\[8\]](#page-8-0). The inclusion of high-lying excited states in  $^{18}$ O or  $^{17}$ O nuclei does not change appreciably the cross sections for the one-neutron transfers. The target overlaps for each nucleus are described in the following section.

FIG. 3. Coupling scheme for projectile overlaps considered in this paper. Continuous and dashed lines correspond to direct and two-step transitions.

## **IV. RESULTS AND DISCUSSIONS**

The main purpose here is to treat three different oneneutron transfer reactions under the same theoretical framework, avoiding arbitrary normalization factors in the calculations. In this sense, the  ${}^{16}O({}^{18}O, {}^{17}O) {}^{17}O$  reaction provides a good workbench to assess the nuclear structure models of the neighboring stable isotopes of oxygen. Such information is required to describe the one-neutron transfer cross sections in the other two systems. Different model spaces and interactions, suitable for <sup>28</sup>*,*29Si and <sup>64</sup>*.*65Ni target nuclei, are used in the calculations of SAs required for the  $^{28}Si(^{18}O, ^{17}O)^{29}Si$ and 64Ni(18O*,* 17O) 65Ni reactions, respectively.

## **A. Transfer to the 16O nucleus**

Two interactions are typically used in shell-model calculations in this mass region: The Zucker-Buck-McGrory (ZBM) [\[40\]](#page-9-0) and the PSDMOD, that is a modified version of the PSD-WBT interaction [\[41\]](#page-9-0). In the first model, a <sup>12</sup>C core is considered, and the valence subspace includes the  $1p_{1/2}$ ,  $1d_{5/2}$ , and  $2s_{1/2}$  orbitals. In the second one, a <sup>4</sup>He core is adopted, and the valence subspace is  $1p_{1/2}$ ,  $1p_{3/2}$ ,  $1d_{3/2}$ ,  $1d_{5/2}$ , and  $2s_{1/2}$ , described by the potential of Ref. [\[41\]](#page-9-0). These two interactions were considered to study the two-neutron transfer in the <sup>16</sup>O(<sup>18</sup>O, <sup>17</sup>O)<sup>18</sup>O, <sup>16</sup>O(*t*, *p*)<sup>18</sup>O [\[5,6\]](#page-8-0) and  ${}^{13}C(^{18}O, {}^{17}O)$   ${}^{14}C$  reactions [\[2\]](#page-8-0). From these works, the ZBM interaction describes the experimental absolute cross sections of the two-neutron transfer reasonably well. Despite that, we still consider the PSDMOD interaction to compare both

FIG. 4. Experimental angular distribution of the cross sections for the one-neutron transfer in the  ${}^{16}O({}^{18}O, {}^{17}O) {}^{17}O$  reaction compared with theoretical predictions. The reaction channels are identified on the graph. The solid blue and dashed red curves correspond to CRC calculations using SAs derived with the ZBM and PSDMOD interactions, respectively.

interactions in the context of one-neutron transfer. In the target nucleus,  $0^{+}$  (g.s.) and  $3^{-}$  (6.05 MeV) of the <sup>16</sup>O nucleus were considered in the coupling scheme of the CRC calculations along with the overlaps with the first three excited states of the <sup>17</sup>O nucleus. The spectroscopic amplitudes for these overlaps can be found in Ref. [\[4\]](#page-8-0).

The experimental angular distribution for one-neutron transfer leading to the ground and  $1/2^+$  states of the <sup>17</sup>O nucleus is shown in Fig. 4. As was already mentioned in Sec. [I,](#page-0-0) the reaction results in identical particles in the outgoing mass partition, both  $17$ O particles in the ground state and in the first excited state. For these cases, theoretical curves correspond to the coherent sum of scattering amplitudes at  $\theta$  and  $(\pi - \theta)$ . Another point to be stressed is that the experimental setup does not distinguish between the <sup>16</sup>O(<sup>18</sup>O, <sup>17</sup>O<sub>g.s.</sub>)<sup>17</sup>O<sub>0.87</sub> and the  ${}^{16}O({}^{18}O, {}^{17}O_{0.87})$ <sup>17</sup>O<sub>g.s.</sub> reaction channels because they have the same *Q* value. In this case, the experimental cross sections were determined from counting events under peak 2

[see Fig.  $2(a)$ ], and data are shown in Fig. 4 along with CRC calculations summed for the two channels that compose this peak.

Results using the PSDMOD interaction to derive the SAs show an overall good agreement with experimental data. The ZBM overestimates the cross sections, even though they also describe the shape of the experimental data. In the analysis of the other two systems, we are considering the PSDMOD for the projectile overlaps.

# **B. Transfer to the 28Si nucleus**

In Ref. [\[7\]](#page-8-0), we have observed that deformation of the target nucleus results in a competition between sequential and simultaneous two-neutron transfers in  $28Si$ . The nuclear surface of the ground state of  $28Si$  is not spherical (reduced electric quadrupole transition probability is  $0.0326 \pm$ 0.0012  $e^2b^2$  [\[42\]](#page-9-0)). Mermaz and co-workers have measured the angular distribution of several multinucleon transfer reactions to  $28$ Si induced by <sup>18</sup>O at 56 MeV [\[18\]](#page-8-0). Single- and multistep mechanisms were considered under the scope of the DWBA and the coupled channel Born approximation approaches, respectively. The authors needed to arbitrarily decrease the effective Coulomb barrier at the surface in order to reproduce the elastic and inelastic channels as well as the shape of angular distributions of the transfer cross sections, Peterson *et al.* [\[43\]](#page-9-0) studied the  $(d, p)$  reaction on <sup>28</sup>Si and adopted the weak-coupling model to treat  $^{29}Si$  as a valence neutron in the  $2s-1d$  shells coupled to the collective states of the  $^{28}Si$ core. Calculations indicated that the one-neutron transfer to  $7/2^+$  (4.08 MeV) in <sup>29</sup>Si proceeds mainly through the lowest collective  $2^+$  state of <sup>28</sup>Si. Moreover, it was shown that this second-order mechanism is negligible for the population of the  $1/2^+$  (g.s.) and  $3/2^+$  (1.27-MeV) states of <sup>29</sup>Si.

In the present paper, the spectroscopic information for the states in the <sup>28</sup>*,*29Si nuclei are extracted from two different phenomenological interactions: the effective PSDMOD and the PSDMWKPN interactions [\[44\]](#page-9-0). The latter is a combination of the Cohen-Kurath interaction  $[45]$  for the *p* shell, the Wildenthal interaction [\[46\]](#page-9-0) for the *sd* shell, and the Millener-Kurath interaction [\[47\]](#page-9-0) for the coupling matrix elements between *p* and *sd* shells.

Within both interactions, the model space assumes  ${}^{4}$ He as a closed core and valence neutrons and protons in the 1*p*3*/*2*,* 1*p*1*/*2*,* 1*d*3*/*2*,* 1*d*5*/*2, and 2*s*1*/*<sup>2</sup> orbitals. This model space is larger compared to the one considered by Peterson and co-workers [\[43\]](#page-9-0). Coupling between single-particle states in the  $2s-1d$  shells and the <sup>28</sup>Si core, which was important to describe the  $(d, p)$  data in Ref.  $[43]$ , is effectively considered within our model space.

The SAs derived from the PSDMOD and PSDMWKPN interactions are listed in Table [II.](#page-5-0) The SA values are very close each other with some deviations, such as in the SA for the  ${}^{28}Si_{g.s.}$ -to- ${}^{29}Si_{g.s.}$  transition. In the last four columns of Table [II,](#page-5-0) we also compare SFs, obtained in this paper with those found by the DWBA analysis in Refs. [\[18](#page-8-0)[,43\]](#page-9-0). The SF for the g.s.-to-g.s. transition from the PSDMOD interaction is close to the value obtained by Mermaz *et al.* [\[18\]](#page-8-0), whereas the PSDMWKPN interaction agrees with the value reported by Peterson *et al.* [\[43\]](#page-9-0).

<span id="page-5-0"></span>TABLE II. One-neutron SAs and spectroscopic factors (SFs) for <sup>28</sup>Si to <sup>29</sup>Si transitions obtained by shell-model calculations using PSDMOD and PSDMWKPN interactions. *nlj* are the principal quantum numbers, the orbital and the total angular momenta of the single neutron. We also include SFs deduced by  $(d, p)$  reactions found in Refs. [\[18,](#page-8-0)[43\]](#page-9-0).

The comparison between the experimental and the theoretical angular distributions of the cross sections for the one-neutron transfer reaction using the PSD-MOD and PSDMWKPN interactions is shown in Fig. [5.](#page-6-0) The overall best description of the experimental data is achieved using SAs from the PSDMWKPN interaction. The <sup>28</sup>Si(<sup>18</sup>O, <sup>17</sup>O<sub>g.s.</sub>)<sup>29</sup>Si<sub>g.s.</sub> reaction channel [Fig. [5\(a\)\]](#page-6-0) exhibits a slightly poor agreement between theoretical curves and experimental data compared to other reaction channels [Figs.  $5(b)$  and  $5(c)$ ], although the two theoretical curves give cross sections of the same order of magnitude as the experimental one. For transitions to the 3*/*2<sup>+</sup> state (1.27 MeV) in <sup>29</sup>Si, the local minimum at 13 $\degree$  (c.m.) is reproduced in both calculations [see Fig.  $5(b)$ ], although calculations with the PSDMOD interaction overestimate the cross sections at  $\theta_{c.m.} > 15^{\circ}$ . In the <sup>28</sup>Si(<sup>18</sup>O, <sup>17</sup>O<sub>0.87</sub>)<sup>29</sup>Si<sub>g.s.</sub> reaction channel, the experimental data are very well described by the PSDMWKPN interaction [Fig.  $5(c)$ ], whereas the PSDMOD calculations are well above the data.

A survey among other microscopic interactions for the <sup>28</sup>*,*29Si nuclei has been considered, but that has led to poor agreement with experimental data and is not shown here. From a simple comparative inspection, the low-quality agreement observed between theory and experimental data for the ground-to-ground transition to the  $^{28}$ Si nucleus seems to be related to its deformation since a better agreement is observed

for the spherical  $^{16}$ O nucleus. On the other hand, quite good agreement has been obtained for the  $^{28}Si(t, p)^{30}Si$  reaction using the PSDMOD interaction [\[7\]](#page-8-0). In fact, measurements at the very forward angle would be helpful to better judge the agreement of calculations in the present paper. The effect of deformation in heavy-ion-induced transfer demands further study.

### **C. Transfer to the 64Ni nucleus**

In the literature, there are some discrepancies between data and theoretical one-neutron SFs for the Ni nuclei. Lee *et al.* [\[48\]](#page-9-0) have performed a systematic reanalysis of the angular distributions measured with (*d,p*) reactions on Ni isotopes using the ADWA for the reaction model. Using large-basis shell-model calculations, an overall deviation of about 25% was observed with respect to the SFs reported in previous works. In some cases, deviations of about 60% can be found as for the ground state of the <sup>65</sup>Ni nucleus (see Table II in Ref. [\[48\]](#page-9-0)).

The two-neutron transfer  ${}^{64}$ Ni( ${}^{18}$ O,  ${}^{16}$ O)  ${}^{66}$ Ni reaction has been studied in Ref. [\[8\]](#page-8-0). In that work, the sequential twoneutron transfer in which transitions to states in the  ${}^{65}Ni$ nucleus are an intermediate step is important in order to interpret the experimental two-neutron transfer cross sections that lead to the  $2^+$  states of the  $66$ Ni nucleus. In the shell-model

<span id="page-6-0"></span>

FIG. 5. Angular distributions of the cross sections for the <sup>28</sup>Si( $^{18}$ O,  $^{17}$ O)<sup>29</sup>Si reaction leading to the population of <sup>29</sup>Si in the ground state (top); (c) <sup>17</sup>O ejectile in the  $1/2^+$  state at 0.87 MeV (middle), and  $^{28}$ Si in the  $3/2^+$  state at 1.27 MeV (bottom). SAs for <sup>17</sup>*,*18O derived in the shell model using the PSDMOD calculation. In the <sup>28</sup>*,*29Si cases, two interactions have been considered: the PSDMOD and the PSDMWKPN.

calculation, the neutron SAs for  ${}^{65}$ Ni were derived using the BJUFF model space. In this model space, <sup>48</sup>Ca is considered as a closed core with valence particles populating the  $1f_{7/2}$ and  $2p_{3/2}$  orbitals for protons and the  $2p_{3/2}$ ,  $1f_{5/2}$ ,  $2p_{1/2}$ , and 1*g*9*/*<sup>2</sup> orbitals for the neutrons. An effective interaction derived from the CD-Bonn nucleon-nucleon potential was adopted [\[8\]](#page-8-0), developed for nickel isotopes with masses near  $A = 64$ . The SA values can be found in Ref. [\[8\]](#page-8-0). This approach produces energy spectra of <sup>64</sup>*,*65Ni isotopes in good agreement with the experimental data within 200 keV of deviation for both negative- and positive-parity states.

Experimental results for the one-neutron transfer reaction on <sup>64</sup>Ni are shown in Fig. 6 along with the theoretical curves using SAs obtained from the shell model. Experimental data points and calculations correspond to the sum of the oneneutron transfer cross sections for the ground 0.06- and 0.31-MeV states of  $^{65}$ Ni (Fig. 6) and for the 0.69-, 1.27-, and 1.41-MeV states of  $^{65}$ Ni with the <sup>17</sup>O ejectile at 0.87 MeV (Fig. 6). The theoretical curves reproduce quite well the bell-like shape of the angular distributions around  $\theta = 30^\circ$ .

FIG. 6. Angular distributions of the one-neutron transfer cross sections leading to the low-lying states in <sup>65</sup>Ni. At the top, summed cross sections for transfers to the g.s., 0.06- and 0.31-MeV states in the 65Ni nucleus. Bottom, summed cross sections for the 0.69-, 1.02-, 1.14-, and 1.27-MeV states in <sup>65</sup>Ni and 0.87 MeV in the <sup>17</sup>O ejectile. SAs for <sup>17</sup>*,*18O and <sup>64</sup>*,*65Ni derived in the shell model using the PSDMOD and BJUFF interactions, respectively.

In general, one can say that the overall agreement between the theoretical calculations and the data is reasonably good, considering that we are not fitting any parameter here.

### **D. Angle-integrated cross sections**

Dominant factors for the angle-integrated cross sections of the one-neutron transfer are the binding energy of the transferred neutrons, the kinematic matching between the relative motion of the cores and the valence particle, and the spin configuration. In the projectile, the binding energy of the valence neutron to the  $17$ O core is a common feature for all three systems. The second factor accounts for the linear and angular momentum dependences in the entrance and exit channels. The final states that satisfy a relation between the transferred angular momentum and the *Q* value, indicated by Brink's rule [\[19\]](#page-8-0), are strongly populated. Finally, the third factor is related to the spin configuration of the transferred nucleon before and after the transfer reaction in which those that take place without spin flip are more favored against reactions that require flipping of the transferred spin [\[49\]](#page-9-0).

Here we compare the experimental angle-integrated cross sections  $(\sigma_{\exp})$  with the theoretical ones derived from the DWBA ( $\sigma_{DWBA}$ ) and CRC ( $\sigma_{CRC}$ ) calculations for the three systems. Quantum-mechanical calculations within the onestep DWBA calculation, using the SFs derived from the shell model, implicitly take the above-mentioned factors into account. Nevertheless, deviations from the data can be observed due to the second-order processes, such as projectile-target excitation prior to the transfer, which may play a role for different target nuclei. These processes can be explicitly included within a CRC model, thus the comparison between

<span id="page-7-0"></span>TABLE III. Experimental and theoretical angle-integrated cross sections (in millibarns) of the one-neutron transfer reactions for the final states in <sup>17</sup>O, <sup>29</sup>Si, and <sup>65</sup>Ni nuclei. We show angle-integrated cross sections obtained using the two interactions considered in this paper within the DWBA and CRC calculations. In the case of 17O, interactions *A* and *B* stand for the PSDMOD and ZBM interactions, respectively. For the  $^{29}$ Si case, they stand for the PSDMWKPN and PSDMOD interactions, respectively. Uncertainties in the experimental angle-integrated cross sections are estimated to be 10% due to systematic uncertainties in the cross sections. Angular ranges for the angle-integrated cross section are specified in the text.

 $a$ Defined as  $\delta_{\text{DWBA}} = \frac{\sigma_{\text{DWBA}} - \sigma_{\text{CRC}}}{\sigma_{\text{CRC}}}$ <u>BA <sup>−σ</sup>CRC</u> .<br><sup>σ</sup>CRC</sub>  ${}^{\text{b}}$ Defined as  $\delta_{\text{exp}} = \frac{\sigma_{\text{exp}} - \sigma_{\text{CRC}}}{\sigma_{\text{CRC}}}$ .

experimental data with the DWBA and CRC cross sections indicates the effect of multistep processes in the nucleon transfer dynamics.

In Table III we list the  $\sigma_{\exp}$  along with theoretical ones for the DWBA and CRC ( $\sigma_{DWBA}$  and  $\sigma_{CRC}$ , respectively) calculations for one-neutron transfer leading to low-lying states in the <sup>17</sup>O, <sup>29</sup>Si, and <sup>65</sup>Ni nuclei. Differential cross sections were integrated from  $8°$  to  $24°$  for  $17^{\circ}$ O, from  $5°$  to 25 $\degree$  for <sup>29</sup>Si, and from 11 $\degree$  to 38 $\degree$  for the <sup>65</sup>Ni. In the DWBA calculations we have considered only the ground states of projectiles and targets in the entrance partition. We also define the deviation of  $\sigma_{\exp}$  and  $\sigma_{\text{DWBA}}$  relative to  $\sigma_{\text{CRC}}$  ( $\sigma_{\exp}$  and  $σ<sub>DWBA</sub>$ , respectively).

In the  $^{18}O + ^{16}O$  system, experimental and CRC angleintegrated cross sections exhibit very good agreement. For the  ${}^{17}O_{g.s.} + {}^{17}O_{g.s.}$  channel, for instance,  $\sigma_{exp} = 4.2$  and  $\sigma_{\text{CRC}} = 4.5$  mb that correspond to a relative deviation of  $-7\%$ using the PSDMOD interaction. This is within the estimated experimental uncertainty of 10%. The angle-integrated cross section obtained within the DWBA approach is 6.5 mb using the same interaction, which is 44% higher than the CRC approach. Similar values is observed in the other channels and when we considered the ZBM interaction. Considering that experimental values are close to the CRC ones and the large values obtained from the DWBA calculation, there is an indication that population of states in  $^{17}$ O through one-neutron transfer is affected by second-order processes.

The comparison between angle-integrated cross sections for the  $^{18}O + ^{28}Si$  system brings an alternative perspective about the effects of second-order processes in the one-neutron transfer. Although the quality of the agreement between the-

ory and experimental data is limited for the  ${}^{17}O_{g.s.} + {}^{29}Si_{1.27}$ at large angles [see Fig.  $5(b)$ ] we note that relative deviation of  $\sigma_{\text{DWBA}}$  is about 15%. The CRC calculation with SAs from the PSDMWKPN interaction reproduces the  $\sigma_{\exp}$  with deviations of 13% and 16% for the <sup>17</sup>O<sub>g.s.</sub> + <sup>29</sup>Si<sub>g.s.</sub> and <sup>17</sup>O<sub>0.87</sub> + <sup>29</sup>Si<sub>g.s.</sub>, respectively. The overall good agreement among  $\sigma_{\rm exp}$ ,  $\sigma_{\rm DWBA}$ , and  $\sigma_{\rm CRC}$  obtained in these two reaction channels indicates that the one-neutron transfer to  $^{28}$ Si proceeds mainly through direct routes connecting the initial and final states. The same conclusion is obtained from the analysis of  $^{28}Si(d, p)$  as well [\[41\]](#page-9-0). However, it is not clear that the same holds in the population of <sup>29</sup>Si<sub>1.27</sub>. For the <sup>18</sup>O + <sup>64</sup>Ni system, the values of  $\sigma_{\text{exp}}$ ,  $\sigma_{\text{DWBA}}$ , and  $\sigma_{\text{CRC}}$  exhibit absolute deviations as high as 30% and in this case is difficult to draw conclusions due to the need to sum different unresolved states in the <sup>65</sup>Ni nucleus. Nevertheless, the deviation between DWBA cross sections and the experimental data seems to be more acentuated than between the CRC calculation and the data.

Summarizing, one-neutron transfer reactions to  ${}^{16}O$  and possibly to <sup>64</sup>Ni are affected by competing processes, such as target and/or projectile excitations that take the flux from the reaction channel considered. On the other hand, in the  $^{28}$ Si nucleus, the ground-to-ground transfer seems to be a single-step process, such as in the  $(d, p)$  reaction.

## **V. CONCLUSIONS**

We present new experimental data for one-neutron transfer to  $^{16}O$ ,  $^{28}Si$ , and  $^{64}Ni$  induced by the  $(^{18}O, ^{17}O)$  reaction at  $E_{\text{lab}} = 84$  MeV. Coupled reaction channel calculations, using <span id="page-8-0"></span>spectroscopic amplitudes derived from shell-model calculations, give a good description of the cross sections to lowlying states in <sup>17</sup>O, <sup>29</sup>Si, and <sup>65</sup>Ni. We emphasize that no adjustable parameters are included in the optical potential for the direct reaction calculations and the present results give good support to sequential two-neutron transfer calculations performed in previous works for the same systems.

Deviations between one-step DWBA and CRC angleintegrated cross sections, using the same spectroscopic amplitudes, indicate that second-order processes are important in the one-neutron transfer to  ${}^{16}O$  and  ${}^{64}Ni$  whereas they are not so relevant in the ground-to-ground transfer in <sup>28</sup>Si. Determination of spectroscopic amplitudes by means of fittings of DWBA calculations to experimental data is a risky procedure

when the transfer can be preceded by inelastic excitation of the projectile and target. Further systematic studies is needed to reveal the key ingredients that induce multistep processes in the one-neutron transfer reactions induced by heavy ions.
