(Received 24 March 2020; accepted 31 July 2020; published 2 September 2020)

Dwarf spheroidal galaxy satellites of the Milky Way are prime targets for indirect detection of dark matter with gamma rays due to their proximity, high dark matter content, and absence of nonthermal emission processes. Recently, the Dark Energy Survey (DES) revealed the existence of new ultrafaint dwarf spheroidal galaxies in the southern-hemisphere sky, therefore ideally located for ground-based observations with the imaging atmospheric Cherenkov telescope array H.E.S.S. We present a search for very-high-energy ($E \gtrsim 100$ GeV) gamma-ray emission using H.E.S.S. observations carried out recently towards Reticulum II, Tucana II, Tucana III, Tucana IV, and Grus II satellites. No significant very-high-energy gamma-ray excess is found from the observations on any individual object nor in the combined analysis of all the datasets. Using the most recent modeling of the dark matter distribution in the dwarf galaxy halo, we compute for the first time on DES satellites individual and combined constraints from Cherenkov telescope

observations on the annihilation cross section of dark matter particles in the form of Weakly Interacting Massive Particles. The combined 95% C.L. observed upper limits reach $\langle\sigma v\rangle \simeq 1 \times 10^{-23} \text{ cm}^3 \text{ s}^{-1}$ in the W^+W^- channel and $4 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}$ in the $\gamma\gamma$ channels for a dark matter mass of 1.5 TeV. The H.E.S.S. constraints well complement the results from Fermi-LAT, HAWC, MAGIC, and VERITAS and are currently the most stringent in the $\gamma\gamma$ channels in the multi-GeV/multi-TeV mass range.

I. INTRODUCTION

Precise cosmological measurements [1] support the theory that most of the matter in the Universe is composed of nonbaryonic cold dark matter (DM). The search for nongravitational interactions of DM is one of the major efforts in contemporary fundamental astrophysics. Despite the worldwide multifaceted efforts that have been deployed over the last decades to detect DM, its nature is presently unknown. Many theoretical models [2] have been devised to propose DM particle candidates. Among them is a Weakly Interacting Massive Particle (WIMP) with mass and coupling at the electroweak scale that provides the cold DM density measured in the Universe today [3], which is popularly acknowledged as the *WIMP miracle*. Among the experimental strategies devised to detect DM, the indirect searches look for the Standard Model particles produced during the DM annihilation or decay. WIMPs could still annihilate today in dense regions of the Universe producing very-high-energy (VHE, $E \gtrsim 100 \text{ GeV}$) gamma rays in the final states that can be eventually detected by ground-based imaging atmospheric Cherenkov telescopes (IACT) such as the High Energy Stereoscopic System (H.E.S.S.).

Among the most favorable environments to look for DM annihilation in VHE gamma rays are dwarf spheroidal galaxies (dSphs) satellites of the Milky Way, with many of them nearby and at high Galactic latitudes. The measured stellar kinematics in dSphs make them the most DM-dominated objects in the Universe. They are composed of old stellar populations and contain little gas which could act as target materials for VHE cosmic rays. No hint is found for nonthermal processes that could give rise to emission from non-DM scenarios which would serve as background for a DM search in VHE gamma rays [4,5]. Despite the lower DM signals expected for dSphs compared to the central region of the Milky Way, they have the advantage of negligible background emission to hide a DM signal.

Numerous dSphs have been discovered via the Sloan Digital Sky Survey [6] covering the Northern celestial hemisphere. More recently ultrafaint dSphs are being unveiled by the ongoing surveys like PanSTARRS [7], and the DES [8], with the prospect of more discoveries with the Large Synoptic Survey Telescope [9]. DES is a southern-hemisphere optical survey providing photometric measurements to detect stellar overdensities with unprecedented sensitivity in the southern sky. The ultrafaint

Milky Way satellites newly discovered by DES are consistent with being dSphs while a fraction of them are referred to as dSph candidates in absence of confirmation from spectroscopic measurements. They represent new promising targets for VHE gamma-ray searches for DM annihilations.

We present here the observations carried out by H.E.S.S. on a selection of DES satellites to search for DM annihilation signals. The targeted systems are Reticulum II (Ret II), Tucana II (Tuc II), Tucana III (Tuc III), and Grus II (Gru II), with Tucana IV (Tuc IV) in the field of view (FoV) of Tuc III observations. The results of the search for DM annihilation signals are presented for individual and combined searches towards these targets. The paper is organized as follows. Section II presents the DM signals expected from the targets. In Secs. III and IV, we present the observational datasets, and the data analysis, respectively. Section V is devoted to the results. We conclude in Sec. VI.

II. DARK MATTER SIGNALS

A. Dark matter distribution and gamma-ray flux

The energy-differential gamma-ray flux expected from the self-annihilation of DM particles of mass m_{DM} in the region of solid angle $\Delta\Omega$ can be written as [2]:

$$\frac{d\Phi_\gamma}{dE_\gamma}(E_\gamma, \Delta\Omega) = \frac{\langle\sigma v\rangle}{8\pi m_{\text{DM}}^2} \sum_f \text{BR}_f \frac{dN^f}{dE_\gamma} J(\Delta\Omega), \quad \text{with}$$

$$J(\Delta\Omega) = \int_{\Delta\Omega} \int_{\text{LoS}} \rho^2(s(r, \theta)) ds d\Omega. \quad (1)$$

The first term groups the total velocity-weighted annihilation cross section $\langle\sigma v\rangle$ and the sum of the annihilation spectra dN^f/dE_γ in the final states f with associated branching ratios BR_f . The second term, often referred to as the J -factor, corresponds to the square of the DM mass density ρ integrated over the line-of-sight (LoS) s and $\Delta\Omega$. The distance from the observer to the annihilation location s is given by $r = (s^2 + s_0^2 - 2s_0s \cos\theta)^{1/2}$, where s_0 is the distance from the target to the Earth and θ the angle between the direction of observation and the dSph center. The DM mass density is inferred from the measurements of the position and LoS velocity of the stars gravitationally bound in the dwarf galaxy potential well through the Jeans

equation [10]. The finite number of kinematic measurements of the member stars leads to an uncertainty on the J -factor; see, e.g., Ref. [11].

The expected DM flux is composed of a continuum spectrum extending up to the DM mass, and a line emission feature. The former contribution arises from the hadronization and/or decay of quarks, heavy leptons, and gauge bosons involved in the annihilation process. The latter comes from the prompt annihilation into γX with $X = \gamma, h, Z$, or a nonstandard model neutral particle, providing a spectral line at an energy $E_\gamma = m_{\text{DM}}[1 - (m_X/2m_{\text{DM}})^2]$. Additional gamma rays are produced when the DM particles self-annihilate into charged particles via processes involving virtual internal bremsstrahlung and final state radiation. Such processes provide a wider linelike feature that peaks at an energy close to m_{DM} .

B. Target selection

Five targets were selected among the 16 newly discovered DES dSphs [12,13]. The selection is based mainly on the DM content and visibility from the H.E.S.S. site. Targets with measured or predicted J -factor close to $\log_{10}(J_{<0.5^\circ}/\text{GeV}^2 \text{cm}^{-2}) \sim 19$ are chosen, with visibility at zenith angles lower than 60° spread all over the year. The priority has been given to targets that are confirmed as dwarf galaxies, followed by the galaxy candidates with the largest J -factor. The chosen targets are outlined in Table I. The low-luminosity Milky Way satellite Ret II has been discovered using photometric data from the DES [12,14]. Located at a distance of 32 kpc from the Sun, it is one of the nearest dSphs after Segue 1 (23 kpc) [15] and Sagittarius (24 kpc) [16]. Ret II is about three times more luminous than Segue 1, which suggests that its DM halo may be more massive than that of Segue 1. This makes it a privileged dSph target for DM searches. Assuming dynamical equilibrium and spherical symmetry, a Jeans analysis of the available kinematic data suggest that the J -factor of Ret II is among the highest of the known dSphs. Its J -factor integrated within a radius of 0.5° reaches $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5}) = 19.6$ [17] based on a kinematic sample of 38 member stars. Alternative studies derived mean $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5})$ values as large as 20.5 [18] and as low as 18.2 [19] within a 0.5° radius. A systematic study presented in Refs. [17,20] shows that its J -factor determination is stable against assumptions in the Jeans analysis. No hints of tidal disruption [21] or a significant binary star population [22] in Ret II have been detected so far. Based on the velocities and metallicities of its stars, Ret II is confirmed as an ultrafaint dwarf galaxy [23]. Present photometric and spectroscopic data cannot constrain the fraction of binary stars in the kinematic stellar sample. In the observed absence of tidal disruption and binary stars that would artificially inflate the velocity dispersion, Ret II is a prime DM target for H.E.S.S.

TABLE I. Selected Milky Way satellites discovered by DES for H.E.S.S. observations. The second column gives the heliocentric distance of these objects. The third column provides their identification status: systems whose photometry makes them compatible with being a dSph but without spectroscopic measurements are classified as not confirmed. The size of the ON region is given in the fourth column. The fifth and sixth columns provide the mean value of the J -factor for an integration angle of 0.5° and its associated 1σ uncertainty. The uncertainty quoted for Ret II takes also into account possible sources of systematic uncertainties [17] while only the statistical uncertainty is considered for Tuc II. The references from which these values are extracted are given in the ninth column. The same quantities are provided in the seventh and eight columns for an integration angle corresponding to the size of the region of interest (ON region). The symbol \dagger marks the systems for which no spectroscopic measurement is available. In such a case, the integration angle for the ON region corresponds to 0.125° as relevant for pointlike emission searches. \ddagger In the absence of measured uncertainty, $\sigma_{J_{\text{ON}}} = 0.7$ is assumed in order to have an estimate of the effect of this uncertainty on the combined results (see Sec. V).

Source name	Heliocentric distance [kpc]	Confirmed dSph	ON region radius [degrees]	$\log_{10} J_{<0.5^\circ}$	$\sigma_{J_{<0.5^\circ}}$	$\log_{10} J_{\text{ON}}$	$\sigma_{J_{\text{ON}}}$	Reference for the J -factor

Grus II \dagger	53	No	0.125	18.7	...	18.1	0.7 \ddagger	[26]

Tuc II is an ultrafaint dSph galaxy Milky Way satellite discovered from DES photometric data [12] located at 57 kpc from the Sun. Spectroscopic measurements of member stars [24] reveal a low internal velocity dispersion. Assuming dynamical equilibrium, spherical symmetry, and a negligible contamination of binary stars in the stellar sample, the J -factor of Tuc II is calculated as $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5}) = 18.7$ within 0.5° [24], which makes it an interesting DM target among known dSphs. Spectroscopic observations of member stars of Tuc II classify it as a dwarf galaxy [24]. No tidal disruption or significant binary star population have been measured so far in this system. In Ref. [27] the J -factor of Tuc II is predicted to be $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5}) = 19.0$ within a 0.5° radius [27]. The conservative estimate is used in what follows.

Among the dSph candidates discovered by DES [12], Tuc III is the nearest low-luminosity Milky Way satellite located at a heliocentric distance of 25 kpc [25]. Spectroscopic measurements show a very low velocity dispersion in the member stars, and only upper limits can be safely derived. Despite its larger size and lower surface brightness compared to any known globular cluster, Tuc III cannot be confirmed as a DM-dominated system, and, therefore, cannot be definitely classified as a dSph. If Tuc III has a DM halo similar to the one of other satellites with similar stellar mass, the J -factor of Tuc III can be as high as $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5}) = 19.4$ within 0.5° [25] making it a very promising DM target that can be conveniently observed by H.E.S.S. However, the derivation of the J -factor from the modeling of the velocity distribution suffers from systematic uncertainties and J -factors as low as $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5}) \simeq 17.8$ are possible [25]. The predicted values from Ref. [26] and Ref. [27] are $\log_{10}(J/\text{GeV}^2 \text{cm}^{-5}) = 19.0$ and 17.7 , respectively, within 0.5° .

No accurate spectroscopic measurements are available for Gru II and Tuc IV. In absence of measurements of the velocity dispersion of member stars, they are classified as likely dSphs [26]. No J -factor can be measured and the empirical law from Ref. [26] is used to provide an estimate of the J -factor of Gru II and Tuc IV.

The determination of the DM density distribution in dSphs is subject to uncertainties that can significantly affect the J -factor estimation. Due to the finite sample of stellar tracers in dSphs, the statistical uncertainty on the J -factor is higher for ultrafaint candidates than that of the classical dSphs such as Sculptor or Draco. The Jeans equation framework assumes dynamical equilibrium of stellar tracers (e.g., no tidal disruption), spherical symmetry of the system, light profile parametrization, and radial dependence of the velocity anisotropy. This set of hypotheses may not be valid in the physical systems, which would lead to systematic uncertainties in the J -factor determination. In what follows, the statistical uncertainties for the computation of the limits are considered when the spectroscopic

measurements are available. Sources of systematic uncertainties in the J -factor determination in dSphs are discussed, for instance, in Refs. [28,29].

The ultrafaint systems Tuc III, Tuc IV, and Gru II lack spectroscopic measurements of their member stars and their J -factor can only be predicted. Assuming these objects to be embedded in spherical cuspy DM halo following the relationship between their enclosed mass, velocity dispersion, and half-light radius, an analytic formula to calculate the J -factors can be derived [19]. An alternative method based on a distance scaling relationship provides a compatible estimate of the J -factor assuming that the stellar systems lie in DM halos similar to those of known dSphs as shown in Ref. [26]. For Tuc III, the J -factor value within 0.5° can be as large as $\log_{10} J = 19.4$ using the lower limit on its mass from the tidal stripping argument [25]. However, the derived value from an upper limit on the LoS velocity dispersion is about two orders of magnitude below. Recent photometric observations classify Tuc III as an ultrafaint dwarf galaxy [23] while spectroscopic measurements failed so far to unambiguously confirm its dynamical status [25]. In absence of lower limits on the velocity dispersion for Tuc IV and Gru II, the J -factor values in the region of interest (ROI) are derived following the methodology of Ref. [26] assuming an inner slope of one for a cuspy DM profile [19]. In the case of Tuc III, Tuc IV, and Gru II, no statistical uncertainty can be derived for their J -factors. $\sigma_{J_{\text{ON}}} = 0.7$ is assumed to have an estimate of the degradation of the H.E.S.S. limits towards these objects when considering the J -factor uncertainty. Such a value is coherent given the measured uncertainty derived for Ret II and Tuc II.

III. OBSERVATIONS AND DATASET

H.E.S.S. is an array of five IACTs situated in the Khomas Highland in Namibia, at 1800 m above the sea level. The observatory consists of four 12 m diameter telescopes (CT1-4) at the corner of a square of side length 120 m and a fifth 28 m diameter telescope (CT5) at the middle of the array since 2012. Given its location in the Southern Hemisphere, H.E.S.S. is best located to observe recently detected DES dSphs compared to other IACTs.

The observations presented here were performed with the full five-telescope array (H.E.S.S. Phase 2) towards a selection of recently discovered dSphs. Dedicated observations were carried out towards Ret II, Tuc II, Tuc III in 2017 and 2018, and Gru II in 2018. Previous observations targeted at another source covered the position of Gru II providing a useful exposure at its nominal position. Given the H.E.S.S. FoV, observations taken towards Tuc III also include Tuc IV. The dedicated observations were taken in the *wobble* mode where the telescope pointing direction is offset from the nominal target position by an angle between 0.5 and 0.7° . The observations selected for the data analysis meet the standard run selection criteria [30]. Table II

TABLE II. Table of Milky Way satellites discovered by DES and consistent with dwarf galaxies observed by H.E.S.S. The second to fifth columns give the distance and the galactic coordinates of each object, respectively. The last two columns provide the live time on target acquired by H.E.S.S. in the 2017 and 2018 observation campaigns and the mean zenith angle of observations. Uncertainties on the distance of the systems are of about 10%.

Source name	RA [hours]	Dec [degrees]	Longitude [degrees]	Latitude [degrees]	Live time [hours]	Mean zenith angle [degrees]

summarizes the main observational characteristics of the selected dSphs.

After the calibration of raw shower images, the reconstruction of the direction and energy of gamma rays is performed using a template-fitting technique [31] in which the recorded images are compared to precalculated showers computed from a semianalytical model. This technique achieves an energy resolution of 10% and an angular resolution of 0.06° at 68% containment radius for gamma-ray energies above 200 GeV. The results presented here have been cross-checked with a different calibration and analysis chain yielding compatible results [32].

A *combined* analysis is used to account for the hybrid nature of the observations. Given the configuration of H.E.S.S. Phase II array, a gamma ray can trigger CT5 alone (monoscopic event), or any combination of two of the five telescopes (stereo event). The event reconstruction can be performed in different modes according to the event class. In order to fully benefit from the flexibility of the H.E.S.S. Phase II array, a combined mode exploits both the monoscopic and stereoscopic reconstructions [33]. The best reconstruction among the mono (CT5 only), stereo (CT1-5), or H.E.S.S. Phase I-like (CT1-4) reconstruction of each gamma-ray-like event is selected from a χ^2 test. Figure 1 shows each selected dSph the gamma-ray excess sky map for which the residual background computation is determined using the *RingBackground* technique [30]. Table III summarizes the available gamma-ray statistics in the source and background regions, the relative size of the background region to the signal region, as well as the significance in the source region. No significant gamma-ray excess is found at the position of the dSph or anywhere in the FoV as shown in Fig. 1.

IV. DATA ANALYSIS

A. Region of interest and background measurement

For each selected system, the ON source signal is computed by integrating all the gamma-ray-like events in a disk of angular radius given in the second column of Table III. For Ret II and Tuc II, a ON region of 0.2° radius is used, divided into two concentric subregions of interest

(ROIs) of 0.1° width each. The size of the ON source region is chosen according to the expected DM signal spatial profile versus background as a function of the distance from the object nominal position in order to maximize the sensitivity. In absence of spectroscopic measurements, Tuc III, Tuc IV, and Gru II are considered as pointlike sources for H.E.S.S. and therefore only one ROI with a 0.125° radius is considered.

The residual background is measured in the OFF-source regions defined according to the *multiple-OFF* method [34]: for each telescope pointing position of the observations, several regions with same solid angle and shape as for the ROIs are defined at the same distance from the pointing position as the ON region. By construction, the centers of the OFF regions lie on a circle of radius equal to the distance between the target position and the pointing position, which leads to identical acceptance in the ON and OFF regions. This method yields smaller systematic errors in the analysis than background determination techniques based on OFF measurements in separated dedicated observations of empty fields of view. A disk around the center of the ON region is excluded for the OFF measurements, with a radius equal to twice the size of the ON region radius, so that the expected DM signal in the OFF regions is negligible. No additional excluded region is used since no VHE gamma-ray sources are detected in the considered FoV. Given the expected source extension of Tuc III and Tuc IV no contamination is expected from one source in the considered signal region of the other. The total number of background events is the sum of all the events that fall in the OFF regions. The parameter α is defined as the ratio between the solid angle size of the OFF and ON regions by $\alpha = \Delta\Omega_{\text{OFF}}/\Delta\Omega_{\text{ON}}$. The excess sky map is obtained by subtracting the total OFF event count weighted by $1/\alpha$ from the ON event count, and the significance is computed following the statistical approach of Ref. [35]. Figure 1 shows the excess significance sky map for all selected systems. No significant gamma-ray excess is found in the ON source region as well as anywhere else in the sky map. Table III provides the size of the ON source region, the number of ON and OFF events, the α values as well as the excess significance for the full ROIs.

FIG. 1. Excess significance maps in the FoV of Ret II, Tuc II, Tuc III, and Gru II, respectively, in Galactic coordinates. Tuc IV is observed in the FoV of Tuc III. The nominal position of the systems is marked with a white-filled triangle. The color scale gives the significance of the excess in numbers of standard deviations. No significant excess is observed in any of the FoV.

B. Statistical analysis and upper limit computation

A two-dimensional (2D)-binned Poisson maximum likelihood analysis is used in order to explore the spatial and spectral characteristics of the expected DM signal with respect to the background. The energy range is divided into

68 logarithmically spaced energy bins i between 150 GeV and 63 TeV, and the spatial bin j corresponds to the number of ROIs defined for each target. For a given DM mass and annihilation channel, the Poisson likelihood function in the bin (i, j) can be written as

TABLE III. Data analysis results for each selected target. The second column gives the size of the ROI. Count numbers measured in the ON and OFF regions are provided in the third and fourth column, respectively. The fifth and sixth column give the ratio of the solid angle size between the OFF and ON regions averaged over all observations, and the measured excess significance between the ON and OFF counts. For the systems marked with the symbol *, the ROI size is chosen as for pointlike emission searches.

Source name	ON region size [degrees]	N_{ON} [counts]	N_{OFF} [counts]	$\bar{\alpha}$	Significance [σ]
Reticulum II	0.200	949	7926	8.0	-0.9
Tucana II	0.200	1170	9704	8.0	-1.0
Tucana III*	0.125	689	9816	15.0	0.9
Tucana IV*	0.125	285	6550	24.1	0.6
Grus II*	0.125	263	4491	16.0	-0.8

$$\begin{aligned}
\mathcal{L}_{ij}(N^S, N^B | N_{\text{ON}}, N_{\text{OFF}}, \alpha) &= \frac{(N_{ij}^S + N_{ij}^B)^{N_{\text{ON},ij}}}{N_{\text{ON},ij}!} e^{-(N_{ij}^S + N_{ij}^B)} \\
&\times \frac{(N_{ij}^{S'} + \alpha_j N_{ij}^B)^{N_{\text{OFF},ij}}}{N_{\text{OFF},ij}!} e^{-(N_{ij}^{S'} + \alpha_j N_{ij}^B)}. \quad (2)
\end{aligned}$$

$N_{\text{ON},ij}$ and $N_{\text{OFF},ij}$ stand for the number of measured events in the ON and OFF regions, respectively. N_{ij}^B is the expected number of background events in the ON region. α_j is defined as the ratio of the solid angle of the OFF and ON regions for the bin j . N_{ij}^S and $N_{ij}^{S'}$ correspond to the number of DM signal events expected in the ON and OFF regions, respectively. They are computed by folding the theoretical DM flux with the energy-dependent acceptance and energy resolution of H.E.S.S. for the considered data set. The continuum signal spectra are extracted from Ref. [36], while the monoenergetic gamma-line signal is a Dirac delta function. The energy resolution of H.E.S.S. is represented by a Gaussian function with a width of $\sigma_E/E = 10\%$. The dependence of the energy resolution on the observational parameters (mean zenith angle, optical efficiency, off-axis angle) and the analysis selection cuts have a negligible impact on the results. The same likelihood analysis technique is applied to look both for the continuum and gamma-line signals.

As discussed in Sec. IV A, $N_{ij}^{S'}$ can be safely taken to $N_{ij}^{S'} \equiv 0$. The total likelihood \mathcal{L} is defined as the product of the \mathcal{L}_{ij} over the ij bins. Since no significant excess between the ON and OFF regions is found in any of the considered systems, upper limits can be computed for any DM mass from a likelihood ratio test statistic (TS) [37] given by:

$$TS = \begin{cases} -2 \ln \frac{\mathcal{L}(N^S(\langle\sigma v\rangle), \widehat{N}^B(\langle\sigma v\rangle))}{\mathcal{L}(0, \widehat{N}^B(0))} & N^S(\widehat{\langle\sigma v\rangle}) < 0 \\ -2 \ln \frac{\mathcal{L}(N^S(\langle\sigma v\rangle), \widehat{N}^B(\langle\sigma v\rangle))}{\mathcal{L}(N^S(\langle\sigma v\rangle), N^B)} & 0 \leq N^S(\widehat{\langle\sigma v\rangle}) \leq N^S(\langle\sigma v\rangle) \\ 0 & N^S(\widehat{\langle\sigma v\rangle}) > N^S(\langle\sigma v\rangle) \end{cases}. \quad (3)$$

\widehat{N}_{ij}^B is obtained through a conditional maximization by solving $d\mathcal{L}/dN_{ij}^B = 0$, while $N_{ij}^S(\widehat{\langle\sigma v\rangle})$ and \widehat{N}_{ij}^B are computed using an unconditional numerical maximization. The procedure described in Ref. [37] has been followed in order to compute upper limits for positive signals. The value of the velocity-weighted annihilation cross section $\langle\sigma v\rangle$ for which $\Delta TS = 2.71$ from the minimum provides one-sided 95% confidence level (C.L.) upper limits on $\langle\sigma v\rangle$.

Due to the finite number of stellar tracers of the DM-induced gravitational potential in a given DES system k , the J -factor can be treated as a statistical variable. Its uncertainty is modeled as a nuisance parameter which follows a log-normal distribution:

$$\mathcal{L}_k^J(J|\bar{J}, \sigma_J) = \frac{1}{\sqrt{2\pi}\sigma_J \log(10) \times J} \times \exp\left(-\frac{(\log_{10} J - \log_{10} \bar{J})^2}{2\sigma_J^2}\right), \quad (4)$$

with mean \bar{J} and width σ_J taken from literature (see Table I). The J -factor, \hat{J} , that maximizes Eq. (4) is derived and then included in the likelihood test as $N_S \rightarrow N_S \hat{J}/\bar{J}$.

V. RESULTS

A. Upper limits on individual systems

Since no significant excess is found in the selected DES dSphs in any ROI, upper limits at 95% C.L. on $\langle\sigma v\rangle$ versus the DM mass are derived for each target following Eq. (3). The upper limits as a function of the DM mass are shown in Fig. 2 for the W^+W^- annihilation channel. The observed limits are plotted together with the mean expected limits and the 1σ and 2σ containment bands. Mean expected limits and statistical uncertainty bands are obtained from 100 Poisson realizations of the background in the ON and OFF regions, respectively. The mean expected limits are given by the mean of the distribution of $\log_{10}(\langle\sigma v\rangle)$ obtained in the realizations and the containment bands by its standard deviation.

The best observed limits are obtained for Ret II. They reach $\langle\sigma v\rangle \simeq 1 \times 10^{-23} \text{ cm}^3 \text{ s}^{-1}$ for a 1.5 TeV DM mass in the W^+W^- annihilation channel. In the case of Tuc III, they reach $\langle\sigma v\rangle \simeq 3 \times 10^{-23} \text{ cm}^3 \text{ s}^{-1}$ for a 1.5 TeV DM mass. Assuming the lower value of the J -factor for Tuc III, the limits degrade by a factor of about 40. The limits on Tuc IV and Gru II are less constraining due to smaller J -factors and datasets.

In addition, a search for monoenergetic gamma-ray lines has been performed on the five targets. The 95% C.L. observed and mean expected limits together with the containment bands are shown in Fig. 3 for the five targets. For Ret II, the observed limit reaches $\langle\sigma v\rangle \simeq 8 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}$ for a 1.5 TeV DM mass.

The search for a DM signal has also been performed in the annihilation channels $ZZ, b\bar{b}, t\bar{t}, e^+e^-, \mu^+\mu^-,$ and $\tau^+\tau^-$. The 95% C.L. upper limits on $\langle\sigma v\rangle$ as a function of m_{DM} are shown in Fig. 4 for the most promising target, Ret II.

The impact of the uncertainty on the J -factor is computed for Ret II and Tuc II, as shown in Fig. 5 for the W^+W^- channel. The limits degrade by a factor of about six and 12 for Ret II and Tuc II, respectively.

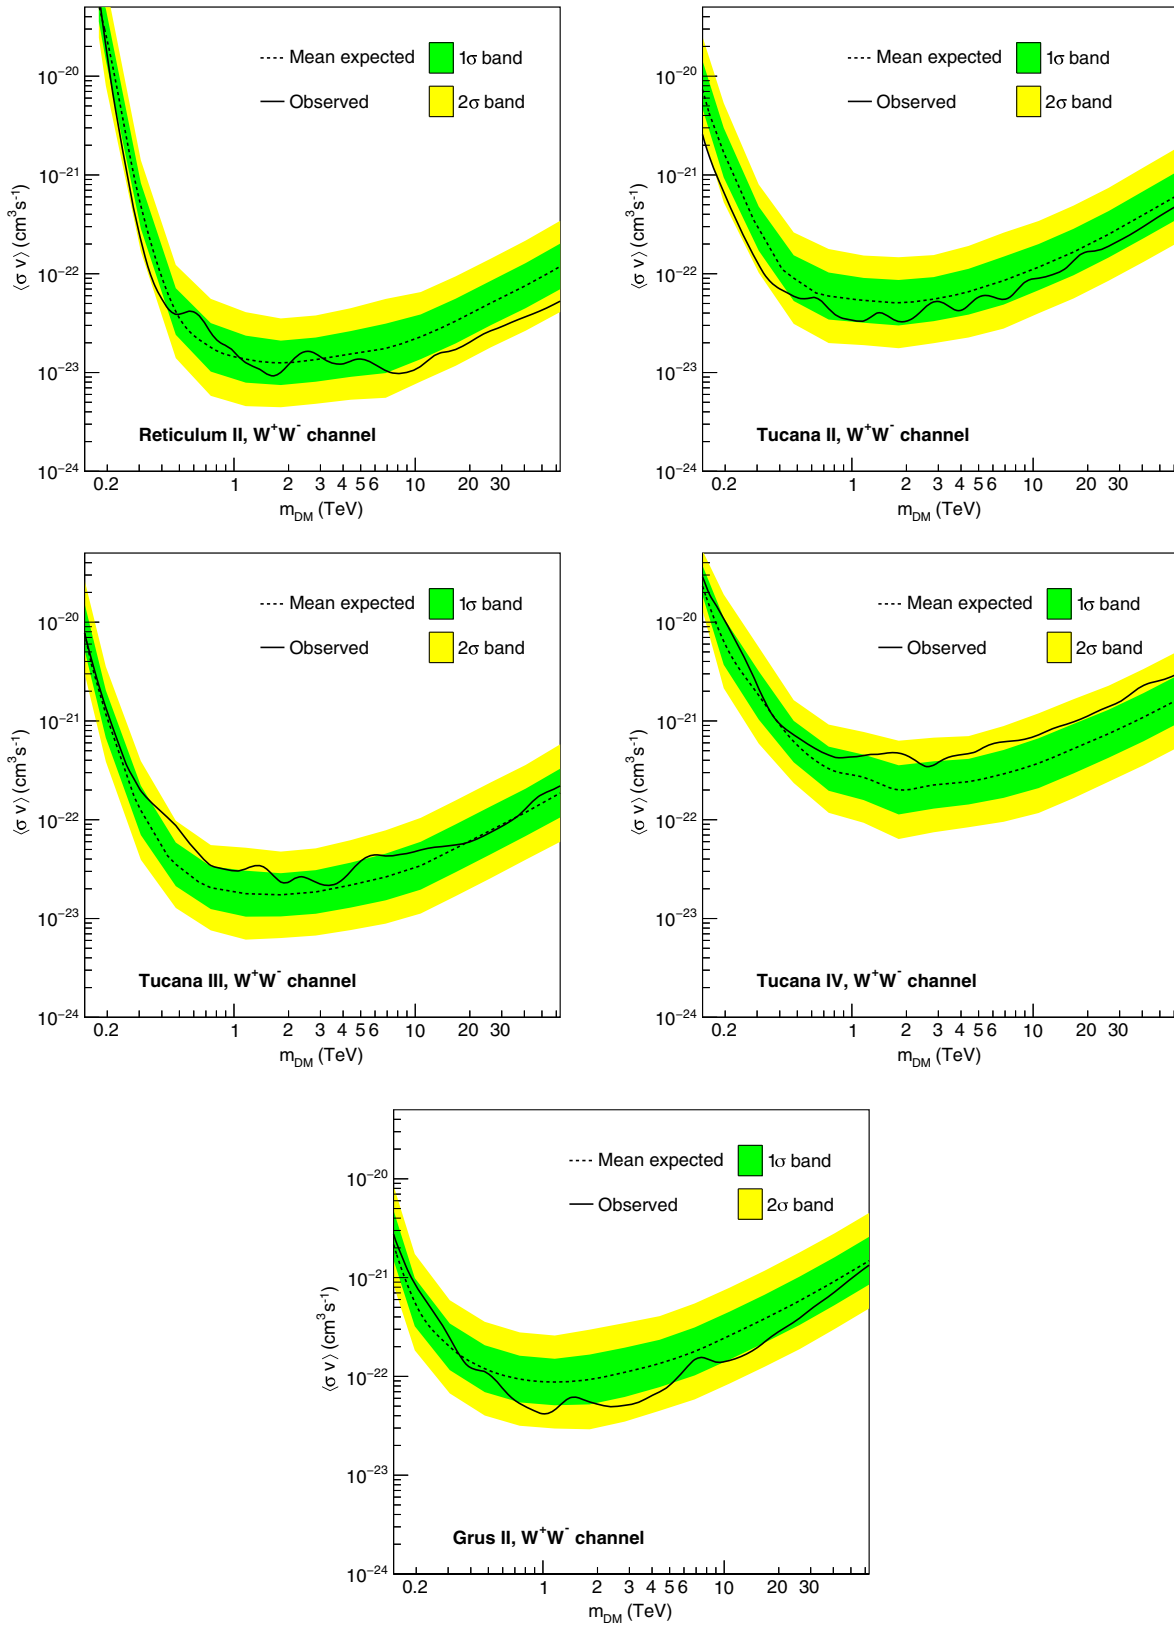

FIG. 2. 95% C.L. upper limits on the annihilation cross section $\langle\sigma v\rangle$ for Ret II, Tuc II, Tuc III, Tuc IV, and Gru II, in the W^+W^- annihilation channel without the uncertainty on the J -factor. Observed limits (solid lines) together with mean expected limits (dashed line) and the 1σ (green area) and 2σ (yellow area) containment bands are shown.

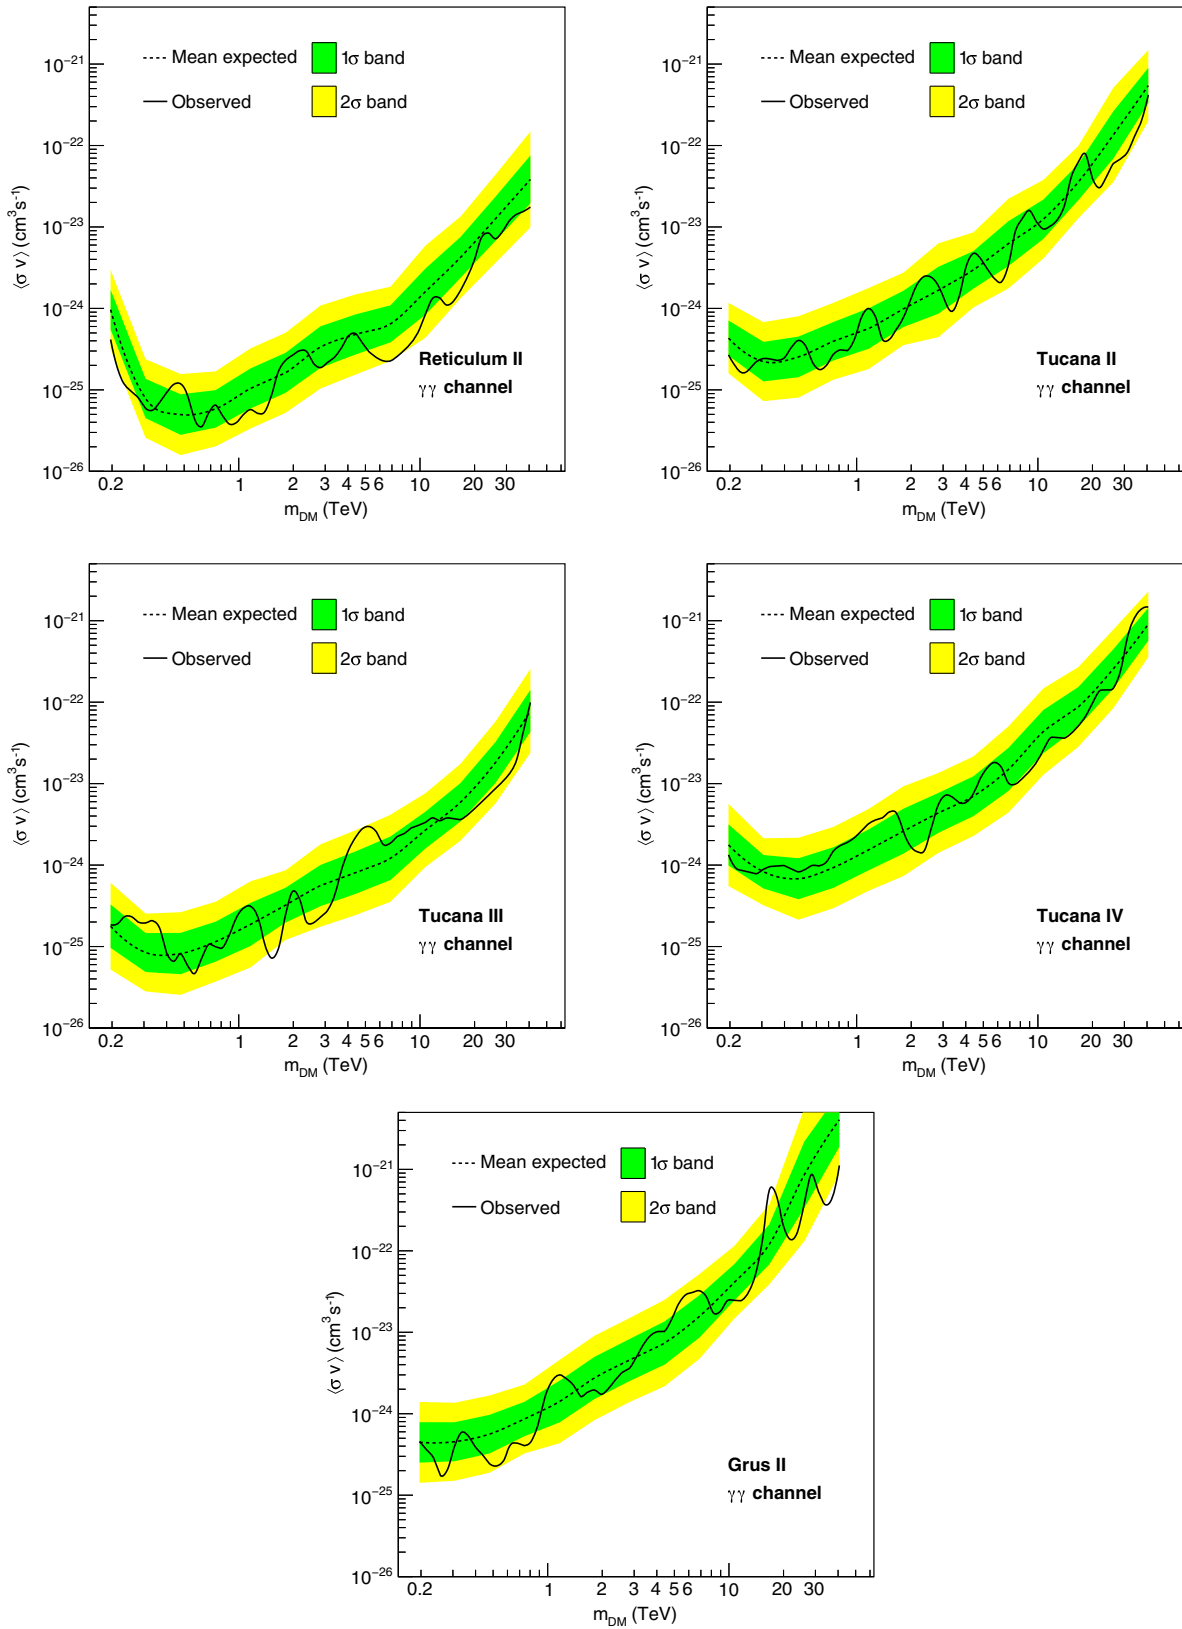

FIG. 3. 95% C.L. upper limits on the annihilation cross section $\langle\sigma v\rangle$ versus the DM mass m_{DM} for Ret II, Tuc II, Tuc III, Tuc IV, Gru II, in the $\gamma\gamma$ annihilation channel, without the uncertainty on the J -factor. Observed limits (solid lines) together with mean expected limits (dashed lines), and the 1σ (green area) and 2σ (yellow area) containment bands are shown.

FIG. 4. 95% C.L. upper limits on the annihilation cross section $\langle\sigma v\rangle$ for Ret II in the $b\bar{b}$, $t\bar{t}$, ZZ , e^+e^- , $\mu^+\mu^-$, $\tau^+\tau^-$ annihilation channels, respectively, without the uncertainty on the J -factor. Observed limits (solid lines) together with mean expected limits (dashed lines) and the 1σ (green area) and 2σ (yellow area) containment bands are shown. The limits for the other targets can be found in Figs. 9–12 in the Appendix.

FIG. 5. 95% C.L. upper limits on the annihilation cross section $\langle\sigma v\rangle$ for Ret II (left panel) and Tuc II (right panel) in the W^+W^- annihilation channel including the uncertainties on the J -factor. Observed limits (solid lines) together with mean expected limits (dashed lines) with 1σ (green area) and 2σ (yellow area) containment bands are shown.

FIG. 6. 95% C.L. observed upper limits on the annihilation cross section $\langle\sigma v\rangle$ versus the DM mass m_{DM} for the combined analysis in the W^+W^- (left panel) and $\gamma\gamma$ (right panel) annihilation channels, respectively, without the uncertainty on the J -factor.

B. Combined upper limits

The hypothesis that all targets are in fact gamma-ray emitters, but too faint to be seen with the given exposure, was tested and no overall significant excess was found. The combination was performed at the likelihood level, where the total likelihood function writes

$$\mathcal{L}_{\text{joint}} = \prod_{k=1}^{N_{\text{targets}}} \mathcal{L}_k, \quad (5)$$

where \mathcal{L}_k is the likelihood of each target k . A strict joint-likelihood maximization was not performed, but the

likelihoods were maximized beforehand. The combined observed limits at 95% C.L. on the W^+W^- and $\gamma\gamma$ channels are shown in the left and right panels of Fig. 6, respectively. For a 1.5 TeV DM mass, they reach $\langle\sigma v\rangle \simeq 1 \times 10^{-23} \text{ cm}^3 \text{ s}^{-1}$ and $4 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}$ in the W^+W^- and $\gamma\gamma$ annihilation channels, respectively. These results degrade of about a factor seven when the uncertainty on the J -factor is included.

The combination of the two confirmed dwarf galaxies, Ret II and Tuc II, is shown as well as the combination of all the five objects. In the former case the limits are driven by Ret II limits, while in the latter the impact of Tuc III is also significant. The combined 95% C.L. observed limits of the

FIG. 7. Combined 95% C.L. observed upper limits on the annihilation cross section $\langle\sigma v\rangle$ versus the DM mass m_{DM} for the combined analysis in the $b\bar{b}$, $t\bar{t}$, W^+W^- , ZZ , e^+e^- , $\mu^+\mu^-$, $\tau^+\tau^-$, and $\gamma\gamma$ annihilation channels, respectively, without the uncertainty on the J -factor.

five objects are plotted together in Fig. 7 for various annihilation channels.

Constraints on $\langle\sigma v\rangle$ from various experiments are compared in Fig. 8 for the W^+W^- (left) and $\gamma\gamma$ (right) annihilation channels, respectively. The results obtained by H.E.S.S. in this work combining the five selected DES dSphs, with and without including the uncertainty on the J -factor are shown together with previous H.E.S.S. results obtained on a selection of classical dSphs [38] including the uncertainty on the J -factor.¹ The results from MAGIC on Segue 1² with (dashed) and without (solid) the uncertainty on the J -factor are extracted from Ref. [40] and Ref. [41], respectively. Results obtained by VERITAS from a combination of five dSphs including Segue 1 [42], with and without uncertainty on the J -factor are plotted together with the stacked limits on 15 dSphs obtained by Fermi-LAT with the uncertainty on the J -factor [43]. The results obtained from the HAWC experiment on 15 targets [44] without the uncertainty on the J -factor as well as results that do not include Triangulum II³ with and without uncertainty on the

¹These results are quoted with and without Sagittarius dSph given that the determination of its dark matter profile is challenging for this tidally disrupted system. See, for instance, Ref. [4].

²The large J -factor value used for Segue 1 in the above mentioned results can be overestimated by a factor up to 100 [39].

³An accurate determination of the J -factor of Triangulum II is difficult due to the reduced number of detected member stars (13) and possible tidal stripping [45]. The total J -factor of Triangulum II used in Ref. [44] is $\log_{10}(J/\text{GeV}^2\text{cm}^{-5}) = 20.44$. Such a large value is quite speculative and may have been artificially obtained by the presence of a binary star with variable radial velocity [45]. The reduced number of member stars makes also the J -factor determination more prone to systematic uncertainties.

FIG. 8. Comparison of the observed limits versus the DM mass m_{DM} in the W^+W^- (left panel) and $\gamma\gamma$ (right panel) annihilation channels, respectively. Constraints are shown for HAWC (507 days of data taking, combination of 15 galaxies) with and without Triangulum II [44], for Fermi-LAT (6 years of data taking, combination of 15 galaxies for W^+W^- [43] and 5.8 years of data taken in the Galactic Center region [47]), for H.E.S.S. (140 h, combination of five classical galaxies) with and without 90 hours of observations on Sagittarius dSph [38,46], for MAGIC (160 h on Segue I) [40,41], and for VERITAS (128 h, combination of five galaxies) [42]. The results marked with * include the uncertainty on the J -factor. See text for more details.

J -factor are also shown. In the $\gamma\gamma$ annihilation channel, the previous H.E.S.S. results on a selection of classical dSphs are extracted from Ref. [46]. The results on Segue 1 from MAGIC [40] as well as those by VERITAS on five dSphs including Segue 1 [42], without uncertainty on the J -factor, are plotted. The Fermi-LAT limits on the Galactic Center [47] are also displayed. The constraints obtained in the $\gamma\gamma$ annihilation channel from H.E.S.S. are particularly relevant to constraint DM models with enhanced linelike signals in the TeV mass range.

VI. SUMMARY AND DISCUSSIONS

H.E.S.S. is the first IACT to observe a selection of ultrafaint dwarf satellites of the Milky Way recently discovered by DES to search for a DM annihilation signal with the highest sensitivity among IACTs towards these objects given its position in the Southern hemisphere. The exposure towards the five selected targets, Ret II, Tuc II, Tuc III, Tuc IV, and Gru II, amounts to about 80 hours of live time. In absence of a significant excess in any of the object FoV, 95% C.L. upper limits have been derived on the DM annihilation cross section as a function of the DM mass in various annihilation channels. The strongest limits from an individual object are obtained for Ret II. Assuming no uncertainty in the J -factor, they reach $\langle\sigma v\rangle \simeq 1 \times 10^{-23} \text{ cm}^3 \text{ s}^{-1}$ and $8 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}$ in the W^+W^- and $\gamma\gamma$ annihilation channels, respectively, for a 1.5 TeV DM mass. Assuming an uncertainty on the J -factor, the limits degrade by about a factor seven. Using a lower mean value for Ret II J -factor would degrade the limits accordingly. The limits from the combined analysis of the five targets are dominated by Ret II limits assuming the conservative J -factor value for Tuc II. In the W^+W^- annihilation channel they reach about the same values within the statistical fluctuations. They go slightly down to $\langle\sigma v\rangle \simeq 9 \times 10^{-24} \text{ cm}^3 \text{ s}^{-1}$ for a 1.5 TeV DM mass when considering only Ret II and Tuc II. The combined limits on the five targets in $\gamma\gamma$ reach $\langle\sigma v\rangle \simeq 4 \times 10^{-26} \text{ cm}^3 \text{ s}^{-1}$ for a 1.5 TeV DM. Including the J -factor uncertainty possibly degrades the combined limits up to a factor of about seven.

The uncertainty on the J -factor for ultrafaint systems is challenging to measure or predict. The limits derived in this work and similar studies are strongly dependent on the choice of the J -factor mean value and its uncertainty for a given system. Most often only the statistical uncertainty on the J -factor coming from the finite number of stellar tracers is considered. Only a few studies investigate the impact of the assumptions made to derive the J -factor value (see, for instance, Refs. [28,48]). Among the possible sources of systematic uncertainty in the J -factor determination [29]

are the assumptions of a single stellar population or spherical symmetry, a constant velocity anisotropy, and the absence of tidal stripping. The selection of member stars for ultrafaint systems is also complex due to the difficulty to distinguish member stars from interlopers in the foreground. Another caveat when comparing limits including the uncertainty on the J -factors from one experiment to another is the treatment of the J -factor uncertainty in the derivation of the limits. Here a log-normal distribution is taken for the J -factor likelihood function while some studies use a *modified* log-normal distribution [26,41]. In addition, the procedure to derive the maximized J -factor may differ from one study to another.

The new results obtained by H.E.S.S. are among the most constraining in the $\gamma\gamma$ annihilation channel above 500 GeV. They are comparable to VERITAS and HAWC limits in the W^+W^- annihilation channel in the multi-GeV and multi-TeV DM mass ranges, respectively. The constraints obtained in the $\gamma\gamma$ annihilation channel are particularly relevant in the context of DM models with enhanced line signals in the TeV DM mass ranges. Among them are models with gamma-ray boxes [49], scalar [50], and Dirac [51] DM models, as well as the canonical Majorana DM triplet fermion known as the *Wino* [52,53], and the DM doublet fermion known as the *Higgsino* [54–56].

The constraints obtained in this work are competitive with other experiments. While the likelihood function definition, the test statistics and the background determination technique may vary from one experiment to another, the results complement each other showing the importance of having instruments with different characteristics that observe a different selection of targets. The IACTs are powerful instruments to investigate the multi-TeV DM not accessible to Fermi-LAT. This is particularly true when it comes to search for TeV DM-induced spectral features close to the DM mass. In the $\gamma\gamma$ channel where the expected signal is very sharp the Fermi-LAT sensitivity range cannot extend beyond a few hundred GeV where its detected photon statistics are very low. The excellent energy resolution of H.E.S.S. is crucial to search for monoenergetic signals expected in the $\gamma\gamma$ annihilation channel. In addition, the H.E.S.S. instrument performance enable to cover the broadest DM mass range among the IACTs for linelike signal searches.

Future studies would greatly benefit from high-quality stellar kinematic datasets towards the most promising ultrafaint dSph satellites discovered by DES, such as Tuc III, Tuc IV, and Gru II in order to improve the knowledge of the DM density distribution in these objects.

ACKNOWLEDGMENTS

The support of the Namibian authorities and of the University of Namibia in facilitating the construction and operation of H.E.S.S. is gratefully acknowledged, as is the support by the German Ministry for Education and Research (BMBF), the Max Planck Society, the German Research Foundation (DFG), the Helmholtz Association, the Alexander von Humboldt Foundation, the French Ministry of Higher Education, Research and Innovation, the Centre National de la Recherche Scientifique (CNRS/IN2P3 and CNRS/INSU), the Commissariat à l'énergie atomique et aux énergies alternatives (CEA), the U.K. Science and Technology Facilities Council (STFC), the Knut and Alice Wallenberg Foundation, the National Science Centre, Poland Grant No. 2016/22/M/ST9/
