At the end of the Hawking evaporation the horizon of a black hole enters a physical region where quantum gravity cannot be neglected. The physics of this region has not been much explored. We characterize its physics and introduce a technique to study it.

DOI: [10.1103/PhysRevD.103.106014](https://doi.org/10.1103/PhysRevD.103.106014)

I. INTRODUCTION

In a spacetime formed by gravitationally collapsed matter, there are three distinct regions in which curvature becomes Planckian. We expect the approximation defined by quantum field theory interacting with classical general relativity to break down in all three of them. The physics of these regions is quite different.

The three regions are illustrated in the Carter-Penrose causal diagram of Fig. 1. The dark grey area is the region where quantum gravity cannot be neglected and the diagram itself becomes unreliable. The light grey area is the collapsing matter and the dashed line is the (trapping) horizon (the event horizon is not determined by classical physics). The three physically distinct regions where curvature becomes Planckian are

1. Region **C**, in the future of the event **c** in the diagram, which is directly affected by the collapsing matter reaching Planckian density.
2. Region **B**, in the future of the event **b** in the diagram, which is affected by the horizon reaching Planckian size because of Hawking's evaporation.
3. Region **A**, in the future of any location like **a** (that is a generic event in the dark grey area distant from the events **b** and **c**) in the diagram, where the curvature becomes Planckian but the classical evolution to the singularity is not causally connected to the collapsing matter or to the horizon.

The physical distance between these regions depends on the age of the black hole at the time when its horizon reaches the quantum region. This age depends in turn on the overall mass of the black hole *before* being shrunk by Hawking evaporation.

To give a rough estimate of these distances we consider for simplicity the interior of a Schwarzschild black hole. (Most of the evaporation takes place at late times.) The line element is

$$ds^2 = -\left(1 - \frac{2Gm}{r}\right)dt^2 + \left(1 - \frac{2Gm}{r}\right)^{-1}dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) \quad (1)$$

We can take the three locations **a**, **b** and **c** to be at the same fixed values of θ , ϕ , r and at three different values t_a , t_b , t_c of the t coordinate. The proper distance dl along a line of constant θ , ϕ , r , namely a nearly horizontal line in the causal diagram, is given by the line element

$$dl = dt\sqrt{\frac{2Gm}{r} - 1}. \quad (2)$$

The quantity dl becomes large approaching the quantum gravitational dark grey region of Fig. 1. Curvature scalars behave as $\sim m/r^3$ and hence become Planckian at $r/L_{\text{Pl}} \sim (m/M_{\text{Pl}})^{1/3}$ where L_{Pl} and M_{Pl} are the Planck length and the Planck mass, giving

$$dl \sim \sqrt{2}(m/M_{\text{Pl}})^{1/3}dt \quad (3)$$

near the quantum gravitational dark grey region of Fig. 1. For a stellar mass ($m \sim M_{\odot} \sim 10^{38}M_{\text{Pl}}$) black hole, if no further mass enters the horizon, the end of the Hawking evaporation is at $t_b - t_c \sim (M_{\odot}/M_{\text{Pl}})^3L_{\text{Pl}}$, hence the distance between **b** and **c** is

FIG. 1. The three regions of a black hole spacetime where quantum gravity becomes relevant. In the dark grey region quantum gravity cannot be neglected and the diagram itself becomes unreliable. The future of the locations **a**, **b** and **c** encounter different quantum gravity phenomena depending, respectively, on the presence of the collapsing matter (**C**), the horizon (**B**), or neither (**A**).

$$L \sim L_{\text{Pl}} \left(\frac{M_{\odot}}{M_{\text{Pl}}} \right)^{\frac{10}{3}} \sim 10^{75} \text{ light years}, \quad (4)$$

which is huge. That is: the locations **b** and **c** are extremely distant from each other [1–4]. This is a rough estimate, but the conclusion is general: the distance between **b** and **c**, which is to say the “depth” of the black hole, is huge, for an old black hole. Notice that what makes this distance large is not the smallness of the r coordinate considered (which is not Planckian): rather, it is the long lifetime of the black hole that builds up the length.

It is worthwhile pausing to ponder this fact: near the end of the Hawking evaporation of an isolated stellar-size black hole, the collapsing matter entering the quantum region is at a—*spatial, not temporal*— distance of 10^{75} light years from the horizon. Locality demands the physics of spatially widely separated phenomena to be independent. It is reasonable to expect quantum gravity to affect the causal structure of spacetime, but in small fluctuations, not by suddenly causally connecting events that are extremely far apart.

It follows that the physics of each of the three regions **A**, **B** and **C** can be studied independently from the others (until something brings them in causal contact). More precisely, the physics of the **A** region can be studied

independently from what happens at **B** or **C**; while these depend on the physics of the **A** region, since this bounds the horizon and the collapsing matter.

Since the physics of the **A** region neither depends on the collapsing star nor on the shrinking horizon, it can be studied in the context of an eternal black hole. This setting gets rid of the collapsing matter, and allows us to neglect the Hawking radiation, whose backreaction shrinks the area of the horizon until it enters the quantum region. There is an extensive recent literature on the possible scenarios for the physics of the **A** region. A much studied possibility is that spacetime continues on the future of the would-be singularity, namely on the future of the dark grey region of Fig. 1, into an antitrapped region, namely a region with the metric of a white hole [5–15].

Here we take this possibility as an assumption. This seems by far the most plausible scenario, the one which is more coherent with the physics that we know. In fact, the entire effect of quantum gravity is a slight violation of the Einstein equations in the high curvature region, which prevents curvature to diverge and allows spacetime to continue. This possibility was noticed long ago, already in the 1950s, by Synge [16].

Following in particular [17–20], we assume here that the anti-trapped region is bounded by a future horizon that connects it to the region external to the black hole, a surprising possibility first noticed in [17]. The full spacetime has therefore the causal structure depicted in the Carter-Penrose diagram in Fig. 2.

The **C** region is where the collapsing matter itself reaches the quantum gravity regime. It is called the “Planck star” phase of the collapsing matter [21]. Here, following [21], we simply assume that some form of matter bounce compatible with this scenario happens.

In this paper we focus on the physics of the **B** region, namely on the events near the end of the Hawking evaporation of the black hole. This is the region where the trapping horizon tunnels into an antitrapping horizon. Covariant loop quantum gravity (LQG) [22] can be utilized to study the region around the classical singularity using the spinfoam formalism [23]. The transition amplitude for the entire quantum region (the whole dark grey region in Fig. 1) was first roughly estimated using LQG in [24,25]. Here we use a similar technique to begin a more refined study of the **B** region only.

In particular, in Sec. II we compute the classical intrinsic and extrinsic geometry of a boundary of the **B** region in terms of a small number of parameters characterizing the spacetime and the transition. The quantum transition amplitude that describes the **B** region is going to be a function of these parameters. Furthermore, in view of the spinfoam transition amplitude calculations, in Sec. III we introduce and study a triangulation of the boundary of **B** and its discrete geometry. In a forthcoming companion paper we introduce a full discretization of the **B** region compatible with the triangulation of its boundary

FIG. 2. Carter-Penrose causal diagram of the black to white transition.

introduced in Sec. III and we use it to explicitly write the transition amplitude for the phenomenon in terms of LQG (spinfoam) techniques.

The main result of this paper is the identification of the four parameters which characterize the quantum transition at the **B** region and the definition of the corresponding transition amplitude as a function of these parameters. The actual computation of this amplitude will be addressed in the forthcoming companion paper.

II. THE BOUNDARY OF THE B REGION

To study the **B** region, we restrict for simplicity to the spherically symmetric case and we assume the rest of spacetime to be classical. For the most part, this is a good approximation, since the curvature is below Planckian values and quantum effects are likely to be negligible. This is however not true for the boundary between the **B** and the **A** region. We therefore simplify the problem by describing the **A** region with an effective classical metric, as in [19].

An effective metric for the entire spacetime that takes into account the effect of Hawking radiation was studied in

[26]. Here we further simplify this scenario by disregarding the presence of Hawking radiation in the last phases of the evaporation, hence around the **B** region, in spite of the radiation being strong in this region. We do not know how good this approximation is. We assume that the black hole has already evaporated to a small size and we take the metric around the **B** region to be well approximated by a Schwarzschild metric, up to quantum corrections in the **A** region.

The effective geometry of the **A** region continuing from the trapped to the antitrapped region can be described by the line element [19]

$$ds_l^2 = -\frac{4(\tau^2 + l)^2}{2m - \tau^2} d\tau^2 + \frac{2m - \tau^2}{\tau^2 + l} dx^2 + (\tau^2 + l)^2 d\Omega^2, \quad (5)$$

where $d\Omega^2$ is the metric of the 2-sphere, $l \ll m$ is an intrinsic parameter of the effective metric and $-\sqrt{2m} < \tau < \sqrt{2m}$. This line element defines a genuine pseudo-Riemannian space, with no divergences and no singularities $\forall l \neq 0$.

In the limit $l \rightarrow 0$, the metric locally converges to the interior Schwarzschild metric for a black hole in $-\sqrt{2m} < \tau < 0$ and to the interior Schwarzschild metric for a white hole in $0 < \tau < \sqrt{2m}$. This can be easily seen by performing the following change of coordinates:

$$r = \tau^2 \quad \text{and} \quad t = x, \quad (6)$$

where r and t are the usual Schwarzschild coordinates. In this limit, $\tau = 0$ becomes the singularity separating the trapped from the antitrapped region. For $l \neq 0$ the curvature remains instead bounded.

Up to terms of order $\mathcal{O}(l/m)$, the curvature scalar $K^2 \sim R_{\mu\nu\rho\sigma} R^{\mu\nu\rho\sigma}$, which is plotted in Fig. 3, is

$$K^2(\tau) = \frac{9l^2 - 24l\tau^2 + 48\tau^4}{(l + \tau^2)^8} m^2. \quad (7)$$

It has *finite* maximum value

FIG. 3. The bounded curvature scalar (7).

$$K^2(0) = \frac{9m^2}{l^6}. \quad (8)$$

The Ricci tensor vanishes up to terms of order $\mathcal{O}(l/m)$.

The spacelike surfaces $\tau = \text{constant}$ can be used to foliate the interior of both the black and the white hole. Each of these surfaces has the topology $S^2 \times \mathbb{R}$. Suppressing one angular coordinate, they can be depicted as long cylinders of different radii and heights. In the interior black hole region ($-\sqrt{2m} < \tau < 0$), as τ increases, the radial size of the cylinder shrinks while the axis of the cylinder gets stretched. At $\tau = 0$ the cylinder reaches a minimal width and maximal length, and then smoothly bounces back and starts increasing its radial size and shrinking its length as τ increases in the interior white hole region ($0 < \tau < \sqrt{2m}$). The cylinder inside the hole never reaches arbitrary small sizes (the singularity), but it rather bounces at a small finite radius l .

The value of l can be roughly fixed by the requirement that $K(0) \sim 1$ (in Planck units), which gives $l \sim m^{1/3}$. This means that the bounce happens at a larger scale than the Planck one. The limit $l \rightarrow 0$ is simply the joining of a Schwarzschild black hole interior and a Schwarzschild white hole interior through the singularity. This is not a Riemann space—it is analogous to a double cone: a space with a singular region of measure zero—but it is a rather well behaved metric manifold, where geodesics can be defined and studied [19].

The presence of a minimum finite radius l in the **A** region has far-reaching consequences for the physics of the **B** region.

A. Choice of the boundary

The idea to define a boundary for the **B** region is to first surround it in the causal diagram with a diamond shaped null surface Σ (see Fig. 2), that is a diamond null surface times a sphere in spacetime, and then, since an appropriate boundary for computing transition amplitudes must be spacelike, to slightly deform Σ into a spacelike surface. This surface is the Heisenberg cut we choose, namely the surface we shall take as the boundary between the quantum and the classical regions. Notice that in quantum gravity, the Heisenberg cut is also a spacetime boundary (see [27], Sec. 5.6.4).

We want now to concretely specify Σ and compute its intrinsic and extrinsic geometry. Since it has been assumed that the dissipative irreversible physics of the Hawking radiation is over at this point, the **B** region must be time-reversal invariant. The surface Σ can consequently be seen as the union of two surfaces, a *past* one Σ^p and a *future* one Σ^f , equal up to time reflection, $\Sigma = \Sigma^p \cup \Sigma^f$. Here, the labels p and f stand for past and future, and later on we shall also use the index $t = \{p, f\}$ (hence Σ^t) where t stand for *time*. Accordingly, we only need to study the past

boundary Σ^p , as the future boundary Σ^f is determined by symmetry.

The metric around the **B** region is assumed to be well approximated by the Schwarzschild metric up to quantum corrections in the **A** region. The past boundary is then contained in the external and in the black hole regions of a Kruskal diagram representing Schwarzschild spacetime. Since both regions are covered by the ingoing Eddington-Finkelstein coordinates, we can use these coordinates to define Σ^p . The line element in these coordinates reads

$$ds^2 = -\left(1 - \frac{2m}{r}\right)dv^2 + 2drdv + r^2d\Omega^2. \quad (9)$$

The Schwarzschild time coordinate t is related to the ingoing Eddington-Finkelstein coordinates by

$$t = v - r^* = v - r - 2m \ln \left| \frac{r}{2m} - 1 \right|, \quad (10)$$

or

$$dt = dv - \frac{dr}{\left(1 - \frac{2m}{r}\right)}. \quad (11)$$

The null past diamond boundary can be defined in the Kruskal diagram as follows. Let S_{out} be a point (a two-sphere in spacetime) outside the horizon at advanced time v_+ and Schwarzschild time $t = 0$. Let S_{in} be a point inside the horizon at advanced time $v_- < v_+$ and Schwarzschild radius $r_- = l$. The null past diamond boundary is taken to be the union of the outgoing past light cone of S_{out} and of the ingoing past light cone of S_{in} from their intersection upward; see Fig. 4.

Note that the presence of a minimum finite radius l in the **A** region fixes the value r_- of the Schwarzschild radius of the point S_{in} . Furthermore, being the Schwarzschild radius r a temporal coordinate inside the black hole, while the radius r_+ of S_{out} is a measure of the spatial coordinate distance of S_{out} from the horizon, the radius $r_- = l$ must not be interpreted as a measure of the spatial coordinate

FIG. 4. The past portion of the boundary surface.

distance of S_{in} from the horizon but as the minimal internal radius reached by the black hole in region **A**.

To simplify the notation, in the following we replace the labels *out* and *in* with the index $\pm = \{+, -\} \equiv \{\text{out}, \text{in}\}$, e.g., $S_+ \equiv S_{\text{out}}$ and $S_- \equiv S_{\text{in}}$.

Next, we define the spacelike past boundary Σ^p by slightly deforming the null past diamond boundary while keeping fixed S_+ and S_- . A convenient choice of deformation is the following one. Consider the surface Σ_-^p of constant Lemaître time coordinate [28,29]

$$t_L = t + 2\sqrt{2mr} + 2m \ln \left| \frac{\sqrt{r/2m} - 1}{\sqrt{r/2m} + 1} \right|, \quad (12)$$

passing by S_- and the surface Σ_+^p defined by

$$v - \beta r = \text{const}, \quad (13)$$

passing by S_+ , for some constant $\beta \in \mathbb{R}$. Let S^p be their intersection; see Fig. 4. We choose the spacelike past boundary Σ^p to be the union of the portion of Σ_-^p between S^p and S_- and the portion of Σ_+^p between S^p and S_+ . The parameter β can be fixed by requiring the continuity of the normal to Σ^p at S^p .

The spacelike future boundary surface Σ^f is defined to be the time-reversal of the surface Σ^p and the full spacelike boundary surface Σ is then partitioned in the four components Σ_+^p , Σ_-^p , Σ_+^f and Σ_-^f ; see Fig. 5. The Carter-Penrose diagram of the **B** region consists of two separate portions of the Kruskal diagram which are appropriately joined. This is the ‘‘cutting and pasting’’ used in [17] in order to write for the first time a metric for the black-to-white transition.

We now need to determine the intrinsic and the extrinsic geometry of Σ .

FIG. 5. Carter-Penrose diagram of the **B** region with the surface Σ and its components highlighted.

B. Intrinsic geometry

The intrinsic geometry of Σ_+^p is obtained by differentiating its defining equation [Eq. (13)],

$$dv = \beta dr, \quad (14)$$

and inserting the result in the line element in Eq. (9). This gives

$$ds_+^2 = \beta \left(2 - \beta \left(1 - \frac{2m}{r} \right) \right) dr^2 + r^2 d\Omega^2. \quad (15)$$

To find the intrinsic geometry of Σ_-^p , we rewrite the explicit expression of the Lemaître time coordinate in equation (12) in terms of the (v, r) coordinates. Then we differentiate it, finding that on a constant t_l surface the following relation is satisfied:

$$dv = \frac{dr}{1 + \sqrt{2m/r}}. \quad (16)$$

Using this relation in the line element in Eq. (9), we obtain that the line element resulting from the intrinsic metric of the Σ_-^p surface is

$$ds_-^2 = dr^2 + r^2 d\Omega^2. \quad (17)$$

That is, Σ_-^p is intrinsically flat.

C. Extrinsic geometry

Next, we want to determine the extrinsic geometry of Σ .

Since the two surfaces Σ_+^p and Σ_-^p are both defined by constraint equations of the form $C = 0$, it is easy to compute their normal 1-forms using

$$n_\mu = - \frac{\partial_\mu C}{|\partial^\nu C \partial_\nu C|^{1/2}}. \quad (18)$$

In Schwarzschild coordinates, the normals to the surfaces Σ_-^p and Σ_+^p are then given by

$$n_\mu^- = \left(-1, -\frac{\sqrt{2mr}}{r-2m}, 0, 0 \right), \quad (19)$$

$$n_\mu^+ = \frac{(-1, \beta - (1 - \frac{2m}{r})^{-1}, 0, 0)}{|\beta(\beta - 2 - \frac{2m\beta}{r})|^{1/2}}. \quad (20)$$

Demanding that the normals match on S^p , uniquely fixes the value of β :

$$\beta = \frac{1}{1 + \sqrt{\frac{2m}{r_{sp}}}}. \quad (21)$$

To deal with the extrinsic curvature of the surfaces Σ_{\pm}^p it is easier to express them as systems of parametric equations $x_{\pm}^{\mu} = x_{\pm}^{\mu}(y_{\pm}^a)$, where y_{\pm}^a are some parameters which serves as intrinsic coordinates to the surfaces. Given a generic surface defined by the system of parametric equations $x^{\mu} = x^{\mu}(y^a)$ for some y^a , the tangent 1-form to the surface e_a^{μ} is given by

$$e_a^{\mu} = \frac{\partial x^{\mu}}{\partial y^a} \quad (22)$$

and the extrinsic curvature tensor k_{ab} of the surface reads

$$k_{ab} = e_a^{\mu} e_b^{\nu} \nabla_{\mu} n_{\nu}. \quad (23)$$

Let k_{ab}^{\pm} be the extrinsic curvature of Σ_{\pm}^p . Then, a straightforward calculation gives

$$k^{-} \equiv k_{ab}^{-} dx^a dx^b = \sqrt{\frac{m}{2r^3}} dr^2 - \sqrt{2mr} d\Omega^2 \quad (24)$$

and

$$k^{+} \equiv k_{ab}^{+} dx^a dx^b = \frac{m\beta^{3/2}(r(3-\beta) + 2m\beta)}{\sqrt{r^5(r(2-\beta) + 2m\beta)}} dr^2 - \frac{r(1-\beta) + 2m\beta}{\sqrt{\beta(2 - (1-2m/r)\beta)}} d\Omega^2. \quad (25)$$

This completes the computation of the geometry of the boundary of **B**. This geometry is entirely determined by four parameters: the mass m , the Schwarzschild radii r_{\pm} of the spheres S_{\pm} , which by construction satisfy

$$r_- < 2m < r_+, \quad (26)$$

and the retarded time $v = v_+ - v_-$. The physical interpretation of these four parameters is transparent. The mass m is the mass of the black hole when the black-to-white transition happens; the retarded time v is the external (asymptotic) time it takes for the transition to happen; the radius r_+ is the minimal external radius where we assume the classical approximation to hold; the radius r_- is the minimal internal radius reached by the black hole interior in region **A**. When m and r_{\pm} are fixed, the value of v can be equivalently determined by fixing β or r_{sp} . These are the only parameters describing the quantum transition.

Quantum gravity should determine a transition amplitude W for the process as a function of these four parameters

$$W = W(m, r_{\pm}, v). \quad (27)$$

In Planck units, the four parameters can be seen as dimensionless. We expect the specific details of the chosen Σ not to matter, as they can be absorbed in a shift of the Heisenberg cut (as long as it does not enter the quantum region).

The task of the forthcoming companion paper is to write an explicit expression for the function $W(m, r_{\pm}, v)$ using the covariant LQG transition amplitudes. These are given in an expansion in number of degrees of freedom. At finite order, the amplitudes are defined for specific discretizations of the geometry. Below we define a first order discretization of Σ in the form of a triangulation. As we shall see in the companion paper, this triangulation can in fact be seen as the boundary of a cellular decomposition of the **B** region.

III. THE TRIANGULATION OF Σ

The topology of the **B** region is $S^2 \times [0, 1] \times [0, 1]$ and the topology of its boundary $\partial B = \Sigma = \Sigma^p \cup \Sigma^f$ is $S^2 \times S^1$.

We can identify two symmetries of the geometry of Σ and one symmetry of its topology:

- (i) The Z_2 time reversal symmetry that exchanges p and f .
- (ii) The $SO(3)$ symmetry inherited by the spherical symmetry of the overall geometry.
- (iii) A Z_2 symmetry that exchanges the internal (minimal radius) sphere S_- and the external (maximal radius) sphere S_+ . This is a symmetry of the topology, but not of the geometry, since S_- and S_+ have different size.

To find a triangulation of Σ we discretize the two spheres S_- and S_+ into regular tetrahedra. This replaces the continuous $SO(3)$ symmetry with the discrete symmetries of a tetrahedron. In particular, we discretize each of the two spheres S_{\pm} in terms of a tetrahedron t_{\pm} . We label the four vertices of each tetrahedron as $v_{\pm a}$ where $a = 1, 2, 3, 4$; and the triangles bounding the tetrahedra as $\ell_{\pm a}$, where the triangle $\ell_{\pm a}$ is opposite to the vertex $v_{\pm a}$.

Thanks to the Z_2 time reversal symmetry, the triangulations describing Σ^p and Σ^f must be topologically equivalent. For this reason, the same construction can be applied to both. A convenient triangulation for Σ^f , illustrated in Figures 6 and 7, is the following one. The placement of the smaller tetrahedron t_- inside the bigger tetrahedron t_+ ,

FIG. 6. The triangulation of Σ^f . The brown tetrahedron t_- is inscribed into the larger violet tetrahedron t_+ . The blue segments connect vertices of the two tetrahedra radially.

FIG. 7. All images represent the triangulation of Σ^f , but with different tetrahedra highlighted. In (a) no tetrahedron is highlighted (the tetrahedron t_- is in brown to remind that it is hollowed inside); in (b) the four T_{-a}^f are highlighted; in (c) three T_{+a}^f out of four are highlighted; in (d) three T_{ab}^f out of six are highlighted; in (e) the remaining three T_{ab}^f are highlighted; in (f) two T_{-a}^f , two T_{+b}^f and two T_{cd}^f are highlighted.

which can be chosen arbitrarily, is taken to be as in Figs. 6 and 7(a), such that the vertex v_{-a} lies on the segment linking the centroid of the tetrahedron t_+ (which coincides with the centroid of the tetrahedron t_-) and the centroid of the face ℓ_{+a} . Then, each vertex v_{+a} of t_+ is linked to the three vertices of the triangle ℓ_{-a} [Figs. 6 and 7(a)], creating 14 tetrahedra in total.

We call T_{+a}^f (violet in Figure 7(b)) the tetrahedron having ℓ_{+a} as one of its faces and T_{-a}^f [brown in Fig. 7(c)] the tetrahedron having ℓ_{-a} as one of its faces. Each of the six remaining tetrahedra [blue in Figs. 7(d) and 7(e)] is bounded by two of the T_{+a}^f tetrahedra and two of the T_{-a}^f tetrahedra. Noting that the labels given to the T_{+a}^f and T_{-a}^f tetrahedra are such that each of the six remaining tetrahedra is bounded by a set of tetrahedra $T_{+b}^f, T_{+c}^f, T_{-d}^f$ and T_{-e}^f , with $b \neq c \neq d \neq e$, we can then label the six remaining tetrahedra as $T_{bc}^f \equiv T_{cb}^f$, where the labels b and c refer to T_{+b}^f and T_{+c}^f . Clearly, from T_{bc}^f one can readily trace back the other two tetrahedra T_{-d}^f and T_{-e}^f .

The full triangulation of Σ is constructed identifying each $\ell_{\pm a}$ face of Σ^p with the $\ell_{\pm a}$ face of Σ^f . This completely defines the triangulation of Σ .

The complication of the triangulation chosen is due to the nontrivial topology of Σ and from the computational opportunity of choosing a triangulation that respects the symmetries of the problem.

A. The dual of the triangulation

In covariant LQG one works with the dual of a cellular decomposition of a spacetime region. More precisely, the spinfoam that captures the discretized degrees of freedom of the geometry is supported by the 2-skeleton of the dual of the cellular decomposition. The boundary of the spinfoam is the boundary spin-network, which is dual to the

FIG. 8. Two-dimensional graph Γ_Σ of the spin-network of Σ . The circles are nodes (dual to tetrahedra) and the segments are links (dual to the triangles).

boundary triangulation. The graph Γ_Σ of the spin-network is the two-skeleton of the dual of the boundary triangulation.

The spin-network graph Γ_Σ for the triangulation we have constructed, is illustrated in Fig. 8. Each circle is a node of the spin-network, and represents a tetrahedron, and each link joining two nodes represent a triangle separating two tetrahedra. (Intersections of links in this two-dimensional graph representation have no meaning.)

Since the information carried by the graph of a spin-network is only in its topology, as long as the latter remains unchanged, the graph can be deformed at will. Although the graphical representation of the dual graph Γ_Σ in Fig. 8 is completely fine to represent the topological information of the spin-network, it is not the best choice to manifestly represent all of its symmetries. A more symmetrical representation is the one in Fig. 9.

Although the graph Γ_Σ is quite complicated, thanks to the symmetries of the problem it has only two kinds of nodes that are topologically distinct: the $T_{\pm a}^f$ nodes and the T_{ab}^f nodes. The symmetries act by permuting the a indices and

FIG. 9. The left figure portrays a two-dimensional representation of the dual of the triangulation of Σ^f and the right figure portrays a three-dimensional representation of the dual Γ_Σ of the full triangulation of Σ , with labels omitted; one can easily label the right figure reading the different labels from the left figure and using $t = p$ for the bottom and $t = f$ for the top.

exchanging p with f or $+$ with $-$. Geometrically, the T_{+a}^t nodes differ from the T_{-a}^t ones, as the last symmetry is not geometrical. For the same reasons, there are only four kind of links up to geometrical symmetries (two kind up to topological symmetries). These correspond to:

- (i) the 4 links ℓ_{+a} dual to triangles forming the discretized sphere S_+ ;
- (ii) the 4 links ℓ_{-a} dual to triangles forming the discretized sphere S_- ; together with the ℓ_{+a} links they connect Σ^p with Σ^f (they are the vertical links in the second panel of Fig. 9);
- (iii) the 24 links $\ell_{(+a)(bc)}^t$ (12 for each t), with $b = a$, $c \neq a$, dual to the internal triangles separating the boundary tetrahedra T_{+a}^t (violet) from the internal tetrahedra T_{bc}^t (blue);
- (iv) the 24 links $\ell_{(-a)(bc)}^t$ (12 for each t), with $a \neq b \neq c$, dual to the internal triangles separating the boundary tetrahedra T_{-a}^t (brown) from the internal tetrahedra T_{bc}^t (blue).

The geometrical data that characterize the discretized geometry (and define coherent spin-network states) are the areas of the triangles and the angles between tetrahedra at these triangles. Hence, the relevant boundary data for the calculation are:

- (i) the 2 areas a_{\pm} of the internal and the external sphere S_{\pm} , which determine the areas associated to the links $\ell_{\pm a}$;
- (ii) the 2 areas A_{\pm} of the triangles dual to the $\ell_{(\pm a)(bc)}^t$ links;
- (iii) the 2 (thin) angles k_{\pm} between Σ_{\pm}^p and Σ_{\pm}^f at the internal and external sphere, which determine directly the angles associated to the links $\ell_{\pm a}$;
- (iv) the two (thick) angles K_{\pm} that depend on the extrinsic curvature of Σ_{\pm} and that are associated to the triangles dual to the $\ell_{(\pm a)(bc)}^t$ links; the angles in Σ^p have the opposite sign of the angles in Σ^f .

The extrinsic coherent state $\psi_{a_{\pm}, k_{\pm}, A_{\pm}, K_{\pm}}$ on the graph Γ_{Σ} defined by the geometrical data $(a_{\pm}, k_{\pm}, A_{\pm}, K_{\pm})$ represents the incoming and outgoing quantum states that correspond to the external classical geometry [22]. The LQG transition amplitude between coherent states will be a function of eight real numbers, with rather clear geometrical interpretation:

$$W(a_{\pm}, k_{\pm}, A_{\pm}, K_{\pm}) = W(\psi_{a_{\pm}, k_{\pm}, A_{\pm}, K_{\pm}}), \quad (28)$$

where $W(\psi)$ for an arbitrary state ψ in the boundary quantum state is defined in [22].

In turn, these eight numbers $c_n = (a_{\pm}, k_{\pm}, A_{\pm}, K_{\pm})$ depend on the geometry of Σ described in the previous section. Hence, they depend on the four parameters m , r_{\pm} , and v defined above. This defines the amplitude for the black-to-white hole transition as a function of these parameters:

$$W(m, r_{\pm}, v) = W(c_n(m, r_{\pm}, v)). \quad (29)$$

Our last task is to compute the functions $c_n(m, r_{\pm}, v)$.

B. Discrete geometrical data

There is no unique or right way to assign discrete geometrical data to the graph Γ_{Σ} starting from the continuous geometry of Σ . Each choice defines a different approximation of the continuous geometry and it has its own strengths and its own weaknesses. In this section we will introduce a convenient set of discrete geometrical data approximating the continuous geometry of Σ . We will discuss the discrete geometry of the triangulation approximating Σ^p . The discrete geometry of the triangulation approximating Σ^f is simply related to the first one by a time reversal transformation.

The area of the spheres S_{\pm} is directly determined by the radii r_{\pm} . Since the four triangles $\ell_{\pm a}$ bounding the tetrahedra t_{\pm} that discretize the spheres S_{\pm} are equal by symmetry, we take their area a_{\pm} to be one fourth of the area of the spheres, that is

$$a_{\pm} = \pi r_{\pm}^2. \quad (30)$$

The side length b_{\pm} of the tetrahedron t_{\pm} is then trivially given by

$$b_{\pm} = \sqrt{\frac{4\pi}{\sqrt{3}}} r_{\pm}. \quad (31)$$

The line element ds^2 on Σ^p can be written as

$$ds^2 = f^2(r)dr^2 + r^2d\Omega^2, \quad (32)$$

where

$$f^2(r) = \beta \left(2 - \beta \left(1 - \frac{2m}{r} \right) \right)$$

on Σ_{+}^p [see Eq. (15)] and $f^2(r) = 1$ on Σ_{-}^p [see Eq. (17)]. We approximate this line element as

$$ds^2 = \alpha^2 dr^2 + r^2 d\Omega^2, \quad (33)$$

where α is a constant that needs to be determined. In order to do so, let V_{Σ^p} and V_{Σ^f} be the volume of the surface Σ^p whose intrinsic geometry is given respectively by Eq. (32) and (33). The volume V_{Σ^p} is given by

$$\begin{aligned}
 V_{\Sigma^p} &= \int_{\Sigma^p} d^3x \sqrt{|\det g^{(3)}|} \\
 &= \int_{\Sigma_+^p} dr d\theta d\phi r^2 |\sin \theta| \sqrt{\left| \beta \left(2 - \beta \left(1 - \frac{2m}{r} \right) \right) \right|} \\
 &\quad + \int_{\Sigma_-^p} dr d\theta d\phi r^2 |\sin \theta| \\
 &= 4\pi \int_{\Sigma_+^p} dr r^2 \sqrt{\left| \beta \left(2 - \beta \left(1 - \frac{2m}{r} \right) \right) \right|} \\
 &\quad + \frac{4\pi}{3} (r_{S^p}^3 - r_-^3).
 \end{aligned}$$

The integral over Σ_+^p can be computed explicitly (with computer algebra) in the case in which β is fixed by the continuity at S^p . We do not give the explicit expression here. The volume $V_{\Sigma^p}^\alpha$ is instead given by

$$\begin{aligned}
 V_{\Sigma^p}^\alpha &= \int_{\Sigma^p} d^3x \sqrt{|\det g_\alpha^{(3)}|} = \int_{\Sigma^p} dr d\theta d\phi \alpha r^2 |\sin \theta| \\
 &= \frac{4\pi\alpha}{3} (r_+^3 - r_-^3).
 \end{aligned}$$

We fix the value of α by requiring that $V_{\Sigma^p}^\alpha = V_{\Sigma^p}$. This explicitly gives the value of α as a function of the spacetime free parameters (m, r_+, r_-, β) .

We can now assign discrete geometrical data to the triangulation starting from the continuous intrinsic geometry in equation (33). Let us first consider the $\alpha = 1$ case. When $\alpha = 1$ the line element describes flat space and the intrinsic discrete geometry of the triangulation is completely determined by the side lengths b_\pm . Let $\tilde{d}_v^{t_\pm}$, $\tilde{d}_f^{t_\pm}$ and \tilde{h}_{t_\pm} be respectively the distance between the centroid and a vertex of the tetrahedron t_\pm , the distance between the centroid and a face of the tetrahedron t_\pm and the height of the tetrahedron t_\pm . Basic geometry shows that

$$\tilde{d}_v^{t_\pm} = \sqrt{\frac{3}{8}} b_\pm, \quad \tilde{d}_f^{t_\pm} = \frac{1}{\sqrt{24}} b_\pm, \quad \tilde{h}_{t_\pm} = \sqrt{\frac{2}{3}} b_\pm. \quad (34)$$

The height \tilde{h}_{T_\pm} of a tetrahedron $T_{\pm a}^p$ (they are all equal by symmetry) relative to the base $\ell_{\pm a}$ can be expressed as

$$\tilde{h}_{T_+} = \tilde{d}_f^{t_+} - \tilde{d}_v^{t_-} \quad \text{and} \quad \tilde{h}_{T_-} = \tilde{d}_v^{t_+} - \tilde{d}_f^{t_-}. \quad (35)$$

It is then possible to define the volumes of all the tetrahedra, except the T_{ab}^p ones, as

$$\tilde{V}_X = \frac{1}{3} \tilde{h}_X a_X, \quad (36)$$

where $X = \{t_+, t_-, T_+, T_-\}$, $a_{t_+} = a_{T_+} = a_+$ and $a_{t_-} = a_{T_-} = a_-$. Finally, the volume \tilde{V}_T of a T_{ab}^p tetrahedron (they are all equal by symmetry) is given by

$$\tilde{V}_T = \frac{1}{6} (\tilde{V}_{t_+} - \tilde{V}_{t_-} - 4\tilde{V}_{T_+} - 4\tilde{V}_{T_-}). \quad (37)$$

This completely determines the intrinsic discrete geometry of the triangulation in the flat case in terms of b_\pm .

When $\alpha \neq 1$ the line element in Eq. (33) describes a three-dimensional cone. We are only interested in the region of the cone in which $r \in [r_-, r_+]$. Hence, in this approximation, Σ^p turns out to be locally flat. However, it cannot be embedded in a flat three-dimensional space in the same way in which a two-dimensional cone cannot be embedded in a flat two-dimensional space.

Let us focus on the three-dimensional curved geometry defined by the line element in Eq. (33). The consequence of the presence of α is simply a stretching of the radial lengths with respect to the geometry discussed in the $\alpha = 1$ case while the tangential lengths remain fixed. In analogy with the $\alpha = 1$ case we can then define the following quantities:

$$d_v^{t_\pm} = \alpha \tilde{d}_v^{t_\pm} = \sqrt{\frac{3}{8}} \alpha b_\pm, \quad (38)$$

$$d_f^{t_\pm} = \alpha \tilde{d}_f^{t_\pm} = \frac{1}{\sqrt{24}} \alpha b_\pm, \quad (39)$$

$$h_{t_\pm} = \alpha \tilde{h}_{t_\pm} = \sqrt{\frac{2}{3}} \alpha b_\pm, \quad (40)$$

$$h_{T_+} = \alpha \tilde{h}_{T_+} = \alpha (\tilde{d}_f^{t_+} - \tilde{d}_v^{t_-}), \quad (41)$$

$$h_{T_-} = \alpha \tilde{h}_{T_-} = \alpha (\tilde{d}_v^{t_+} - \tilde{d}_f^{t_-}). \quad (42)$$

The volumes of all the tetrahedra, except the T_{ab}^p ones, can be then written as

$$V_X = \frac{1}{3} h_X a_X = \frac{1}{3} \alpha \tilde{h}_X a_X = \alpha \tilde{V}_X, \quad (43)$$

where $X = \{t_+, t_-, T_+, T_-\}$, $a_{t_+} = a_{T_+} = a_+$ and $a_{t_-} = a_{T_-} = a_-$. Furthermore, since the curved counterpart of Eq. (37) must still be valid, we can write

$$\begin{aligned}
 V_T &= \frac{1}{6} (V_{t_+} - V_{t_-} - 4V_{T_+} - 4V_{T_-}) \\
 &= \frac{\alpha}{6} (\tilde{V}_{t_+} - \tilde{V}_{t_-} - 4\tilde{V}_{T_+} - 4\tilde{V}_{T_-}) \\
 &= \alpha \tilde{V}_T.
 \end{aligned} \quad (44)$$

The intrinsic discrete geometry of the triangulation is thus completely determined in terms of b_\pm and α .

We are interested in the value of the areas A_\pm of the triangles dual to the $\ell_{(\pm a)(bc)}^p$ links. These values are given by

 FIG. 10. Definition of k_+ .

$$A_{\pm} = \frac{1}{2} b_{\pm} h_{\pm}, \quad (45)$$

where h_{\pm} is the height of the triangles dual to $\ell_{(\pm a)(bc)}^p$ relative to b_{\pm} . Basic geometry shows that

$$h_{\pm} = \sqrt{h_{r_{\pm}}^2 + \frac{1}{12} b_{\pm}^2}. \quad (46)$$

So

$$A_{\pm} = \pi r_{\pm}^2 \sqrt{\frac{\alpha^2}{18} \left(1 - 3 \frac{r_{\mp}}{r_{\pm}}\right)^2 + \frac{2}{3}} \quad (47)$$

With α fixed by the value of the total volume of Σ^p , Eq. (47) explicitly gives the value of the areas A_{\pm} in terms of the spacetime free parameters (m, r_+, r_-, β) .

Let us now focus on the extrinsic discrete geometry. The angles k_{\pm} , which are represented in Fig. 10, are defined as

$$\cos k_{\pm} \stackrel{\text{def}}{=} (g^{\mu\nu} n_{\mu}^{\pm f} n_{\nu}^{\pm p})|_{S_{\pm}}. \quad (48)$$

It is then straightforward to find

$$\cos k_+ = \frac{1 + [(1 - 2m/r_+)\beta - 1]^2}{|\beta(\beta - 2 - 2m\beta/r_+)|(1 - 2m/r_+)} \quad (49)$$

and

$$\cos k_- = \frac{1 + 2m/r_-}{1 - 2m/r_-}. \quad (50)$$

The angles K_{\pm} bear the extrinsic curvature of Σ_{\pm} . We choose to define them as the average of the extrinsic curvature, shared over the 12 triangles $l_{(\pm a)(bc)}^t$:

$$K_{\pm} = \frac{1}{12} \int_{\Sigma_{\pm}} k_a^a. \quad (51)$$

We have

$$(k^+)_a^a = \left(1 - \frac{2m}{r}\right) \frac{m\beta^{3/2}(r(3-\beta) + 2m\beta)}{\sqrt{r^5(r(2-\beta) + 2m\beta)}} - \frac{2}{r^2} \frac{r(1-\beta) + 2m\beta}{\sqrt{\beta(2 - (1 - 2m/r)\beta)}} \quad (52)$$

and

$$(k^-)_a^a = -\sqrt{\frac{m}{2r^3}} \left(3 + \frac{2m}{r}\right). \quad (53)$$

For the time being, we leave the integral in Eq. (51) unsolved.

Hence, we have found analytic expressions for the four areas a_{\pm} and A_{\pm} and the four angles k_{\pm} and K_{\pm} as functions of the four parameters m, r_{\pm} and β (the parameter β can equivalently be traded for r_{Sp} or v).

IV. CONCLUSIONS

The above construction defines the black-to-white hole transition amplitude $W(m, r_{\pm}, v)$ as a function of the physical parameters (m, r_{\pm}, v) that characterize the transition and in terms of covariant LQG transition amplitudes. A number of questions, which we list here, remain open.

- (i) To compute the amplitude $W(\psi_{a_{\pm}, k_{\pm}, A_{\pm}, K_{\pm}})$ to the first relevant order, we need to find a spinfoam bounded by Γ_{Σ} . This will be done in a forthcoming companion paper.
- (ii) The amplitude is then given by a complicated multiple group integral, which is hard to study. Asymptotic techniques, and in particular those recently developed in [30] are likely to be essential for this. Alternatively, a numerical approach, following [31,32] may provide insights in the amplitude.
- (iii) The question of eventual infrared divergences in the amplitudes and, eventually, how to deal with them, needs to be addressed.
- (iv) To compute probabilities from amplitudes we have to address the problem of the normalization. This can be solved using the techniques developed in the general boundary formulation of quantum gravity. See in particular [33]. Obviously the probabilities computed give the relative likelihood of a transition within the space of the parameter considered, and not the relative probability with respect to alternative scenarios on the end of the life of a black hole.
- (v) We have taken a number of approximations which we do not control. Physical intuition suggests that the approximation given by disregarding a direct effect of Hawking radiation in the last phases of the evaporation, besides having already shrunk the horizon, may be of particular interest to check.
- (vi) The black-to-white hole transition may have important astrophysical and cosmological implications. White hole produced by the transition of Planck size holes may be stable [34] and form a component of dark matter. Alternatively, if the transition can happen at larger black hole masses, it may be related to cosmic rays and fast radio bursts [35–37]. A control on the amplitude of this transition should help to shed light on these possibilities.
