Real part of the forward elastic nuclear amplitude for $pp, \bar{p}p, \pi^+p, \pi^-p, K^+p$, and K^-p scattering between 70 and 200 GeV/c

L. A. Fajardo, R. Majka,* J. N. Marx,* P. Némethy,* L. Rosselet,[†] J. Sandweiss, A. Schiz,[‡] and A. J. Slaughter Yale University, New Haven, Connecticut 06520

C. Ankenbrandt, M. Atac, R. Brown,[§] S. Ecklund,[¶] P. J. Gollon,** J. Lach, J. MacLachlan, A. Roberts, and G. Shen^{††} Fermi National Accelerator Laboratory, Batavia, Illinois 60510 (Received 6 March 1980)

We have measured the elastic cross section for pp, pp, π^+p , π^-p , K^+p , and K^-p scattering at incident momenta of 70, 100, 125, 150, 175, and 200 GeV/c. The range of the four-momentum transfer squared t varied with the beam momentum from $0.0016 \le -t \le 0.36$ (GeV/c)² at 200 GeV/c to $0.0018 \le -t \le 0.0625$ (GeV/c)² at 70 GeV/c. The conventional parametrization of the t dependence of the nuclear amplitude by a simple exponential in t was found to be inadequate. An excellent fit to the data was obtained by a parametrization motivated by the additive quark model. Using this parametrization we determined the ratio of the real to the imaginary part of the nuclear amplitude by the Coulomb-interference method.

I. INTRODUCTION

Dispersion relations for nuclear scattering are based on the assumptions of unitarity, analyticity, and crossing symmetry and on the energy dependence of the total cross section. Measurements of the real part of the elastic nuclear amplitude provide a means of checking the validity of these assumptions and allow a glimpse at the behavior of the total cross sections at higher energies.

We have measured the elastic differential cross section for pp, $\bar{p}p$, π^*p , π^-p , K^*p , and K^-p scattering. The measurements were made at Fermilab with incident momenta of 70, 100, 125, 150, 175, and 200 GeV/c. The high spatial resolution of our apparatus allowed a very accurate determination of the scattering angle and thus of the four-momentum transfer squared t. The t range of the measurements depended on the incident momentum and varied from $0.0018 \le -t \le 0.36$ (GeV/ $c)^2$ at 70 GeV/c to $0.0016 \le -t \le 0.36$ (GeV/ $c)^2$ at 200 GeV/c.

The real part of the forward nuclear amplitude has been measured extensively for pp scattering up to CERN ISR energies.¹ The real parts of $\pi^- p$ scattering have been measured² up to 140 GeV/c, while those for $\pi^+ p$ and $K^+ p$ scattering are known^{3,4} up to 52 GeV/c. The real parts for $K^- p$ and $\overline{p}p$ scattering have not been measured^{5,6} above 15 GeV/c. Our experiment measured three reactions simultaneously $(pp, \pi^+ p, K^+ p$ and $pp, \pi^- p, K^- p)$ and measured all six reactions with the same apparatus.

A. Differential cross section

In the t range studied in this experiment the differential cross section is determined by both

the Coulomb and nuclear scattering amplitudes:

. .

. . .

$$d\sigma/dt = \pi |f_{C} + f_{n}|^{2} .$$
 (1)

At small -t the Coulomb amplitude is dominant and is given by the expression

$$f_{\mathcal{C}} = (2z_a e^2/c) G_a(t) G_p(t) \exp(iz_a \Omega)/t , \qquad (2)$$

where $z_a e$ is the charge of the incident particle *a*. $G_a(t)$ and $G_p(t)$ are the electromagnetic form factors of the incident particle *a* and the target proton. We use the dipole form for the protons and the monopole form for the pions and kaons:

. . .

$$G_{p}(t) = 1/(1 + v_{p} |t|)^{2},$$
 (3a)

$$G_{\pi}(t) = 1/(1+2v_{\pi}|t|),$$
 (3b)

$$G_K(t) = 1/(1+2v_K |t|),$$
 (3c)

$$v_{p} = r_{p}^{2} / 12\hbar^{2}$$
, (3d)

$$v_{z} = r_{z}^{2}/12\hbar^{2}$$
, (3e)

$$v_{\mathcal{K}} = r_{\mathcal{K}}^2 / 12\hbar^2 \,. \tag{3f}$$

where the values of r are the electromagneticform-factor radii obtained from Refs. 7-9. The values of the radii used throughout the analysis are

 $r_p = 0.805 \text{ fm}$, (3g)

$$r_{\pi} = 0.711 \text{ fm}$$
, (3h)

$$r_{\rm K} = 0.565 \,\,{\rm fm}$$
 (3i)

Since the form factors are a small correction to the Coulomb amplitude at small -t, we ignore the experimental uncertainties of the electromagnetic radii. In Eq. (2) the Coulomb phase shift Ω is given by West and Yennie¹⁰ as

$$\Omega = \alpha \ln\{1.124/[b(0) + 4v_p + 4v_q] |t|\}, \tag{4}$$

24

46

where α is the fine-structure constant and b(0) is the nuclear slope at t=0. We define b(t) below.

Traditionally, real-part measurements have been analyzed with the nuclear amplitude parametrized as an exponential with a constant slope B. However, recent results from experiments at Fermilab,^{11,12} SLAC,¹³ and the ISR (Ref. 14) show a more complicated t dependence of the nuclear slope. To explore this behavior we employ two parametrizations for the nuclear amplitude and refer to them as the exponential and form-factor parametrizations. We define the exponential nuclear amplitude as follows:

$$f_n^e = (\sigma_{tot}/4\pi\hbar)(i+\rho) \exp[(Bt+Ct^2)/2],$$
 (5)

a. . .

where σ_{tot} is the total cross section and where Band C are the constant nuclear slope and curvature. The real and imaginary parts are assumed to have the same functional dependence on t and spin effects are neglected. Thus we define ρ as the ratio of the real to imaginary part of the nuclear amplitude at t=0.

As we have shown in Ref. 11, the nuclear amplitude can be parametrized by a form suggested in the theoretical models of Chou and Yang¹⁵ and versions of the additive quark model (AQM). These models attribute the major part of the small -t elastic-cross-section variation to the hadronic form factors of the target and the projectile. These form factors are assumed to be the same as the electromagnetic ones. In the AQM form factors describe the spatial distribution of clothed quarks; in the very small -t region, the scattering is dominated by single quarkquark scattering. Specifically we use the form for the nuclear amplitude suggested by Bialas et al.¹⁶ and Levin and Shekhter.¹⁷ We define the form-factor nuclear amplitude as follows:

$$f_n^{\text{ff}} = (\sigma_{\text{tot}}/4\pi\hbar)(i+\rho)G_a(t)G_p(t)\exp(ut/2), \qquad (6)$$

where σ_{tot} , $G_a(t)$, $G_p(t)$ are defined above and u is the reduced nuclear slope. We discuss below the sensitivity of our results to the precise values of the electromagnetic radii used. In the AQM (Ref. 18) the radius of the clothed quark is given by $r_q = (2\hbar^2 u)^{1/2}$. Again we assume the real and imaginary parts have the same functional dependence on t, neglect spin effects, and define ρ to be the ratio of real to imaginary parts.

In summary, we can write the differential cross section as the sum of three terms:

$$d\sigma/dt = \sigma_C + \sigma_I + \sigma_n, \tag{7}$$

where σ_C , σ_I , and σ_n are the Coulomb, interference, and nuclear contributions, respectively. The exponential parametrization of the cross section is given by sum of the three terms below:

$$\sigma_C = (4\pi e^4/c^2) G_a^2 G_p^2/t^2, \qquad (8a)$$

 $\sigma_I^e = \alpha \sigma_{tot} G_a G_p (z_a \rho \cos \Omega + \sin \Omega) \exp[(Bt + Ct^2)/2]/t,$

$$\sigma_n^e = (\sigma_{tot}^2 / 16\pi\hbar^2)(1+\rho^2) \exp(Bt+Ct^2) .$$
 (8c)

Similarly the form-factor parametrization of the cross section is given by the sum of the three terms below:

$$\sigma_{C} = (4\pi e^{4}/c^{2})G_{a}^{2}G_{p}^{2}/t^{2}, \qquad (9a)$$

$$\sigma_I^{\rm ff} = \alpha \sigma_{\rm tot} G_a^2 G_p^2 (z_a \rho \cos \Omega + \sin \Omega) \exp(ut/2)/t,$$

$$\sigma_n^{\rm ff} = (\sigma_{\rm tot}^2 / 16\pi\hbar^2)(1+\rho^2)G_a^2 G_{\rho}^2 \exp(ut) . \qquad (9c)$$

In both cases the magnitude and sign of ρ can be determined from the interference term. While the Coulomb term is sharply decreasing $(1/t^2)$ and the nuclear term is nearly flat, the interference term is distinguished by a 1/t dependence and has its maximum effect on $d\sigma/dt$ in the range $0.001 \leq -t \leq 0.003$ (GeV/c)². However, the accurate determination of ρ requires considerable care in the determination of the nuclear slope in the forward direction. We have paid particular attention to the problem of determining the correct nuclear cross section in the forward direction.

We define the nuclear slope b(t) and the nuclear curvature c(t) as follows:

$$b(t) = d(\ln\sigma_n)/dt, \qquad (10a)$$

$$c(t) = \frac{1}{2}db/dt . \tag{10b}$$

Thus for the exponential cross section b and c are

$$b^{e}(t) = B - 2C |t|,$$
 (11a)

$$c^{\boldsymbol{e}}(t) = C . \tag{11b}$$

For pp the form-factor slope and curvature are

$$b_{p}^{ff}(t) = u + 8v_{p}(1 + v_{p} |t|)^{-1},$$
 (12a)

$$c_{p}^{ff}(t) = 4v_{p}^{2}(1+v_{p}|t|)^{-2}$$
 (12b)

For either πp or Kp the form-factor slope and curvature are

$$b_{a}^{ff}(t) = u + 4v_{a}(1 + 2v_{a}|t|)^{-1} + 4v_{p}(1 + v_{p}|t|)^{-1}, \quad (12c)$$

$$c_{a}^{ff}(t) = 4v_{a}^{2}(1 + 2v_{a}|t|)^{-2} + 2v_{p}^{2}(1 + v_{p}|t|)^{-2}. \quad (12d)$$

B. Dispersion relations

In 1954 Gell-Mann, Goldberger, and Thirring¹⁹ used causality arguments in the context of quantum electrodynamics to show that the transition amplitudes can be analytically continued to complex values of the energy and to obtain dispersion relations for the amplitude. However, for S- matrix theory it is difficult to rigorously establish the connection between causality and analyticity.²⁰ S-matrix dispersion relations are thus based on the reasonable assumption of analyticity. In addition crossing symmetry and the optical theorem are used to relate the real part of the scattering amplitude to the integral over the particle and antiparticle total cross sections. However, the contour of integration also includes contributions from pole terms due to intermediate and exchange states and from unphysical cuts along the real axis due to inelastic reactions.

The dispersion relations for πp elastic scattering (by virtue of the pion's spin-zero and nonexotic channels) have been proved from axioms of field theory.²¹ For pp and Kp elastic scattering, dispersion relations have not been proved in general but have been shown to be valid to all orders in perturbation theory.

For πp scattering the principal pole and unphysical cut contributions are small and well understood, while for Kp and pp they are substantial and have large uncertainties. On a practical level the integration over the total cross sections is made difficult by regions at low energies where the total cross sections have not been measured. At high energies the total cross section varies slowly, while the integral over the total cross sections is sharply peaked. Thus by means of a Taylor-series expansion, derivative dispersion relations²² show that the real part becomes a local function of the total cross section and is insensitive to its value at very high energies.

We compare our results with the calculations of Hendrick *et al.*,²³ Hohler *et al.*,²⁴ and Dumbrajs²⁵ and Lipkin.²⁶ The first three calculations use analytic dispersion relations and a detailed fit to total-cross-section measurements. Hendrick *et al.* and Hohler *et al.* extrapolate the total cross sections to very high energies using a $\ln^2(E)$ dependence, while Dumbrajs uses a $[\ln(E)]^{0.967}$ dependence. Lipkin employs derivative dispersion relations²⁷ and fits the total cross sections at Fermilab energies with a two-component Pomeron model. This model gives the total cross section as rising with an $E^{0.13}$ dependence.

II. APPARATUS AND DATA ACQUISITION

The experiment was performed in the Meson Laboratory at Fermilab. The apparatus and data acquisition are discussed in the preceding article.¹¹ Using the four Čerenkov counters we determined that the contamination of the kaon signal by pions and protons was less than 0.5%. Surrounding the target were two *u*-shaped scintillation counters, RV1 and RV2, with a 1-cm-thick lead sheet between them. These counters were used to detect converted γ rays and recoil protons with kinetic energy greater than 250 MeV. We used RV1 and RV2 to help separate inelastic reactions for scatters with -t less than 0.2 (GeV/c)².

The scintillation counter V was much smaller than the one described in the preceding article. Figure 1 shows the placement of this counter relative to the beam center and relative to the projection of the aperture of the last spectrometer magnet onto the veto plane. The beam was focused on the veto, such that the veto would detect unscattered beam tracks. The size of the veto varied with momentum such that scatters with -t less than 0.001 (GeV/c)² were also vetoed. However, primarily because of multiple scattering in the beam line, only about 95% of the beam could be focused on the veto at a given momentum.

Most of the 5% beam halo was rejected by the analog calculator, HFSD (hardware focus scatter detector). The HSD test required that either the vertical or the horizontal projection of the scattering angle correspond to a scatter with -t greater than 0.001 (GeV/c)². In Figs. 2(a) and 2(b) the HSD efficiency in the horizontal projection is shown as a function of q_x (q_x is defined below) at 70 and 200 GeV/c. At 200 GeV/c and -t = 0.0016 (GeV/c)² the combined HSD efficiency of both projections is better than 99%.

For most of our running the accelerator operated at 300 or 400 GeV with a repetition rate of 10 sec and a 1-sec spill time. The beam contained typically 5×10^5 particles per accelerator pulse. Approximately 400 triggers were recorded per second; out of these 80 were beam events, 20 were PAE's (prescaled accepted events), and the remainder scatters. The relative fraction of

FIG. 1. Veto-plane geometry. The small rectangle represents the counter V; the shaded region denotes the projection of the downstream spectrometer magnet onto the veto plane, and the X indicates where the beam axis enters the page. The circles are the loci of particles with 200-GeV/c incident momentum that scattered from the beam axis with the indicated values of |t| in units of $(\text{GeV}/c)^2$.

FIG. 2. HSD efficiency in the x direction as a function of q_x at (a) 70 GeV/c and (b) 200 GeV/c. The error bars indicate the statistical uncertainty of the curves.

events recorded involving a particular particle type (π , K, or p) was scaled to result in apparatus live time of 60%.

Data were also taken with the liquid hydrogen removed from the target assembly. These data were used to subtract the contribution of smallangle scatters that occurred outside the liquidhydrogen (LH_2) target, but due to our finite angular resolution were reconstructed inside the target region. The target-empty and target-full runs were interspersed and taken under the same conditions.

III. ANALYSIS

A. Overview

The significant effects of multiple Coulomb scattering and resolution near t=0 suggested that the comparison between data and theory be made by modifying the theory to include the effects of the apparatus. The sum of these corrections is largest at small -t and is between 4 and 6% near -t=0.0016 (GeV/c)². These corrections depend strongly on the t dependence of the differential cross section. The three contributions to the differential cross section, σ_C , σ_I , and σ_n , have corrections each with a different functional dependence on t. However, σ_I and σ_n have to be determined from the data. Assuming the theoretical cross sections, Eqs. (8) and (9), the corrections due to multiple scattering in the LH₂ were found analytically. The resolution and acceptance corrections were then included numerically via a Monte Carlo simulation. The corrected theoretical cross sections were then fit to the data. The details of this analysis are found in Ref. 28. Below we provide a brief description.

To facilitate the analysis, the variable q was used:

$$q = (-t)^{1/2} \simeq p_{\text{beam}} \theta$$

and

$$d\sigma/dq = -2(-t)^{1/2} d\sigma/dt$$

where p_{beam} is the incident momentum and θ is the scattering angle. The horizontal and vertical projections of q were called q_x and q_y . There are two major reasons for this choice of variable. First the angular resolution of the apparatus, $\Delta \theta$, is approximately constant as a function of the scattering angle θ . However, the *t* resolution of the apparatus is proportional to $\theta \Delta \theta$ and thus varies by a factor of 14 over the t range of interest at 200 GeV/c. Since q is proportional to θ , the q resolution is approximately constant in qand the data could be subdivided in uniform q bins. Second, the cross section $d\sigma/dq$ over equal q bins is a more slowly varying function than $d\sigma/dt$ over equal t bins. Thus the binning of $d\sigma/dq$ populates the bins more uniformly. This reduces the sensitivity of the fitting to the integration over the bin and to the migration of events between bins due to resolution and multiple scattering. While the analysis was made using q and $d\sigma/dq$, we present our final results in terms of t and $d\sigma/dt$ for convenience.

B. Event reconstruction

The data-reduction process kept only events with a single unambiguous track throughout the apparatus. Typically each proportional wire chamber (PWC) had one unambiguous coordinate about 95% of the time. However, the lack of redundancy in these PWC's allowed only 50% of all the recorded events to be fully reconstructed.

In the alignment procedure unscattered beam events were used to determine the relative spatial position of the PWC's. The PWC's on the block were aligned assuming a straight trajectory, while the PWC's downstream of the spectrometer mag-

(13)

nets were aligned assuming no momentum loss. The center of the beam distribution at the second focus PWC was defined to be the central beam momentum. We determined the central value of the beam momentum using the differences between the refractive indices for pions, kaons, and protons in the DISC Čerenkov counter.²⁹ In Table I the central beam momentum and percent error used in the analysis are presented.

Several spatial and kinematic quantities were calculated for each reconstructed beam or scatter event. The incident momentum was determined from the displacement from the beam center in the PWC at the second focus. The high-resolution PWC's (stations 1-4) were used to measure the scattering angle and the position of the scattering vertex. PWC stations 3, 4, and 6 were used to determine the outgoing momentum and the track position in the veto plane.

Beam events were also used to determine the qresolution of the apparatus. This resolution is the sum in quadrature of three parts: the PWC angular resolution, the q width of multiple scattering in the LH_2 , and the q smearing due to multiple scattering in the PWC's. In Fig. 3(a) we show the momentum dependence of the q resolution with LH₂ in the target. The multiple-scattering contributions are constant as a function of momentum, while the PWC q resolution varies linearly with momentum. By comparing the target-full and target-empty distributions, the different components can be evaluated. In Ref. 30 we reported on measurements of the widths of multiple-Coulomb-scattering distributions for hydrogen and other nuclei. We find that our measured hydrogen width is in excellent agreement with Moliere's³¹ prediction.

The missing-mass squared of the undetected recoil particle m_r^2 is given by

$$m_{r}^{2} = t + m_{p}^{2} + 2m_{p}\Delta E, \qquad (14)$$

where m_{ρ} is the mass of the target proton and ΔE is the energy loss. In Fig. 3(b), the resolution

TABLE I. Momenta used in the analysis.

| Nominal momentum (GeV/c) | Beam momentum (GeV/c) | Momentum uncertainty $(\Delta p_c/p)$ |
|--------------------------------|-----------------------------|---|
| 70 | 70.00 | 0.0036 |
| 100 | 100.00 | 0.0030 |
| 125 | 124.77 | 0.0016 |
| 150 | 151.44 | 0.0033 |
| 175 | 174.33 | 0.0037 |
| 200 | 200.80 | 0.0038 |

FIG. 3. Apparatus resolution as a function of momentum: (a) q resolution and (b) recoil mass squared. The circles and x's were determined from the data, while the lines were computed from the predicted resolution of the apparatus. The solid line is the constant contribution due to multiple scattering, while the vertically striped band is the angle-dependent PWC resolution. The horizontally striped band is the sum in quadrature of these two contributions.

of the m_r^2 is shown as a function of momentum. From the reconstructed spatial and kinematic quantities, the position of apertures, the target, and the veto counter V were determined and the appropriate cuts selected. A brief description of the most important cuts is given in Table II. These cuts were applied to both the data and Monte Carlo distributions.

C. Monte Carlo simulation

A Monte Carlo simulation determined the spatial acceptance of the apertures and the migration of events due to PWC resolution and multiple scattering in the PWC's. The Monte Carlo events were generated using beam events to determine the incident phase space. Since we found no significant difference in the phase space of pions, kaons, and protons, the Monte Carlo incident phase space was based on all three particles.

| Cut no. | Description |
|---------|--|
| (1) | The limiting aperture of the high-resolution PWC's was the sen- sitive area of station 4. Tracks were required to be within its reduced area. |
| (2) | The spectrometer-magnet channel cross section was a rectangle with rounded corners as shown in Fig. 1. The limiting aperture of the spectrometer magnets was its most downstream exit. Tracks were required to be within its reduced area. |
| (3) | Tracks in the veto plane were required to be outside an enlarged veto region. See Fig. 1. |
| (4) | The longitudinal position of the interaction vertex was required to be within the target region. |
| (5) | The recoil mass squared m_r^2 as defined in the text was required to be in the neighborhood of the proton mass squared. |
| (6) | Since stations 1 and 2 defined the incident-beam phase space, an in- efficient or inactive PWC area was of no consequence. In station 3 the redundancy of x , y , u , and v measurements made such ineffi- ciencies negligible. However, in station 4 there is no redundancy and tracks were required to be outside of inefficient or inactive areas. |
| (7) | The final aperture of the apparatus was station 6. All tracks were required to be within its sensitive area. |

TABLE II. Principal cuts used in the analysis.

Thus only one Monte Carlo distribution at each momentum and beam charge was used.

The polar and azimuthal scattering angles and the longitudinal position of the scattering vertex were generated from a uniform random distribution. Multiple scattering in the PWC's was included as the track was propagated through the apparatus. The PWC spatial resolution was simulated and spatial and kinematic quantities were reconstructed. The same cuts applied to the reconstructed data quantities were also applied to the Monte Carlo-reconstructed quantities. In Fig. 4 a typical acceptance is shown as a function of q. At q = 0.040 GeV/c [-t = 0.0016 (GeV/c) $(c)^{2}$] the acceptance is typically 50% and rapidly rises to a maximum of 75 to 80%. At $\theta = 1$ mrad the vertical apertures of the magnet and PWC stations 4 and 6 combine to sharply decrease the acceptance. At larger angles ($\theta = 2.5$ mrad) the acceptance flattens out between 10 and 15%. The statistical accuracy of the acceptance distributions is better than 0.3% per *q* bin and is approximately ten times smaller than the statistical error of the data.

Because of the sharp behavior of the acceptance, extensive studies and checks were made for systematic effects. The most important of these were detailed comparison of the data and Monte Carlo distributions of kinematic and spatial quantitles. At each energy and beam charge the majority particle's data distributions were compared with the Monte Carlo distributions weighted by the appropriate cross sections. We found that these distributions were in very good agreement.

D. Target-empty subtraction

The normalized target-full and target-empty distributions, N^{F} and N^{MT} , were obtained as follows:

$$N^{F}(q_{i}) = N^{F}_{sc}(q_{i}) R^{F}_{s} / N^{F}_{b}, \qquad (15a)$$

FIG. 4. Apparatus acceptance as a function of q at 200 GeV/c.

where $N_{sc}^{F}(q_{i})$ and $N_{sc}^{MT}(q_{i})$ are the number of fulland empty-target scatter events that passed all the cuts and had q in the range $q_i - \Delta q/2 \leq q$ $\leq q_i + \Delta q/2$; N_b^F and N_b^{MT} are the number of fulland empty-target reconstructed beam events. The bin size of the distribution, Δq , varied from 0.002 GeV/c at 70 GeV/c to 0.005 GeV/c at 200 GeV/c. The sampling rate R_s is given by

$$R_s = N_{s \cdot b} / N_s, \tag{15c}$$

where N_s is the total number of reconstructed scatter events and $N_{s,b}$ is the total number of reconstructed scatter events that are also beam events. Typically R_s was $\frac{1}{225}$ for target-full runs and $\frac{1}{450}$ for target-empty runs. The ratio, N_b/R_s is the total incident flux corrected for dead-time corrections and absorption losses in the apparatus

The data scattering distribution $S_D(q_i)$ is given by

$$S_{D}(q_{i}) = [N^{F}(q_{i}) - N^{MT}(q_{i})]/(DL \Delta q), \qquad (16)$$

where D is the number of protons per unit volume of LH_2 and L is the target length. The targetempty correction $N^{\rm MT}$ is largest at 200 GeV/c where it is 30% of N^{F} at $-t = 0.0016 \ (\text{GeV}/c)^{2}$, but rapidly decreases to zero at $-t = 0.01 (\text{GeV}/c)^2$. The statistical error of N^{F} and N^{MT} are dominated by the statistical errors of R_s^F and R_s^{MT} which are typically 1% and 3%, respectively, and are independent of t. In summary, $S_D(q_i)$ is the differential cross section for scattering in the liquid hydrogen as measured by our apparatus.

E. Corrections to theoretical cross sections

The theoretical cross sections given by Eqs. (8) and (9) were modified to include the following corrections: multiple scattering, resolution, acceptance, HSD efficiency, and radiative losses.

Since our multiple-Coulomb-scattering distribution width is in very good agreement with Moliere's prediction, we extend the Moliere formalism to include the interference and nuclear contributions. This transforms the theoretical cross sections of Eqs. (8) and (9) into Moliere distributions, S_{MS}^{e} and S_{MS}^{ff} , due to multiple scattering in the liquid hydrogen. In the t range of interest these distributions are approximated by

$$S_{MS}^{e} = \sigma_{C} \left(1 - \epsilon_{C}\right)^{-1} + \sigma_{I}^{e} \left(1 + \epsilon_{I}\right) + \sigma_{n}^{e} \left(1 + \epsilon_{n}^{e}\right), \quad (17a)$$

$$S_{\rm MS}^{\rm ff} = \sigma_C \left(1 - \epsilon_C\right)^{-1} + \sigma_I^{\rm ff} \left(1 + \epsilon_I\right) + \sigma_n^{\rm ff} \left(1 + \epsilon_n^{\rm ff}\right), \qquad (17b)$$

where ϵ_c is Bethe's result in Ref. 31 due to pure Coulomb scattering, ϵ_I is the multiple-scattering correction due to the interference term, and ϵ_n is the double-nuclear-scattering correction. These corrections are given as follows:

$$\epsilon_{c} = (4w^{2}/|t|)[1+0.043\ln(0.16|t|/w^{2})], \qquad (17c)$$

$$\epsilon_I = (w^2 / |t|) + (1.333 w^4 / t^2),$$
 (17d)

$$\epsilon_n^e = DL\sigma_{tot}^2 (1+\rho^2)/64\pi\hbar^2 b^e(0) \exp[(Bt+Ct^2)/2],$$
(17e)

$$\epsilon_n^{ft} = DL\sigma_{tot}^2 (1+\rho^2)/64\pi\hbar^2 b^{ff}(0)G_a(t)G_p(t) \exp(-ut/2),$$
(17f)

where w is the 1/e width of the projected Coulomb-multiple-scattering Gaussian distribution. D and L, as defined above, are the number of protons per unit volume of LH_2 and the target length. Since L is 52.7 cm, then w is 3.68 MeV/ c. At -t = 0.0016 (GeV/c)², ϵ_c and ϵ_I are 4% and 1% corrections and rapidly decrease with increasing -t. The double-scattering correction ϵ_n is less than 1% in our *t* range. The details of the multiple-scattering corrections are found in Ref. 28.

The theoretical cross section corrected for acceptance and resolution, $S_{MS,A,R}(q_i)$ is given by

$$S_{\text{MS},A,R}(q_i) = \int_{q_i^* \Delta q/2}^{q_i^* \Delta q/2} dq' \int_0^\infty 2q'' dq'' S_{\text{MS}}(q'') R(q'',q'),$$
(18)

where R(q'', q') is the probability that a scatter generated with q = q'' passed all the aperture and kinematic cuts and was reconstructed as a scatter with q = q'. The function R(q'', q') is numerically generated by the Monte Carlo simulation. It would be extremely time consuming to evaluate the above integral every time a parameter was changed in the fitting procedure. To avoid this, the cross section $S_{MS}(q)$ was expanded into a series such that the parameters of the fit are decoupled from q. For the exponential case we write symbolically

$$S_{MS}^{e} = \sum_{j} g_{j}^{e}(\rho, B, C, \sigma_{tot}) h_{j}^{e}(q), \qquad (19)$$

where g_j is a function only of the parameters to be varied and h_j is a function only of q. In Ref. 28 g_{j}^{e} , g_{j}^{ff} , h_{j}^{e} , and h_{j}^{ff} are explicitly defined. We found that a series expansion of 100 terms was sufficiently accurate (1 part in 10^8). The integration over the Monte Carlo events is performed only once and $S_{MS,A,R}(q_i)$ is written as

$$S_{\text{MS},A,R}(q_i) = \sum_j g_j^e(\rho, B, C, \sigma_{\text{tot}}) \langle h_j^e(q_i) \rangle, \qquad (20)$$

where

$$\langle h_j^e(q_i) \rangle = \int_{q_i^{-\Delta q/2}}^{q_i^{+\Delta q/2}} dq' \int_0^\infty 2q'' dq'' h_j^e(q'') R(q'',q') \,.$$

The theoretical cross section with all our corrections is given by

$$S_{\text{th}}(q_i) = S_{\text{MS},A,R}[1 + \epsilon_{\text{rad}}(q_i)]/E_{\text{HSD}}(q_i), \qquad (21)$$

where ϵ_{rad} is the radiative correction and E_{HSD} is the total HSD efficiency. We use the calculations of Sogard³² to determine the loss of events, ϵ_{rad} , from the elastic peak due to the radiation of photons. In this experiment the correction is significant only for pions; it increases from zero at t=0 to about 5% at -t=0.36 (GeV/c)² for the missing-mass-squared cut used in the analysis and for the width of the elastic peak. The HSD efficiency E_{HSD} is 0.99 at -t=0.0016 (GeV/c)² and rapidly becomes 1.0 with increasing -t.

The scintillation counters RV1, RV2, VH2, and VH3 were used to remove a 2 to 3% nonelastic background. The final missing-mass-squared distribution showed that the inelastic contamination of the elastic peak was less than 1%. No additional correction for inelastic contamination was made.

F. Fitting procedure

The fitting procedure consisted of minimizing the following χ^2 :

$$\chi^{2} = \sum_{i} \left[S_{D}(q_{i}) - A_{n} S_{th}(q_{i}) \right]^{2} / \sigma_{i}^{2}, \qquad (22)$$

where the summation index *i* indicates the *i*th *q* bin, σ_i is the statistical error of $S_D(q_i)$, and A_n is an arbitrary normalization parameter. The χ^2 was minimized by the program MINUIT (Ref. 33) with the statistical errors on the parameters calculated by the subroutine HESSE.

To remove the effects of multiple scattering, resolution, acceptance, and normalization, the corrected-data cross section $d\sigma^{p}/dt$ is given by

$$d\sigma^{D}/dt = (d\sigma/dt) \{ S_{D}(q_{i})/[A_{n}S_{th}^{*}(q_{i})] \}, \qquad (23)$$

where $d\sigma/dt$ is the cross section given by Eq. (9) and $S_{th}^*(q_i)$ is $S_{th}(q_i)$ evaluated with our final parameters. Because of the extensive length of the corrected-cross-section tables, we do not publish them here, but do include them in Ref. 28.

IV. RESULTS

A. The nuclear slope

Since the determination of ρ is strongly correlated to the determination of the nuclear slope at small -t, we first discuss the structure of the nuclear cross section. As mentioned above recent experimental results¹¹⁻¹⁴ have observed substantial deviations from a constant exponential slope for -t > 0.025 (GeV/c)². As we show below,

the nuclear curvature *C* is approximately 5 (GeV/ *c*)⁻⁴ for all six reactions. In the absence of direct experimental evidence below -t = 0.025 (GeV/*c*)², we assume that this curvature extends down to t=0. Thus even in the small *t* range, $0.0 \le -t$ ≤ 0.10 (GeV/*c*)², the variation of the nuclear slope b(t) is 1 (GeV/*c*)⁻² which has a significant effect on the determination of ρ .

The nuclear curvature at large -t is demonstrated in Fig. 5, where $d\sigma/dt$ for pp scattering at 200 GeV/c is shown. The theoretical curve was obtained by fitting the data in the range 0.0016 $\leq -t \leq 0.09$ (GeV/c)² with the exponential cross section Eq. (8) and C = 0. We note that the experimental cross section does not decrease as a simple exponential. Similar behavior is observed for all six reactions between 125 and 200 GeV/c(below 125 GeV/c our t range is too small to observe curvature). By fitting the data with Eq. (8) and allowing B and C to vary, we get a much better representation of the data. In Table III we present B and C for all six reactions at 200 GeV/ c. The data were fit in the range $0.01 \le -t \le 0.36$ $(\text{GeV}/c)^2$ with the exponential cross section Eq. (8) and ρ fixed to our final value (presented in the next section). We see that the values of C are nearly particle independent and are approximately 5 (GeV/c)⁻⁴.

However, the following considerations suggest that an alternative formulation for the nuclear cross section should be used. We find that our values of B and C depend on the t range of the fit. There is also considerable evidence from other experiments that a constant curvature does not describe the data well.¹¹⁻¹⁴ In addition our reduced t range at lower momenta does not allow a very accurate simultaneous determination of both B and C, although the values of B and C were consistent with those found at 200 GeV/c.

FIG. 5. d_{σ}/dt vs t for pp elastic scattering at 200 GeV/ c. The theoretical curve is the exponential cross section with C=0 fit to the data in the range $0.0016 \le -t \le 0.09$ (GeV/c)².

TABLE III. Exponential fit^a at 200 GeV/c.

^a The range of the fit was $0.01 \le -t \le 0.36 \ (\text{GeV}/c)^2$.

^bThe number of degrees of freedom DOF was 97 for all six fits.

We found in a related experiment¹¹ on elastic of pp, π^*p , and π^-p scattering at 200 GeV/c with a high-statistics sample in the range $0.025 \le -t \le 0.62$ (GeV/c)², that the AQM formulation fit the data rather well. Similarly we find with this experiment that the form-factor cross section, Eq. (9) with only one free parameter u, fits very well all six hadronic interactions. We find that the χ^2 's for the form-factor fits are comparable to those of the exponential cross section with both B and C free to vary. Also, the value of u is insensitive to the t range of the fit.

The local nuclear slope b(t) provides a mechanism for making a detailed comparison between data and theory. Using the values of u from our final fits at 200 GeV/c (presented in the next section), we calculate the form-factor nuclear slope $b^{ff}(t)$ given by Eq. (12). In Fig. 6 we compare $b^{ff}(t)$ to previous measurements of the nuclear slope for pp, $\pi^* p$, and $\pi^- p$ at approximately 200 GeV/c. The slope $b^{ff}(t)$ is shown by the solid line and is extended beyond the t range of our fits by the dotted line. The dashed lines represent the envelope of the uncertainties of the local slopes from fits made to our data using the t intervals employed by Schiz et al. Our results are in rather good agreement with previous measurements.

Our data indicate that the changing curvature is exhibited by all six reactions from 100 to 200 GeV/c. In Figs. 7(a)-7(f) we compare the formfactor slope $b^{ff}(t)$ with the exponential parametrization of the nuclear slope $b^e(t)$ of Ayres *et al.*¹² and Akerlof *et al.*¹² at -t = 0.1 and $0.2 (\text{GeV}/c)^2$. We note the excellent agreement of the local slopes at -t = 0.2(GeV/c)². At -t = 0.1 (GeV/c)² our local slopes are substantially higher than the values of Ayres *et al.* and Akerlof *et al.*, indicating that the curvature is increasing with decreasing -t for all six reactions.

The form-factor cross section provides an elegant explanation for the large curvature that we measure at low -t and the small curvature that Ayres *et al.* and Akerlof *et al.* measure at higher -t. For instance, in pp scattering the form-factor curvature $c^{\text{ff}}(t)$ equals 4.9 $(\text{GeV}/c)^{-4}$ at t=0.2 $(\text{GeV}/c)^2$, which is in good agreement with C=5 $(\text{GeV}/c)^{-4}$. At t=0.4 $(\text{GeV}/c)^2$, the curvature

FIG. 6. Local slopes as a function of t for pp, π^*p , and π^-p elastic scattering. The data are from Akerlof et al., Ref. 12; Ayres et al., Ref. 12; Barbiellini et al., Ref. 14; Bartenev et al., Ref. 35; Burq et al., Ref. 14; Schamberger et al., Ref. 36; and Schiz et al., Ref. 14; Schamberger et al., Ref. 36; and Schiz et al., Ref. 11. The solid line is the form-factor slope, $b^{\text{tf}}(t)$, as determined from the values of u in Table IV and is extended beyond the t range of the fits by the dotted line. The dashed line represents the envelope of the uncertainties of the local slopes from fits made to our data using the same t intervals employed by Schiz et al.

FIG. 7. Local slopes as a function of momentum at -t=0.1 and 0.2 $(\text{GeV}/c)^2$ for (a) pp, (b) $\pi^* p$, (c) $K^* p$, (d) $\overline{p}p$, (e) πp , and K p elastic scattering. The slopes from this experiment are calculated using $b^{ff}(t)$ with the values of u from Table IV. The slopes of Ayres et al. and Akerlof et al. (Ref. 12) are calculated using $b^{e}(t)$ with their values of B and C.

has decreased to $c^{ff}(t) = 2.3 \ (\text{GeV}/c)^{-4}$ which is in good agreement with previous measurements¹² of C in this t range. Calculating $c^{ff}(t)$ for other reactions, we see that the curvature is almost particle and momentum independent. This is also in good agreement with previous measurements.

Because of the short lever arm and low statistics at large -t of this data, we are unable to fit for the nuclear form-factor radii. However, in our previous result¹¹ we were able to fit for the proton and pion nuclear radii. The fits tended to give values of proton radius 7% smaller than the electromagnetic values, while the pion radius was consistent with the electromagnetic measurements. For kaons we have no such independent check and

FIG. 8. Sensitivity of the parameters to the upper limit of the t range of the fit at 200 GeV/c for pp, $\pi^+ p$, $K^{\dagger}p$, $\overline{p}p$, $\pi^{\bullet}p$, and $K^{\bullet}p$. The form-factor cross section and the exponential cross section with C=0 were fit to the data over the t range 0.0016 $({\rm GeV}/c)^2 \leqslant -t \leqslant -t_{\rm max}$. In (a) the resulting slope parameters u and B are arbitrarily superimposed. In (b) the resulting values of ρ are shown. For both (a) and (b) the dashed line is drawn through the values found in Table IV.

TABLE IV. (Continued).

only one experimental measure of the kaon radius.⁹ To first order our values of ρ are insensitive to small changes in the radii, since the values of uwill vary to compensate.

To illustrate the stability of the form-factor fits. the data at 200 GeV/c were fit with the formfactor cross section in the intervals $0.0016 \leq -t$ $\leq -t_{max}$. To contrast our sensitivity fits were also made with the exponential cross section with C=0. For both types of fits the values of $-t_{max}$ ranged from 0.05 to 0.36 $(\text{GeV}/c)^2$. In Fig. 8(a) the fitted values of B and u are plotted as a function of $-t_{\text{max}}$ for all six reactions at 200 GeV/c. For convenience B and u are superimposed and a dashed line goes through the value of u from our final fits. We note as the range of the fit increased B decreased, while u remained constant within statistical errors. The χ^2 per degree of freedom also rapidly increased for the exponential case but remained near one for the form-factor case. Since ρ is strongly correlated to the nuclear slope, the variation of ρ follows the variation of B and u. In addition, the variations of ρ for particle and antiparticle will be reversed. This behavior is shown in Fig. 8(b), where a dashed line goes through the value of ρ from our final

fits. For small $-t_{max}$ the values of ρ for both formulations converge, although with large uncertainties. At lower momenta the same behavior is noted, but over reduced t ranges. Results of fits to the data with the exponential cross section and C fixed to the values of Table III are similar to those with the form factor, but with slightly larger variations of ρ and B as a function of $-t_{max}$.

In summary, we choose the form-factor cross section, Eq. (9), since it gives a good representation of the data and makes the determination of ρ less sensitive to the fitting range. A fit over a larger t interval increases the statistical certainty in ρ by increasing the certainty in the slope parameter.

B. The real parts

In Table IV we present the results of fitting the data with the form-factor cross section over the t ranges shown in Table V. The t range was the same for all six particles at a given momentum. The parameters ρ , u, and A_n were allowed to vary except at 70 GeV/c, where u was held constant. The value of u at 70 GeV/c was determined by fitting the values of u from higher momenta to the logarithmic function u_f given by

| Momentum (GeV/c) | t range [(GeV/c) ²] |
|---|---|
| +70 -70 +100 +125 -125 | $\begin{array}{c} 0.0018 {-} 0.0625 \\ 0.0018 {-} 0.0625 \\ 0.0016 {-} 0.1225 \\ 0.0015 {-} 0.1592 \\ 0.0015 {-} 0.1592 \end{array}$ |
| + 150 -150 +175 -175 +200 -200 | $\begin{array}{c} 0.0015 {-} 0.2025 \\ 0.0015 {-} 0.2025 \\ 0.0016 {-} 0.2500 \\ 0.0016 {-} 0.2500 \\ 0.0016 {-} 0.3600 \\ 0.0016 {-} 0.3600 \end{array}$ |

TABLE V. *t* ranges for the fits of Table IV.

$$u_f = a + b \ln(p_{\text{heam}}) . \tag{24}$$

The total cross section σ_{tot} was held fixed to the values of Carroll *et al.*³⁴

In Figs. 9(a)-9(f) the corrected-data and formfactor cross sections are compared over the full *t* range for all six particles at all six momenta. In Figs. 10(a)-10(f) we compare the data and form-factor cross sections divided by the formfactor cross section with $\rho = 0$ over the fitting interval.

Studies were made to determine the sensitivity of the results to variations of the more important cuts. Each of the first five cuts in Table II were made significantly more restrictive and were applied one at a time to both data and Monte Carlo distributions. New fits were made for all particles at all energies; the resulting values of ρ , u, and A_n were all within the statistical errors of our final results. We emphasize that the data for three particles of like charge at a given momentum had the same cuts applied. In addition only the veto cut varied significantly between momenta due to the changing veto size.

We believe that the normalization parameter A_n was needed to compensate for losses of beam events due to PWC inefficiencies. Although the Monte Carlo calculation simulated the *t*-dependent effects of these inefficiencies (Cut 6 in Table II), we had no reliable way of estimating these effects on the overall normalization. We expect that the values of A_n should then be the same for all three particles taken simultaneously. In Tables III and IV we see that the values of A_n are in good agreement for the like-charge particles at a given momentum. At 200 GeV/c the beam area was smallest and thus more sensitive to these corrections.

FIG. 9. $d\sigma/dt$ vs -t at all incident momenta for (a) pp, (b) π^*p , (c) K^*p , (d) $\overline{p}p$, (e) π^-p , and (f) K^-p elastic scattering. The solid line is the result of the fits given in Table IV. The cross sections have been multiplied by the indicated factor.

FIG. 9. (Continued)

Measurements were also made at 100 GeV/c with negative-charge particles. But because of problems during the data acquisition, we have not included them in our results.

In the fitting procedure we found that the statistical errors on ρ , u, and A_n are symmetric and parabolic and that the χ^2 contours are smooth and ellipsoidal. The dependence of ρ , u, and A_n on each other and other quantities are given by the derivatives in Table VI for the typical case of $\pi^* p$ scattering at 125 GeV/c. The derivatives $d\rho/du$, $d\rho/dA_n$, and du/dA_n were determined by fixing the parameter in the denominator to a different value and allowing the other two parameters to vary. The derivatives with respect to other quantities were determined by allowing all three

FIG. 10. $d\sigma/dt$ measured and $d\sigma/dt$ theoretical (solid line) divided by $d\sigma/dt$ theoretical, but with $\rho = 0$ for (a) pp, (b) π^*p , (c) K^*p , (d) \overline{pp} , (e) π^-p , and (f) K^-p . $d\sigma/dt$ theoretical is the form-factor cross section as parametrized in Table IV. The dashed line is to guide the eye.

parameters to vary. The values of these derivatives for each fit are given in Ref. 28. We found that $(d\rho/du)\sigma_u$ and $(d\rho/dA_n)\sigma_{An}$ comprise about half of the statistical error of ρ . Since the total cross sections have uncertainties between 0.1 to 0.25%, they contribute very little to the systematic error. The main contributions to the systematic errors come from the uncertainty of the absolute momentum ($\Delta p/p$ was about 0.3%) and the uncertainty of the target-empty subtraction (about 3.0%). The largest error to ρ from the momentum uncertainty occurs at 70 GeV/c where it is 0.008. The largest error on ρ due to the target-empty subtraction is 0.008 at 200 GeV/c. Typically the two errors add in quadrature to a 0.01 error in ρ . We believe the systematic errors are point to point, rather than scale shifts and are added quadratically with our statistical errors to give the total error. The statistical, systematic, and total errors for ρ and u are also included in Table IV.

D. Discussion

In Figs. 11(a)-11(f) we compare our values of ρ for all six reactions with previous measurements and various dispersion-relation predictions. For $\pi^* p$ the values of ρ are quite consistent with

FIG. 11. ρ as a function of momentum for (a) pp, (b) π^*p , (c) K^*p , (d) $\overline{p}p$, (e) π^-p , and (f) K^-p . The data are from Refs. 1-6, respectively, and from this experiment. The curves are dispersion-relation predictions from Refs. 24-27.

TABLE VII. Results of fitting the pp cross sections of Jenkins *et al.* with the form-factor formulation. The quantities ρ_J are from Jenkins *et al.*, while ρ_{ff} are from these fits.

^a The values of u were obtained from an $a + b \ln(momentum)$ fit to our values of u.

^bThe total cross sections used are those used by Jenkins *et al*.

the predictions of Hendrick *et al.* and Höhler *et al.*, while those of Lipkin are slightly low. However for $\pi^{-}p$ the values of ρ are more consistent with Lipkin, while those of Hendrick *et al.* and Höhler *et al.* seem a little high. For K^*p and K^-p the predictions of Hendrick *et al.* and Lipkin fit the data well, while the results of Dumbrajs are somewhat low. The predictions of Lipkin and Hendrick *et al.* are in very good agreement with the $\overline{p}p$ real parts.

Our pp results are higher than dispersion predictions and previous experimental results. We believe that this is due to the steeper slope we have measured in the forward direction. In order to verify this, we fit the data of Jenkins *et al.*¹ with the form-factor cross section. Since their *t* range is severely limited, we use the values of *u* given by the function u_f [Eq. (24)]. In Table VII we present the results of the fits, in which the χ^2 's are as good as with their exponential fits. In Fig. 12 we have plotted the refitted real parts

FIG. 12. ρ for pp elastic scattering versus momentum but with the differential cross sections of Jenkins *et al.*, Ref. 1, refitted (see text and Table VII).

of Jenkins *et al*. and see that they are in good agreement with our results.

On the other hand, we can fit our data at 200 GeV/c using the exponential cross section and the slope of Jenkins *et al.*, $B = 11.56 \pm 0.12 \, (\text{GeV}/c)^{-2}$. Our values of ρ are then consistent with their published results, but only if we use the limited trange $0.0016 \le -t \le 0.04 \ (\text{GeV}/c)^2$. If we extend the range of our fit to $-t_{max} = 0.09 (\text{GeV}/c)^2$, the steep fall off of our data forces ρ to be inconsistent. The slopes that Jenkins *et al.* use come from a logarithmic fit to a previous measurement³⁵ made in the range $0.005 \le -t \le 0.09 \ (\text{GeV}/c)^2$. To compare slopes we fit our data with the exponential cross section and C = 0.0 (GeV/c)⁻⁴ and $-t_{max}$ $=0.09 (GeV/c)^2$. We obtain $B=12.24\pm0.17 (GeV/c)^2$ c)⁻², which still leaves a discrepancy in the slope of 0.73 $(\text{GeV}/c)^{-2}$.

V. CONCLUSIONS

We find that the real parts for $\bar{p}p$, $\pi^* p$, $\pi^- p$, $K^* p$, and $K^- p$ are in good agreement with dispersion relations. The real parts for pp, however, are higher than dispersion relations and indicate that ρ_{pp} goes through zero near 175 GeV/c. Hendrick *et al.* point out that the contributions from pole terms and unphysical cuts for pp and $\bar{p}p$ scattering are still significant at these energies. Since the contributions are the same for both reactions, it is then puzzling to have such good agreement between our $\bar{p}p$ results and the dispersion relations of Hendrick *et al.* and Lipkin.

As derivative dispersion relations show, the real part at high energies becomes a local function of the total cross section. Specifically the real part is strongly correlated to the first derivative of the total cross section with respect to energy. This is reflected in the similarity of the different computations of dispersion relations even when they differ in their extrapolations to higher energies. Our results are consistent with increasing total cross sections for all six reactions. In particular, following the cross-section predictions of Lipkin, we expect the $\bar{p}p$ total cross section to start increasing in the neighborhood of 300 GeV/c.
