We evaluate the Kobayashi-Maskawa (KM) matrix using a maximum-likelihood method which takes into account experimental errors on input data and "systematic errors" associated with theoretical approximations. We carefully reconsider the constraints from meson decays and mixings as well as *CP* violation. We derive values for all matrix elements with errors smaller than 0.008, show that the ratio $|U_{ub}/U_{cb}|$ must be bigger than 0.036, and that the phase angle δ of the KM representation is smaller than π . Surprisingly our conclusions depend very weakly on the value of the top-quark mass. Any experiment violating the constraints of our fitted KM matrix would imply physics beyond the standard model with three generations and a minimal Higgs sector.

In the past three years our knowledge of meson mixing and CP violation has considerably progressed. On the experimental front $B_d^0 \overline{B}_d^0$ mixing has been firmly established, direct CP violation (ϵ') has been observed. Various experimental and theoretical bounds limit the mass of the top quark to the range 70-200 GeV. On the theoretical side we have witnessed progress in calculating longdistance weak-interaction parameters using lattice techniques and the $1/N_c$ expansion. We reassess our knowledge of the minimal standard-model parameters in light of these developments.

The strategy that we use in our search for the structure of the Kobayashi-Maskawa (KM) matrix can be sketched as follows. The light-quark matrix elements $|U_{ud}|$ and $|U_{us}|$ are directly determined by data on superallowed nuclear β decays and K and hyperon decays. The rest of the Cabibbo matrix $|U_{cd}|$ and $|U_{cs}|$ will be determined to a higher precision from the unitarity of the matrix than from direct measurements. The rest of the matrix elements are determined from the data:

$$\Gamma_{B} \sim |U_{cb}|^{2} , \Delta m (B_{d}^{0} \overline{B}_{d}^{0}) \sim m_{t}^{2} |U_{tb} U_{td}^{*}|^{2} , \epsilon \sim m_{t}^{2} \mathrm{Im}[(U_{ts} U_{td}^{*})^{2}] + m_{c}^{2} \mathrm{Im}[(U_{cs} U_{cd}^{*})^{2}] , \epsilon' \sim (\mathrm{ln} m_{t}^{2})[\mathrm{Im}(U_{ts} U_{td}^{*})] .$$

The matrix elements are also restricted by unitarity; e.g., in the limit that all angles are small one can derive that

$$|U_{td}| = |U_{cb}| \left[s_1 + \frac{|U_{ub}|}{|U_{cb}|} \right] .$$
 (1)

Here s_1 is the Cabibbo angle.

We note that theoretical calculations of the quantities listed above are becoming more reliable. The bag parameters, which gave the biggest uncertainty, seem to be under control in lattice calculations, at least for the *B* mesons.¹ The $1/N_c$ expansion gives similar answers.² One can, thus, with a reasonable amount of confidence, use the method outlined above to derive limits on the KM matrix elements. As we want to establish reliable bounds, we shall exclude from our analysis data for which the theory is not under control.

Our main result is that the KM matrix elements are constrained to the intervals

$$U = \begin{bmatrix} 0.9748 - 0.9761 & 0.2173 - 0.2230 & 0.0013 - 0.008\\ 0.2169 - 0.2226 & 0.9734 - 0.9752 & 0.039 - 0.062\\ 0.004 - 0.020 & 0.037 - 0.060 & 0.9980 - 0.9992 \end{bmatrix}.$$
(2)

The intervals correspond to 2σ deviations from the fitted value. The phase δ must be less than π and $|U_{ub}|/|U_{cb}| > 0.036$. The latter result follows from the fact that ϵ is proportional to the KM angle $\sin\theta_3$. Nonvanishing values of ϵ prevent $\sin\theta_3$, and therefore $|U_{ub}|$, from vanishing. In the Wolfenstein parametrization³ Eq. (2) corresponds to the following parameter intervals, again at the 2σ level:

$$A = 0.94 - 2.6, \ \rho = 0.30 - 0.70, \ \eta = 0.14 - 0.53$$
 (3)

Our results have implications for further study of the weak interactions of *b*-flavored mesons. One can obtain constraints for $B_s^0 \overline{B}_s^0$ mixing $[\Delta m (B_s^0 \overline{B}_s^0) \sim m_t^2 | U_{tb} U_{ts}^*|^2]$ and *CP* violation in the *B* system, i.e., the asymmetry between like-sign dileptons from semileptonic decays of $B^0 \overline{B}^0$ pairs:

$$A_{B} = \frac{l^{+}l^{+} - l^{-}l^{-}}{l^{+}l^{+} + l^{-}l^{-}} \sim \frac{m_{c}^{2} \sin\delta}{m_{c}^{2}} .$$
 (4)

The observation of A_B will turn out to be extremely difficult as $\delta \simeq \pi$.

We want to stress here that our results will hold only in an $SU(2) \times U(1)$ model with three generations and a minimal Higgs sector. Slightly extended versions of the standard model, e.g., assuming a richer Higgs sector, could jeopardize the lower bound⁴ on m_t and modify the analysis of *B* mixing.⁵

The structure of this paper is as follows. First, optimistically taking the theoretical formalism at face value, we shall produce bounds on the various parameters and observables that occur in decays and mixing of B mesons and in CP violation. These limits should only be considered as best guesses. We shall refer to this approach in the following as case 1. We then consider the effect of theoretical uncertainties and produce absolute bounds, the violation of which would imply that new physics beyond the standard model is needed. This will constitute case 2. Throughout our analysis, we shall carefully define the probabilistic meaning of the produced limits. We discuss the input of our analysis next.

We use a mixing matrix which is unitary:

$$U = \begin{bmatrix} c_1 & -s_1c_3 & -s_1s_3 \\ s_1c_2 & c_1c_2c_3 - s_2s_3e^{i\delta} & c_1c_2s_3 + s_2c_3e^{i\delta} \\ s_1s_2 & c_1s_2c_3 + c_2s_3e^{i\delta} & c_1s_2s_3 + c_2c_3e^{i\delta} \end{bmatrix}.$$
 (5)

Given the awkwardness of the interpretation of the angles and phase, we shall later give bounds both for these and for the absolute values of the matrix elements themselves.

We first impose experimental bounds on the KM matrix elements from neutron⁶ and hyperon⁷ β -decay measurements, as well as from data on ν and $\overline{\nu}$ production of charm:⁸ $|U_{ud}|=0.9747\pm0.0011$, $|U_{us}|=0.2197\pm0.019$, and $|U_{cd}|=0.21\pm0.03$. In principle, one can also make use of the constraint⁹ $|U_{cs}|=0.96\pm0.12$ from $D \rightarrow Ke\nu$ (case 1), but this is not model independent, the absolute limit being $|U_{cs}| > 0.66$ (case 2).

The next two observables will be related to *B* physics. *B* mesons constitute a borderline case of the applicability of perturbative QCD. Nonperturbative corrections come from the fact that the quarks are bound within the meson (this is in principle measurable through the decay constant f_B) and from the possibility of bound intermediate states (this is parametrized by a bag parameter B_B). Apart from these factored corrections, which are in principle calculable through lattice calculations or by $1/N_c$ expansions, the dependence on other parameters should be well represented by perturbative calculations as momentum transfers are high.

Consider first the *B* meson width. Most of the theoretical complications can be avoided by considering the semileptonic decay width for which the final-state interactions are negligible. This quantity can then be related to the total *B* width via the measured semileptonic branching fraction $B_{\rm sl}$. Thus our first constraint will be

$$\Gamma_{B} = \frac{1}{B_{\rm sl}} \frac{|U_{cb}|^{2} G_{F}^{2} m_{b}^{5}}{192\pi^{2}} f\left(\frac{m_{c}}{m_{b}}\right) X_{\rm QCD}$$
$$= [(1.15 \pm 0.14) \text{ ps}]^{-1}, \qquad (6)$$

with $f(x)=1-8x^2+8x^6-24x^4\ln(x)$ a phase-space factor and

$$X_{\rm QCD} = 1 - \frac{2\alpha_s(\Lambda_{\rm QCD}; m_b^2)}{3\pi} (\pi^2 - \frac{25}{4})$$

a QCD correction factor. We use for Γ_B the value of Ref. 10: $(1.15\pm0.14)\times10^{-13}$ ps. Another value was published last year,¹¹ giving $\tau_B = (1.31\pm0.14)\times10^{-13}$ ps. We have checked that this ambiguity hardly affects the fit and the numbers we give are compatible with both τ_B values. The main uncertainty comes from the value of the bottom-quark mass which we shall allow to be in the range 4.6–5.0 GeV. The QCD corrections introduce $\Lambda_{\rm QCD}$, which we shall first restrict to the range 0.1–0.3 GeV (case 1), and then vary up to 0.4 GeV (case 2). The value of m_c enters in the phase-space corrections, but given the smallness of m_c/m_b its precise value is not too important. We shall allow it to range between its current value 1.25 GeV and its highest constituent value 1.8 GeV. Equation (6) also shows that the dependence on the heavy-quark mass makes any constraints from the *D* lifetime useless for our purpose.

The second quantity which we shall study will be the $B_d^0 \overline{B}_d^0$ mixing¹² parameter

$$\frac{\delta m}{\Gamma} = \left[\frac{G_F^2 m_B}{6\pi^2 \Gamma_B}\right] (B_B f_B^2) |V_{tb}^* V_{td}|^2 I\left[\frac{m_c}{m_t}\right] \eta_{\text{QCD}} .$$
(7)

The first factor introduces experimentally measured quantities; the second takes long-range corrections into account. The third factor depends on two unmeasured Kobayashi-Maksawa matrix elements. η_{QCD} is a QCD correction factor for which we use an exact result¹³ and, finally, I(x) is a phase-space factor¹⁴ that depends quadratically on m_t for large- m_t values. We take into account the new limits on the top-quark mass. UA2 has derived a new upper bound on m_t of the order of 180 GeV from electroweak radiative corrections.¹⁵ In case 1 we will assume that the bound is to 150 GeV, and take the conservative value 200 GeV in case 2. This is only to demonstrate that the exact value is not important. The new Collider Detector at Fermilab and UA2 results¹⁶ seem to indicate $m_t > 70$ GeV, a limit that we shall implement for both cases. As the dependence on m_W and m_B is small, no new parameter is introduced,¹⁷ except the product $B_B f_B^2$. Because of the smallness of momentum transfers, this quantity is not perturbatively calculable. The calculation of these long-range constants now seems to be under control in lattice studies as a result of the discovery of the CP-switching symmetry.¹ The bag parameter and the decay constant are calculated to be $B_B = 1.011 \pm 0.19$ and $f_B = 0.105 \pm 0.035$ GeV. This is in qualitative agreement with results from $1/N_c$ expansion² and from sum-rule methods,¹⁸ which give $B_B = \frac{3}{4}$ and $B_B f_h^2 = (0.115 \pm 0.015 \text{ GeV})^2$ and $(0.190 \pm 0.03 \text{ GeV})^2$, respectively. We choose here to implement the lattice OCD result as it is based on a more fundamental approach. This result, however, still uses a quenched approximation and involves as extrapolation to the B meson mass. It is therefore not totally reliable. We first choose

to combine the errors on f_B and B_B in quadrature and assume a Gaussian probability distribution (case 1: $f_B^2 B_B = 0.011 \pm 0.0095 \text{ GeV}^2$) and subsequently use only bounds with a flat probability (case 2: $0.0027 < f_B^2 B_B < 0.04 \text{ GeV}^2$).

In principle, one could include lepton distributions from semileptonic B decays. These can be used to determine the ratio $|U_{ub}|/|U_{cb}|$. We have shown¹⁹ however that, in the context of the Altarelli model,²⁰ the theory is arbitrary enough to accommodate values for that ratio as high as 0.21 whereas the usual bounds from this model are of the order of 0.14. This analysis has recently been confirmed and extended to other models.²¹ The CLEO Collaboration has performed a detailed analysis of their data,²² and their results $|U_{ub}| / |U_{cb}| < 0.14$, $|U_{cb}| = 0.044$ ± 0.010 will be considered in case 1. We shall assume the conservative bound $|U_{ub}|/|U_{cb}| < 0.21$ in case 2. Also, bounds on $|U_{ub}|/|U_{cb}|$ can in principle be drawn from the nonobservation of charmless B decays,²³ but the interpretation of the branching ratios is very uncertain, and bounds as high as 0.25 have been given.²⁴

Finally, we introduce the *CP*-violation parameters of the $K^{0}\overline{K}^{0}$ system in the analysis. As in the *B* mixing case, the long-range contributions can be factored out into a bag parameter B_{K} and a decay constant f_{K} , which has been measured to be 0.169 GeV. The kaon bag parameter is calculable on the lattice, but the result is much more uncertain due to the inapplicability of the *CP*switching symmetry. Gavela *et al.*²⁵ quote the estimate $B_{K}=0.86\pm0.11$. Large- N_{c} expansion gives² $B_{K}=\frac{2}{3}\pm0.1$ and two recent sum-rule estimates²⁶ yield $B_{K}=0.50\pm0.22$ and $B_{K}=0.58\pm0.16$. In case 1, we shall take the lattice estimate at face value, assuming that the probability distribution is Gaussian. In case 2 we shall be much more conservative and limit the value of B_{K} to the interval [0.3, 1.0].

The expression for ϵ is well known:²⁷

$$\epsilon \approx \left[\frac{e^{i\pi/4}}{2\sqrt{2}\Delta m} \right] \operatorname{Im}(\mathcal{M}_{\Delta S=2}) . \tag{8}$$

We here assumed that the $\Delta S = 2$ box diagram dominates the amplitude \mathcal{M} , which is proportional to $B_K f_K^2$, and made use of the fact that the contribution from CP violation in $K \rightarrow 2\pi$ decay is experimentally negligible. The mass difference of the $K^0 \overline{K}^0$ system Δm , for which nonperturbative contributions are not under control, is fortunately experimentally known to be 3.521 μ eV. The expression for \mathcal{M} is given in Ref. 27. It depends on m_c , m_b , m_t , and Λ_{QCD} and introduces the products $|U_{ts}U_{td}^*|^2$ and $|U_{cs}U_{cd}^*|^2$.

We then consider the direct CP-violation parameter²⁸ ϵ' . We limit ourselves to the leading contribution from the QCD penguin diagram and make use of the fact that for $K \rightarrow \pi\pi$ decay, the ratio $\operatorname{Re} A_2/\operatorname{Re} A_0$ is experimentally known to be $\approx \frac{1}{22}$. We so obtain

$$\frac{\epsilon'}{\epsilon} = -\frac{\operatorname{Re}A_2/\operatorname{Re}A_0}{|\epsilon|} \frac{c_2 s_2 s_3 \sin(\delta)}{c_1 c_3} H_p , \qquad (9)$$

with H_p the penguin height. The expression for H_p is given in Ref. 29. It depends on the same parameters as well as on an arbitrary hadronic scale μ which enters only via logarithms. We shall vary its value between 0.6 and 1 GeV. Another approach based on a $1/N_c$ expansion is discussed in the literature. All scales are fixed here, but the strong dependence on the strange-quark mass replaces the arbitrariness of our scale μ . We have checked numerically that for reasonable strange-quark masses it leads to the same results as Eq. (9).

Our various inputs, both for the parameter ranges and for the experimental values, are summarized in the first columns of Tables I and II. The problem thus amounts to fitting 10 observables q_i (i=1-10) to theoretical expressions $t_i(p_a)$ which contain 12 parameters p_a (a=1-12). The range of these parameters is constrained by theoretical arguments. Most previous studies have fixed some of the parameters to preferred values and then varied others to get "bounds" on them. This procedure has the advantage of simplifying the physical discussion, but the reliability of the produced bounds is questionable. We choose here to fit all the observables simultaneously and to let all the parameters vary in ranges tabulated in Table II. To get the best value for all q_i and p_a , we minimize a likelihood function. This function is normally defined by the probability density

$$L_{\theta} = \prod \exp\{[q_i - t_i(p_a)]/2\delta q_i\}^2.$$

We adopt the equivalent definition

$$L_1 = \left[\sum \left[\frac{q_i - t_i(p_a)}{\delta q_i} \right]^2 \right]^{1/2} . \tag{10}$$

The maximum of L_1 defines the best fit. To evaluate the errors, one should in principle calculate integrals such as

$$P_{\theta} = \int_{p_1}^{p_2} dp_b \int d^{11} p_a J L_{\theta} ,$$

with J a Jacobian, and from these subsequently calculate the probability for p_b to be in the interval $[p_1,p_2]$. These integrals are unfortunately extremely hard to evaluate numerically as L_{θ} is null in most regions of parameter space. A similar procedure should be adopted to calculate the constraints on the various q_i from the joint fit. Given these difficulties, we choose another procedure to define the various errors. We consider the quantity

$$\sigma_1 = \min_{p_a} (L_1 |_{p_b \in [p_1, p_2]}) , \qquad (11)$$

which is the minimum of the likelihood function for p_b in the interval $[p_1, p_2]$. As the observables are independently measured, the probabilistic significance of σ_1 is the same as that of the usual standard deviation. However, this definition is not totally satisfactory as a fit with all quantities away from their central value by an amount δq_i is equivalent to a fit where one of them is off by $\sqrt{10\delta q_i}$. One does not want a large number of good fits to cover up a large discrepancy for a single quantity. We shall thus also use the alternative likelihood function

TABLE I. Allowed ranges of observables. The signification of σ is explained in the text. In the last two columns the top values refer to absolute bounds, the second line to our best estimate.

$$L_2 = \max_{P_a} \left[\frac{|q_i - t_i(p_a)|}{\delta q_i} \right]$$
(12)

and the corresponding standard deviation

$$\sigma_2 = \min_{p_a} (L_2|_{p_b \in [p_1, p_2]}) .$$
(13)

As a disagreement of 1 standard deviation on all q_i would not lead to a problem at the 3σ level, we shall adopt this second approach to evaluate absolute bounds (case 2). The first approach, which takes into account all the q_i simultaneously, is in principle superior and will be used in case 1.

Case 1 is an elaborate version of the usual analysis proposed by many authors for the analysis of $B\overline{B}$ mixing and gives the region of parameter space where the theory would be most comfortable. Case 2 is derived from our own work on $B\overline{B}$ mixing^{14, 19, 30} which does not lead to any significant lower bound on the top-quark mass. If this kind of analysis were to disagree with experimental results, we feel that there would be a serious problem for the standard model.

The bounds for both cases are shown in Tables I and

II. We stress that these limits hold individually for each quantity; e.g., it is not true that if all parameters but one are fixed to their best fit value, the error will be as indicated. Likewise, the best fit is given only as an indication and is not compelling in a strict statistical sense. We should mention that there is no perfect fit. The minimum number of standard deviations, σ , is always bigger than 0.8 in case 1 and 0.5 in case 2. This is due to the value of $|U_{ud}|$ which is always fitted slightly higher than its measured mean. We have already given in Eq. (2) the bounds on the KM matrix elements, corresponding to case 1. We want to emphasize that the smallness of the values of $|U_{ub}|/|U_{cb}|$ allowed at present is of the order of 0.03 and almost any value within the present experimental limits can be accommodated.

As an example of the power and use of our fit, we compare our results for $|V_{cd}/V_{cs}|^2$ with a recent Mark III results.³¹ Neglecting theoretical uncertainties, they obtain $|V_{cd}/V_{cs}|^2=0.41-0.095$ at the 1σ level, with a central value of 0.059. Our fits give $|V_{cd}/V_{cs}|^2=0.049-0.052$ (0.048-0.053) at the 2σ level in case 1 and (2) which are compatible with the Mark III bounds and can be used to constrain the theoretical uncertainties of their analysis.

We can translate these results into the Wolfenstein parametrization [see Eq. (3)]. Our phase convention gives³²

TABLE II. Allowed ranges of the input parameters. The signification of σ is explained in the text. In the last two columns the top values refer to absolute bounds, the second line to our best estimate.

$$U = \begin{bmatrix} 1 - \frac{\lambda^2}{2} & -\lambda & -A\lambda^3 \sqrt{\rho^2 + \eta^2} \\ \lambda & 1 - \frac{\lambda^2}{2} & \frac{A\lambda^2(\rho + i\eta)}{\sqrt{\rho^2 + \eta^2}} \\ A\lambda^3 \sqrt{(1-\rho)^2 + \eta^2} & \frac{A\lambda^2(1-\rho + i\eta)}{\sqrt{(1-\rho)^2 + \eta^2}} & -e^{i\delta} \end{bmatrix}$$

We obtain the following formulas for λ , A, ρ , and η :

$$\lambda = s_1$$
, (1)

$$A^{2} = \frac{s_{2}^{2} + s_{3}^{2} + 2\sqrt{1 - \sin^{2}(\delta)}s_{2}s_{3}}{s_{3}^{4}} , \qquad (15b)$$

$$p = \frac{s_3[s_2\sqrt{1-\sin^2(\delta)}+s_3]}{s_2^2+s_3^2+2\sqrt{1-\sin^2(\delta)}s_2s_3},$$
 (15c)

$$\eta = \frac{s_3 s_2 \sin(\delta)}{s_2^2 + s_3^2 + 2\sqrt{1 - \sin^2(\delta)} s_2 s_3} .$$
(15d)

Translating our fits in term of these parameters gives, at the 2σ level, A = 0.94-4.8 (0.94-2.6), $\rho = 0.26-0.87$ (0.30-0.70), and $\eta = 0.08-0.6$ (0.14-0.53), with the numbers in parentheses for case 1 and the others for case 2.

CP violation can be described by a parametrizationinvariant quantity J, proportional to the area of the unitary triangles.³³ With our choice (5), this quantity becomes

5a)

$$J = s_1^2 s_2 s_3 c_1 c_2 \sin(\delta) .$$
 (16)

We obtain $J = 1.14 \times 10^{-5}$ to 3.54×10^{-5} (6.97×10⁻⁶ to 4.23×10^{-5}) at the 2σ level in case 1 (2).

We now examine the various ways through which these results might be improved. First, the bounds of Table I can be used backwards; i.e., they give the precision which should be aimed at to improve our knowledge of (10). Accordingly, a measurement of $|U_{ub}/U_{cb}|$ at the level claimed last year at ARGUS would help. $B\overline{B}$ mixing would need to be measured at the 5% level and ϵ'/ϵ at the 20% level. Similarly, the error on ϵ should be reduced by a factor of 3. As far as the parameters of the theory are concerned, very little improvement from experimental inputs can now be expected. Conversely, our determination of the KM matrix is insensitive to the precise value of m_t . We have checked this fact by repeating the above procedure for case 2 with the top-quark mass fixed at 110 GeV. The resulting

(14)

HOW WELL DO WE KNOW THE KOBAYASHI-MASKAWA MATRIX?

bounds are the same, showing improvement only at the 1% level, except for $|U_{td}|$ which would be restrained by the interval [0.0048, 0.0123] at the 2σ level.

We can also translate our results into definite bounds on quantities so far unobserved. For B_s mixing, we use the fact that

$$\Delta m (B_s^0 \overline{B}_s^0) = \frac{|U_{ts}|^2}{|U_{td}^*|^2} \Delta m (B_d^0 \overline{B}_d^0) .$$
(17)

The values we obtain are high: at the 2σ level, $\Delta m (B_s^0 \overline{B}_s^0) / \Gamma = 3.6-42$ (3.4-136), the first interval being in case 1 and the second in case 2. These results can be modified by differences in the long-range constants B, f_B for $(b\overline{s})$ and $(b\overline{d})$ mesons.

We also consider the *CP*-violating asymmetry in *B* decays:

$$A_{B} = \frac{N(l^{+}l^{+}) - N(l^{-}l^{-})}{N(l^{+}l^{+}) + N(l^{-}l^{-})} = \frac{\rho - 1/\rho}{\rho + 1/\rho}$$
(18)

with $\rho = |(M_{12}^* - i\Gamma_{12}^*/2)/(M_{12} - i\Gamma_{12}/2)|$. The formulas for M_{12} and Γ_{12} are well known³⁴ and lead to the following conclusions: A_B is negative and, at the 2σ level, $A_B = -1.33 \times 10^{-3}$ to -5.8×10^{-5} (-2.4×10^{-3} to -2.0×10^{-5}) for case 1 (2). A measurement of a positive A_B , or of any value outside the previous bounds, would endanger the standard model.

Finally, we can utilize the approach of case 2 to see if some parametrizations of the KM matrix are now ruled out. We illustrate this using the Fritzsch parametrization

of the KM matrix.³⁵ It implies that

$$s_1 = |\sqrt{m_d / m_s} + e^{i\delta} \sqrt{m_u / m_c}|$$
, (19a)

$$s_2 = \frac{|\sqrt{m_d/m_s}|}{s_1} r$$
, (19b)

$$s_3 = \frac{|\sqrt{m_u/m_c}|}{s_1}$$
, (19c)

$$r \approx |\sqrt{m_c / m_t} + e^{i(\delta + \tau)} \sqrt{m_s / m_b}| , \qquad (19d)$$

with τ an arbitrary phase. We fixed the ratios of quark masses as in Ref. 32 except for m_c/m_t which results from our fit. If we take these relations at face value, then the model is excluded at the 2.2 σ level in case 2. If we allow Eqs. (19) to reproduce the KM matrix elements within 10%, then the model is allowed, and we get an upper bound $m_t < 117$ GeV at the 2σ level.³⁶

In conclusion, we have presented here precise bounds within which the standard model remains valid and thus given the precision which the experiments should aim at to reveal new physics, or to submit the electroweak theory to its most stringent tests.
