ν_2 MAGNETIC MOMENT

Must vanish for Majorana neutrino or purely chiral massless Dirac neutrino. The value of the magnetic moment for the standard SU(2)×U(1) elec-The value of the Magliett model to the Standard SO(2)×O(1) electroweak theory extended to include massive neutrinos (see FUJIKAWA 80) is $\mu_{\nu}=3eG_{F}m_{\nu}/(8\pi^{2}\sqrt{2})=(3.2\times 10^{-19})m_{\nu}\mu_{B}$ where m_{ν} is in eV and $\mu_{B}=e\hbar/2m_{e}$ is the Bohr magneton. Given the upper bound $m_{\nu_{2}}<0.17$ MeV, it follows that for the extended standard electroweak theory, $\mu(\nu_{2})<0.51\times 10^{-13}~\mu_{B}$.

NONSTANDARD CONTRIBUTIONS TO NEUTRINO SCATTERING

We report limits on the so-called neutrino charge radius squared in this section. This quantity is not an observable, physical quantity and this is reflected in the fact that it is gauge dependent (see LEE 77C). It is not necessarily positive. A more general interpretation of the experimental results is that they are limits on certain nonstandard contributions to neutrino scattering.

 $J = \frac{1}{2}$

Existence indirectly established from au decay data combined with u reaction data. See for example FELDMAN 81. ALBRECHT 92Q rules out J=3/2 by establishing that the ρ^- is not in a pure $H_{\rho}{=}{-}1$ helicity state in $\tau^- \rightarrow \rho^- \nu_{\tau}$.

Not in general a mass eigenstate. See note on neutrinos in the ν_{e} section above.

ν_{τ} MASS

Applies to ν_3 , the primary mass eigenstate in ν_{τ} . Would also apply to any other ν_i which mixes strongly in ν_{τ} and has sufficiently small mass that it can occur in the respective decays. (This would be nontrivial only for a hypothetical $j \geq 4$, given the ν_e and ν_μ mass limits above.) See also the Listings in the Neutrino Bounds from Astrophysics and Cosmology section.

- 1 BUSKULIC 95H bound comes from a two-dimensional fit of the visible energy and invariant mass distribution of $\tau\to 5\pi (\pi^0)\nu_\tau$ decays. 2 AKERS 95D bound comes from analysis of $\tau^-\to 3\pi^-2\pi^+\nu_\tau$ decay mode.
- ³ DOLGOV 95 removes earlier assumptions (DOLGOV 93) about thermal equilibrium below T_{QCD} for wrong-helicity Divac neutrinos (ENQVIST 93, FULLER 91) to set more stringent limits.
- 4 SIGL 95 exclude massive Dirac or Majorana neutrinos with lifetimes between 10^{-3} and 10^8 seconds if the decay products are predominantly γ or $e^+\,e^-$
- 10° seconds if the decay products are predominantly γ or e · e · .

 5 DODELSON 94 calculate constraints on ν_τ mass and lifetime from nucleosynthesis for 4 generic decay modes. Limits depend strongly on decay mode. Quoted limit is valid for all decay modes of Majorana neutrinos with lifetime greater than about 300 s. For Dirac neutrinos limits change to < 0.3 or > 33.

 6 KAWASAKI 94 excluded region is for Majorana neutrino with lifetime > 1000 s. Other
- limits are given as a function of $u_{ au}$ lifetime for decays of the type $u_{ au}
 ightarrow
 u_{\mu} \phi$ where ϕ
- 7 BALEST 93 derive limit by comparing their m_{τ} measurement (which depends on $m_{\nu_-})$ to BAI 92 and BACINO 788 m_{τ} threshold measurements.
- 8 CINABRO 93 bound comes from analysis of au^{-} \rightarrow 3 π^- 2 π^+ ν_{τ} and $\tau^ \rightarrow$ $2\pi^-\pi^+2\pi^0\,
 u_ au$ decay modes.
- 9 DOLGOV 93 assumes neutrino lifetime >100 s. For Majorana neutrinos, the low mass limit is 0.5 MeV. KAWANO 92 points out that these bounds can be overcome for a Dirac
- imit is 0.5 MeV. NAWAND 92 points out that these bounds can be overcome for a Dirac neutrino if it possesses a magnetic moment.

 10 ENQVIST 93 bases limit on the fact that thermalized wrong-helicity Dirac neutrinos would speed up expansion of early universe, thus reducing the primordial abundance. FULLER 91 exploits the same mechanism but in the older calculation obtains a larger production rate for these states, and hence a lower limit. Neutrino lifetime assumed to exceed nucleosynthesis time. \sim 1 s.
- 11 MAYLE 93 recalculates cooling rate enhancement by escape of wrong-helicity Dirac neutrinos using the Livermore Supernova Explosion Code, obtains more restrictive result than the "very conservative" BURROWS 92 limit because of higher core temperature.
- 12 There would be an increased SN 1987A cooling rate if Dirac neutrino mass is included; this does not apply for Majorana neutrinos. Limit is on $\sqrt{m^2_{~\nu_{\mu}} + m^2_{~\nu_{\tau}}}$, and error becomes very large if ν_{τ} is nonrelativistic, which occurs near the lab limit of 31 MeV. RAJPOOT 93 notes that limit could be evaded with new physics.
- 13 ALBRECHT 92M reports measurement of a slightly lower au mass, which has the effect of reducing the $u_{ au}$ mass reported in ALBRECHT 88B. Bound is from analysis of $au^ 3\pi^-2\pi^+\nu_{\tau}$ mode. 14 BURROWS 92 limit for Dirac neutrinos only.
- 15 Assumes neutrino lifetime >1 s. For Dirac neutrinos. See also ENQVIST 93.
- 19 Assumes neutrino litetime >1 s. For Dirac neutrinos. See also ENQVIS1 y3. 16 KOLB 91 exclusion region is for Dirac neutrino with lifetime >1 s; other limits are given. 17 NATALE 91 published result multiplied by $\sqrt{8}\sqrt{4}$ at the advice of the author. 18 GRIFOLS 90B estimated error is a factor of 3. 19 GAEMERS 89 published result (< 0.03) corrected via the GANDHI 91 erratum.

ν_3 (MEAN LIFE) / MASS

These limits often apply to ν_{μ} (ν_2) also.

- 20 SIGL 95 exclude 1 s $\lesssim \tau \lesssim 10^8$ s for MeV-mass τ nuetrinos from SN 1987A decaying radiatively, and eliminates the lower limit using other published results. 21 BLUDMAN 92 sets additional limits by this method for higher mass ranges. Cosmological
- limits are also obtained.
- limits are also obtained. 22 Nonobservation of γ 's in coincidence with ν 's from SN 1987A. Results should be divided by the $\tau_{\nu} \to \gamma {\rm X}$ branching ratio.
- 23 DODELSON 92 range is for wrong-helicity keV mass Dirac ν 's from the core of neutron star in SN 1987A decaying to ν 's that would have interacted in KAM2 or IMB detectors.
- 24 GRANEK 91 considers heavy neutrino decays to $\gamma\nu_L$ and $3\nu_L$, where m_{ν_l} <100 keV. Lifetime is calculated as a function of heavy neutrino mass, branching ratio into $\gamma\nu_L$,
- $^{25}\,\rm WALKER$ 90 uses SN 1987A γ flux limits after 289 days to find $m_{\tau}~>~1.1\times 10^{15}\,\rm eV\,s.$
- 26 CHUPP 89 should be multiplied by a branching ratio (about 1) and a detection efficiency (about 1/4), and pertains to radiative decay of any neutrino to a lighter or sterile neutrino. 27 TERASAWA 88 finds only $10^2 < \tau < 10^4$ allowed for 30–70 MeV ν 's from primordal
- 28 KAWASAKI 86 concludes that light elements in primordal nucleosynthesis would be destroyed by radiative decay of neutrinos with 10 MeV $<\!m_{\nu}<\!1$ GeV unless $\tau\lesssim10^4\,\mathrm{s}.$
- ²⁹LINDLEY 85 considers destruction of cosmologically-produced light elements, and finds
- The considers destination of cosmologically-produced in the elements, and finds $\tau < 2 \times 10^3$ s for 10 MeV $< m_{\nu} < 100$ MeV. See also LINDLEY 79.

 30 BINETRUY 84 finds $\tau < 10^8$ s for neutrinos in a radiation-dominated universe. 31 SARKAR 84 finds $\tau < 20$ s at $m_{\nu} = 10$ MeV, with higher limits for other m_{ν} , and claims that all masses between 1 MeV and 50 MeV are ruled out.
- 32 HENRY 81 uses UV flux from clusters of galaxies to find $au > 1.1 imes 10^{25} ext{ s}$ for radiative
- adecay. 33 KIMBLE 81 uses extreme UV flux limits to find $\tau>10^{22}-10^{23}$ s. 34 REPHAELI 81 consider ν decay γ effect on neutral H in early universe; based on M31 HI concludes $\tau>10^{24}$ s. 35 DERUJULA 80 finds $\tau>3\times10^{23}$ s based on CDM neutrino decay contribution to UV
- 36 STECKER 80 limit based on UV background; result given is $\tau > 4 \times 10^{22}\,\mathrm{s}$ at $m_{\nu} = 20\,$
- 37 DICUS 78 considers effect of ν decay photons on light-element production, and finds lifetime must be less than "hours." See also DICUS 77.

 38 FALK 78 finds lifetime constraints based on supernova energetics.
- 39 COWSIK 77 considers varity of scenarios. For neutrinos produced in the big bang, present limits on optical photon flux require $\tau>10^{23}\,\mathrm{s}$ for $m_{\nu}\sim 1$ eV. See also COWSIK 79 and GOLDMAN 79.

ν₃ MAGNETIC MOMENT

Must vanish for Majorana neutrino or purely chiral massless Dirac neutrino. The value of the magnetic moment for the standard $SU(2) \times U(1)$ electroweak theory extended to include massive neutrinos (see FUJIKAWA 80) is $\mu_{\nu}=3eG_Fm_{\nu}/(8\pi^2\sqrt{2})=(3.20\times 10^{-19})m_{\nu}\mu_B$ where m_{ν} is in eV and $\mu_B=e\hbar/2m_e$ is the Bohr magneton. Given the upper bound $m_{\nu_3}<35$ MeV, it follows that for the extended standard electroweak theory, $\mu(\nu_3)<1.1\times 10^{-11}~\mu_B$.

Lepton Particle Listings

Number of Light Neutrino Types

Number of Light Neutrino Types

The neutrinos referred to in this section are those of the Standard SU(2)×U(1) Electroweak Model possibly extended to allow nonzero neutrino masses. Light neutrinos are those with $m_{\nu} < m_{Z}/2$. The limits are on the number of neutrino families or species, including

THE NUMBER OF LIGHT NEUTRINO TYPES FROM COLLIDER EXPERIMENTS

(by Dean Karlen, Carleton University)

The most precise measurements of the number of light neutrino types, N_{ν} , come from studies of Z production in e^+e^- collisions. At the time of this report, the most recent combined analysis of the four LEP experiments [1] included nearly 8 million visible Z decays. The invisible partial width, $\Gamma_{\rm inv}$, is determined from these data by subtracting the measured visible partial widths, corresponding to Z decays into quarks and charged leptons, from the total Z width. The invisible width is assumed to be due to N_{ν} light neutrino species each contributing the neutrino partial width Γ_{ν} as given by the Standard Model. In order to reduce the model dependence, the Standard Model value for the ratio of the neutrino to charged leptonic partial widths, $(\Gamma_{\nu}/\Gamma_{\ell})_{SM} = 1.992$, is used instead of $(\Gamma_{\nu})_{\rm SM}$ to determine the number of light neutrino types:

$$N_{\nu} = \frac{\Gamma_{\rm inv}}{\Gamma_{\ell}} \left(\frac{\Gamma_{\ell}}{\Gamma_{\nu}} \right)_{\rm SM}$$

The combined LEP result is $N_{\nu} = 2.991 \pm 0.016$.

In the past, when only small samples of Z decays had been recorded by the LEP experiments and by the Mark II at SLC, the uncertainty in N_{ν} was reduced by using Standard Model fits to the measured hadronic cross sections at several centerof-mass energies near the Z resonance. Since this method is much more dependent on the Standard Model, the approach described above is favored.

Before the advent of the SLC and LEP, limits on the number of neutrino generations were placed by experiments at lower-energy e^+e^- colliders by measuring the cross section of the process $e^+e^- \to \nu \overline{\nu} \gamma$. The ASP, CELLO, MAC, MARK J, and VENUS experiments observed a total of 3.9 events above background [2], leading to a 95% CL limit of N_{ν} < 4.8. This process has a much larger cross section at center-of-mass energies near the Z mass and has been measured at LEP by the ALEPH, L3, and OPAL experiments [3]. Each experiment has observed several hundred of these events, and the combined result is $N_{\nu} = 3.09 \pm 0.13$.

Experiments at $p\bar{p}$ colliders also placed limits on N_{ν} by determining the total Z width from the observed ratio of $W^{\pm} \to \ell^{\pm} \nu$ to $Z \to \ell^{+} \ell^{-}$ events [4]. This involved a calculation that assumed Standard Model values for the total W width and the ratio of W and Z leptonic partial widths, and used an estimate of the ratio of Z to W production cross sections. Now that the Z width is very precisely known from the LEP experiments, the approach is now one of those used to determine the W width.

Massive Neutrinos and Lepton Mixing, Searches for

Searches for massive neutral leptons and the effects of nonzero neutrino masses are listed here. These results are divided into the following main sections:

- A. Heavy neutral lepton mass limits;
- B. Sum of neutrino masses;
- C. Searches for neutrinoless double- β decay (see the note by P. Vogel on "Searches for neutrinoless double- β decay" preceding this section);
- D. Other bounds from nuclear and particle decays;
- E. Bounds from particle decays;
- F. Solar ν experiments (see the note on "Solar Neutrinos" by K. Nakamura preceding this section);
- G. Astrophysical neutrino observations;
- H. Reactor $\overline{\nu}_e$ disappearance experiments;
- I. Accelerator neutrino appearance experiments;
- J. Disappearance experiments with accelerator and radioactive source neutrinos.

Direct searches for masses of dominantly coupled neutrinos are listed in the appropriate section on ν_e , ν_μ , or ν_τ . Searches for massive charged leptons are given elsewhere, and searches for the mixing of (μ^-e^+) and (μ^+e^-) are given in the muon listings.

Discussion of the ν_e and ν_μ mass limits and the theory of mixing are given in the note on "Neutrinos" by R.E. Shrock in the ν_e section near the beginning of these Particle Listings. Several reviews are also listed there.

Most of the results of the present section are correlated upper bounds on mixing matrix coefficients U_{aj} versus neutrino mass. In some of these cases (e.g. accelerator neutrino oscillation experiments), results are presented assuming that mixing occurs only between two neutrino species. In this case limits or results can be shown as allowed regions on a plot of $|\Delta m^2|$ as a function of $\sin^2 2\theta$, where $\Delta m^2 = m_{\nu_i}^2 - m_{\nu_j}^2$. Although there are three flavors, data are usually analyzed assuming an oscillation between just two of them, e.g., $\nu_{\tau} \leftrightarrow \nu_{e}$. The same remark applies to lepton-number violating mixing between two

states, e.g., $\nu_e \leftrightarrow \overline{\nu}_{\mu}$ or $\nu_{\mu} \leftrightarrow \overline{\nu}_{\mu}$. However, in a comprehensive analysis of all current data on limits on (or positive reports of) neutrino oscillations, one should use a three-generation mixing framework.

The simplest situation occurs in an "appearance" experiment, where one searches for interactions by neutrinos of a variety not expected in the beam. An example is the search for $\overline{\nu}_e$ interactions in a beam of neutrinos from the π^+ decay chain, which (among other possibilities) might be taken as evidence for $\overline{\nu}_{\mu} \to \overline{\nu}_{e}$. For oscillation between two states, the probability that the "wrong" state will appear is given by Eq. 5 in Shrock's "Note on Neutrinos" at the beginning of the Quark and Lepton Particle Listings. For our present purposes, this may be rewritten as

$$P = \sin^2 2\theta \, \sin^2(1.27\Delta m^2 L/E) \,, \tag{1}$$

where L is the distance from the neutrino's production point to its interaction point, and E is its energy. In the above, $|\Delta m^2|$ is in eV² and L/E is in km/GeV or m/MeV. Since in a real experiment L and E have some spread, one must average P over the appropriate distributions. As an example, let us make the somewhat unrealistic assumption that $b \equiv 1.27L/E$ has a Gaussian distribution with standard deviation σ_b about a central value b_0 . Then:

$$\langle P \rangle = \frac{1}{2} \sin^2 2\theta [1 - \cos(2b_0 \Delta m^2) \exp(-2\sigma_b^2 (\Delta m^2)^2)] \tag{2}$$

The value of $\langle P \rangle$ is set by the experiment. For example, if 230 interactions of the expected flavor are detected and none of the wrong flavor are seen, then P=0.010 at the 90% CL. We can then solve the above expression for $\sin^2 2\theta$ as a function of $|\Delta m^2|$. This function is shown in Fig. 1 for the parameter assumptions given in the caption. Note that:

- (a) since the fast oscillations are completely washed out by the resolution for large $|\Delta m^2|$, $\sin^2 2\theta = 2 \langle P \rangle$ in this region;
- (b) the maximum excursion to the left is to approximately $\langle P \rangle$, and it occurs at $|\Delta m^2| = \pi/2b_0 \text{ eV}^2$;
- (c) for large $\sin^2 2\theta$, $\Delta m^2 \propto (\sin^2 2\theta)^{-1/2}$; and
- (d) the intercept at $\sin^2 2\theta = 1$ is at $\sqrt{\langle P \rangle}/b_0$.

The intercept for large $|\Delta m^2|$ is just a measure of running time and backgrounds, while the intercept at $\sin^2 2\theta = 1$ also depends on the mean value of L/E. The wiggles depend on the experimental resolution, but aside from such details the two intercepts completely describe the exclusion region: For large $|\Delta m^2|$, $\sin^2 2\theta$ is constant, and for large $\sin^2 2\theta$ the constant slope is known. For these reasons, it is (nearly) sufficient to summarize the results of an experiment by stating the two intercepts, as is done in the following tables. The reader is referred to the original papers for the two-dimensional plots expressing the actual limits.

Lepton Particle Listings

Massive Neutrinos and Lepton Mixing

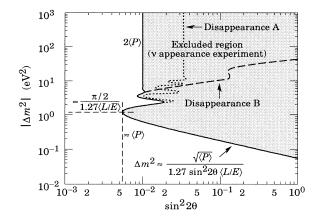

Figure 1: Neutrino oscillation parameter ranges excluded by a toy experiment in which one searches for the appearance of neutrinos not expected in the beam. The probability of appearance, in this case 0.5% at some specified CL, is set by the number of right-flavor events observed and/or information about the flux and cross sections. Here it is assumed that $\langle L/E \rangle = 1$ km GeV⁻¹, and that the distribution of L/E is Gaussian with a 20% standard deviation. The wiggle structure is determined by the resolution function, and the intercepts are determined by the appearance probability and $\langle L/E \rangle$. The leftmost excursion relative to the high- $|\Delta m^2|$ limit and the slope of the lower part of the curve are independent of the experiment. In a disappearance experiment, high- $|\Delta m^2|$ sensitivity is lost unless the incident flux is known. These two possibilities are shown qualitatively by the dashed lines marked "Disappearance A" and "Disappearance B."

If a positive effect is claimed, then the excluded region becomes an included region. This is the case for the HIRATA 92 analysis of $R(\mu/e)$ for atmospheric neutrinos.

In a "disappearance" experiment, one looks for the attenuation of the beam neutrinos (for example, ν_k) by mixing with at least one other neutrino eigenstate. (We label such experiments as $\nu_k \not\rightarrow \nu_k$.) These experiments fall into two general classes:

(a) Those in which the beam neutrino flux is known, from theory or other measurements. In the high- $|\Delta m^2|$ region, where the oscillation length is small compared to the size of the apparatus, the oscillations are in both directions and the beam intensity is reduced by a factor of two (for two-component mixing). In this case, indicated qualitatively by the "Disappearance A" curve in Fig. 1. sensitivity is maintained for large $|\Delta m^2|$, but with no simple rule relating this asymptote to the maximum excursion to the left. An example is provided by the VUILLEUMIER 82 measurements at the Gösgen reactor.

(b) Those in which the intensity must be measured in the apparatus itself (two detectors, or a "long" detector). Then above some minimum $|\Delta m^2|$ the equilibrium is established upstream, and there is no change in intensity over the length of the apparatus. As a result, sensitivity is lost at high $|\Delta m^2|$, as is qualitatively indicated by the curve "Disappearance B" in Fig. 1. See, for example, DYDAK 84.

Finally, there are more complicated cases, such as in the HIRATA 92B analysis of the Kamiokande II solar neutrino data in terms of the MSW parameters. An irregular region on the $|\Delta m^2|$ vs $\sin^2 2\theta$ is excluded for a combination of physical reasons. It is difficult to represent adequately these graphical data within the strictures of our tables.

(A) Heavy neutral leptons

Stable Neutral Heavy Lepton MASS LIMITS ——

 1 ADEVA 90s limits for the heavy neutrino apply if the mixing with the charged leptons satisfies $|U_1j|^2+|U_2j|^2+|U_3j|^2>6.2\times10^{-8}$ at $m_{L^0}=$ 20 GeV and $>5.1\times10^{-10}$ for $m_{L^0}=$ 40 GeV.

Neutral Heavy Lepton MASS LIMITS

Limits apply only to heavy lepton type given in comment at right of data Listings. See review above for description of types.

Massive Neutrinos and Lepton Mixing

- 2 ADRIANI 92I is a search for isosinglet heavy lepton N_ℓ which might be produced from $Z\to\nu_\ell\,N_\ell$, then decay via a number of different channels. Limits are weaker for decay lengths longer than about 1 m.
- 3 ADEVA 90s limits for the heavy neutrino apply if the mixing with the charged leptons satisfies $|U_1j|^2 + |U_2j|^2 + |U_3j|^2 > 6.2 \times 10^{-8}$ at $m_{L^0} = 20$ GeV and $> 5.1 \times 10^{-10}$ for $m_{L^0} = 40$ GeV.
- 4 AKRAWY 90L limits valid if coupling strength is greater than a mass-dependent value, e.g., 4.9×10^{-7} at $m_{L^0}=20$ GeV, 3.5×10^{-8} at 30 GeV, 4×10^{-9} at 40 GeV.
- ⁵ ABREU 92B limit is for mixing matrix element ≈ 1 for coupling to e or μ . Reduced somewhat for coupling to τ , increased somewhat for smaller mixing matrix element. Replaces ABREU 91F.
- ⁶ Limits apply for $\ell=e,\,\mu,\,$ or au and for $V\!-\!A$ decays of Dirac neutrinos.
- 7 BURCHAT 90 searched for Z decay to unstable L^0 pairs at SLC. It includes the analyses reported in JUNG 90, ABRAMS 89C, and WENDT 87.
- ⁸ For 25 $< m_{I^0} <$ 42.7 GeV, DECAMP 90F exclude an L^0 for all values of $|U_{\ell\,\hat{I}}|^2$.
- 9 SHAW 89 also excludes the mass region from 8.0 to 27.2 GeV for Dirac L^0 and from 8.1 to 23.6 GeV for Majorana L^0 with equal full-strength couplings to e and μ . SHAW 89
- to 23.8 SeV for Majorana L^{-} with equal full-strength couplings to e and μ . Shaw 89 also gives correlated bounds on lepton mixing. 10 AKERLOF 88 is PEP e^+e^- experiment at $E_{\rm cm}=29$ GeV. The L^0 is assumed to decay via V-A to e or μ or τ plus a virtual W. 11 MISHRA 87 is Fermilab neutrino experiment looking for either dimuon or double vertex
- events (hence long-lived).
- 12 WENDT 87 is MARK-II search at PEP for heavy u with decay length 1–20 cm (hence
- long-inved). 13 BADIER 86 is a search for a long-lived penetrating sequential lepton produced in π^-- nucleon collisions with lifetimes in the range from $5\times 10^{-7}-5\times 10^{-11}\,\mathrm{s}$ and decaying into at least two charged particles. U_{ej} and $U_{m,j}$ are mixing angles to ν_e and ν_μ . See also the BADIER 86 entry in the section "Searches for Massive Neutrinos and Lepton Mixing".

- 14 FARGION 95 bound is sensitive to assumed u concentration in the Galaxy. See also
- KONOPLICH 94.

 15 These results assume that neutrinos make up dark matter in the galactic halo.
- $^{16}\mathrm{Limits}$ based on annihilations in the sun and are due to an absence of high energy neutrinos detected in underground experiments.
- 17 MORI 92B results assume that neutrinos make up dark matter in the galactic halo. Limits based on annihilations in earth are also given.
- 18 REUSSER 91 uses existing etaeta detector (see FISHER 89) to search for CDM Dirac
- 19 ENQVIST 89 argue that there is no cosmological upper bound on heavy neutrinos.

(B) Sum of neutrino masses

The limits on low mass $(m_{\nu} \lesssim 1 \text{ MeV})$ neutrinos apply to $m_{\rm tot}$ given by

$$m_{
m tot} = \sum_{
u} (g_{
u}/2) m_{
u} \; ,$$

where g_{ν} is the number of spin degrees of freedom for ν plus $\overline{\nu}$: $g_{\nu} = 4$ for neutrinos with Dirac masses; $g_{\nu} = 2$ for Majorana neutrinos. The limits on high mass $(m_{\nu} > 1 \text{ MeV})$ neutrinos apply separately to each neutrino type.

Limit on Total ν MASS, m_{tot}

(Defined in the above note), of effectively stable neutrinos (i.e., those with mean lives greater than or equal to the age of the universe). These papers assumed Dirac neutrinos. When necessary, we have generalized the results reported so they apply to $m_{
m tot}$ - For other limits, see SZALAY 76, VYSOTSKY 77, BERNSTEIN 81, FREESE 84, SCHRAMM 84, and COWSIK 85.

 $^{\rm 21}\,{\rm These}$ results apply to heavy Majorana neutrinos and are summarized by the equation: >1.2 GeV (G_F/G_R) . The bound saturates, and if G_R is too small no mass range $m_{\nu} > 1.2$ is allowed

(C) Searches for neutrinoless double- β decay

LIMITS FROM NEUTRINOLESS $\beta\beta$ DECAY

(Revised 1995 by Petr Vogel, Caltech)

Limits on an effective Majorana neutrino mass and a leptonnumber violating current admixture can be obtained from lifetime limits on $0\nu\beta\beta$ nuclear decay. The derived quantities are model-dependent, so the half-life measurements are given first. Where possible we list the references for the matrix elements used in the subsequent analysis. Since rates for the more conventional $2\nu\beta\beta$ decay serve to calibrate the theory, results for this process are also given. As an indication of the spread among different ways of evaluating the matrix elements, we show in Fig. 1 some representative examples for the most popular nuclei. For further calculations, see, e.g., Ref. 1.

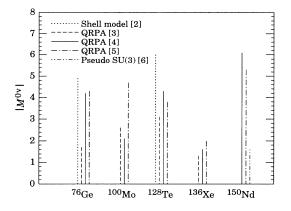

Figure 1: Nuclear matrix elements for $0\nu\beta\beta$ decay calculated by a subset of different methods and different authors for the most popular double-beta decay candidate nuclei. Recalculated from the published half-lives using consistent phase-space factors and $g_A = 1.25$. The QRPA [3] value is for $\alpha' = -390 \text{ MeV fm}^3$.

Lepton Particle Listings

Massive Neutrinos and Lepton Mixing

To define the limits on lepton-number violating right-handed current admixtures, we display the relevant part of a phenomenological current-current weak interaction Hamiltonian:

$$\begin{split} H_W = & (G_F/\sqrt{2}) \\ \times & (J_L \cdot j_L^\dagger + \kappa J_R \cdot j_L^\dagger + \eta J_L \cdot j_R^\dagger + \lambda J_R \cdot j_R^\dagger) + \text{h.c.} \end{split}$$

where $j_L^\mu=\bar{e}_L\gamma^\mu\nu_{eL},~j_R^\mu=\bar{e}_R\gamma^\mu\nu_{eR},$ and J_L^μ and J_R^μ are lefthanded and right-handed hadronic weak currents. Experiments are not sensitive to κ , but quote limits on quantities proportional to η and λ .* In analogy to $\langle m_{\nu} \rangle$ (see Eq. 11 in the "Note on Neutrinos" at the beginning of the Neutrino Particle Listings), the quantities extracted from experiments are $\langle \eta
angle = \eta \sum U_{1j} V_{1j}$ and $\langle \lambda
angle = \lambda \sum U_{1j} V_{1j},$ where V_{ij} is a matrix analogous to U_{ij} (see Eq. 2 in the "Note on Neutrinos"), but describing the mixing among right-handed neutrinos. The quantities $\langle \eta \rangle$ and $\langle \lambda \rangle$ therefore vanish for massless or unmixed neutrinos. Also, as in the case of $\langle m_{\nu} \rangle$, cancellations are possible in $\langle \eta \rangle$ and $\langle \lambda \rangle$. The limits on $\langle \eta \rangle$ are of order 10^{-8} while the limits on $\langle \lambda \rangle$ are of order 10^{-6} . The reader is warned that a number of earlier experiments did not distinguish between η and λ . Because of evolving reporting conventions and matrix element calculations, we have not tabulated the admixture parameters for experiments published earlier than 1989.

See the section on Majoron searches for additional limits set by these experiments.

Footnotes and References

- * We have previously used a less accepted but more explicit notation in which $\eta_{RL} \equiv \kappa$, $\eta_{LR} \equiv \eta$, and $\eta_{RR} \equiv \lambda$.

 22 ARNOLD 95 final result, $(0.0375^{+0.0035}_{-0.0021})\times 10^{21}$ y, has been submitted for publication to 7. Phys.

Isotope. 25 GEORGADZE 95 result for this and other modes are also give in DANEVICH 95. Result for 2ν decay omitted because of authors' caveats.

To 2D decay of mitted because of authors careass.

ALESSANDRELLO 94 state that their present limit excludes a significant contribution from the 0ν channel of ¹³⁰Te even if the large lifetime obtained in the geochemical experiment of BERNATOWICZ 92 is assumed.

To 2. Figs. 23 BARABASH 95 cannot distinguish 0ν and 2ν , but it is inferred indirectly that the 0ν mode accounts for less than 0.026% of their event sample. They also note that their result disagrees with the previous experiment by the NEMO group (BLUM 92, but also see DASSIE 95).

 $^{^{24}}$ BELLOTTI 87 searches for γ rays for 2^+ state decays in corresponding Xe isotopes. Limit for 130 Te case argues for dominant $0^+\!\rightarrow 0^+$ transition in known decay of this isotope.

- 27 In PIEPKE 94, the studied excited states of 116 Sn have energies above the ground state of 1.2935 MeV for the 2^+ state, 1.7568 MeV for the 0_1^+ state, and 2.0273 for the 0_2^+ state. 28 Limit in the case of a transition induced by a Majorana mass.

- ²⁹Limit for lepton-number violating right-handed current-induced (RHC) decay.

 ³⁰ BERNATOWICZ 92 finds ¹²⁸Te/¹³⁰Te activity ratio from slope of ¹²⁸Xe/¹³²Xe vs. 130 Xe/132 Xe ratios during extraction, and normalizes to lead-dated ages for the 130 Te lifetime. The authors state that their results imply that "(a) the double beta decay of lifetime. The authors state that their results imply that "(a) the double beta decay of 128Te has been firmly established and its half-life has been determined ... without any ambiguity due to trapped Xe interferences... (b) Theoretical calculations ... underestimate the [long half-lives of 128Te 130Te] by 1 or 2 orders of magnitude, pointing to a real supression in the 2*v* decay rate of these isotopes. (c) Despite [this], most \$\beta\$-models predict a ratio of 2*v* decay widths ... in fair agreement with observation." Further details of the experiment are given in BERNATOWICZ 93. Our listed half-life has been revised downward from the published value by the authors, on the basis of reevaluated cosmic-ray ¹²⁸Xe production corrections.
- 31 BLUM 92 reports lifetime limits for the decay of ¹⁰⁰Mo to several excited states of 100 Ru. Limits for decay to the $^{+}_{1}$ state are about 30% higher if decay to the $^{+}$ states are assumed negligible. Uses 99.5% enriched 100 Mo.
- are assumed negligible. Uses 99.5% enriched $^{-2}$ Mo. $^{-2}$ KUDOMI 92 reports lifetime limits for 0ν and 2ν decays to four excited states of the daughter 10 Ru. The limits were obtained from searches for the two individual electrons in coincidence with photons from the decays of the excited states. The experiment was performed in the Kamioka underground laboratory. See EJIRI 91 for the group's ground-state transition measurement.
- 33 REUSSER 92 contains the final results for the search for neutrinoless double beta decay of $^{76}{\sf Ge}$ in the Gotthard tunnel underground laboratory. Supersedes FISHER 89
- ³⁴ AVIGNONE 91 reports confirmation of the MILEY 90 and VASENKO 90 observations of $2\nu\beta\beta$ decay of ⁷⁶Ge. Error is 2σ .
- 35 BELLOTTI 91 uses difference between natural and enriched 136 Xe runs to obtain etaeta0u
- 35 BELLOTTI 91 uses difference between natural and enriched 136 Xe runs to obtain $\beta\beta0\nu$ limits, leading to "less stringent, but safer limits." 36 TURKEVICH 91 observes activity in old U sample. The authors compare their results with theoretical calculations. They state "Using the phase-space factors of Boehm and Vogel (BOEHM 87) leads to matrix element values for the 238 U transition in the same range as deduced for 130 Te and 76 Ge. On the other hand, the latest theoretical estimates (STAUDT 90) give an upper limit that is 10 times lower. This large discrepancy implies either a defect in the calculations or the presence of a faster path than the standard two-neutrino mode in this case. "See BOEHM 87 and STAUDT 90. 37 MILEY 90 claims only "suggestive evidence" for the decay. Error is 2σ . 38 VASENKO 90 limit based on background statistics. Maximum likelihood solution is >2000.

- 39 MORALES 88 notes a 2.5 sigma coincidence rate between electrons with energy 1483.7 \pm 0.5 keV in the Ge detector and photons with energy 558 \pm 15 keV in the NaI detector, close to the region where neutrinoless 0⁺ \rightarrow 2⁺ 76 Ge decay should be expected. However, a further study reported in MORALES 91 rejects this peak at the 95% CL.
- 40 HUBERT 85 gives lifetime limits on neutrinoless double eta decay of 76 Ge to excited states
- 41 KIRSTEN 83 reports " 2σ " error. References are given to earlier determinations of the 130 Te lifetime.

$\langle m_{\nu} \rangle$, The Effective Weighted Sum of Majorana Neutrino Masses Contributing to Neutrinoless Double β Decay

 $\langle m_{
u} \rangle = |\Sigma| U_{1j}^2 m_{
u_j}|$, where the sum goes from 1 to n and where n= number of neutrino generations, and ν_j is a Majorana neutrino. Note that U_{1j}^2 , not $|U_{1j}|^2$, occurs in the sum. The possibility of cancellations has been stressed.

- 42 DANEVICH 95 is identical to GEORGADZE 95. 43 ALSTON-GARNJOST 93 use the "conservative matrix elements of Engel et al. (ENGEL 88).

- GEL 88). On the basis of these calculations, the BALYSH 92 mass range would be 45 BALYSH 92 uses the MUTO 89 matrix elements.
 46 BERNATOWICZ 92 finds these majoron mass limits assuming that the measured geochemical decay width is a limit on the 0ν decay width. The range is the range found using matrix elements from HAXTON 84, TOMODA 87, and SUHONEN 91. Further details of the experiment are given in BERNATOWICZ 93.
- 47 ELLIOTT 92 uses the matrix elements of HAXTON 84.

- 48 REUSSER 92 contains the final results for the search for neutrinoless double beta decay of ⁷⁶Ge in the Gotthard tunnel underground laboratory. Range comes from range of nuclear matrix elements used to relate neutrino mass to lifetime limit (ENGEL 88, HAXTON 84, and MUTO 89).
- 49 BELLOTTI 91 range of limits comes from range of theoretical calculations considered. Analysis uses difference between natural and enriched 136 Xe runs to obtain the $^{\beta}$ 80 $^{\nu}$ limits, leading to "less stringent, but safer limits."
- $^{50}\,\mathrm{WONG}$ 91 uses the quasiparticle random phase approximation of ENGEL 88 to extract
- the above limit for the case of a transition caused by a Majorana neutrino mass.

 51 VASENKO 90 range comes from range of nuclear matrix elements of HAXTON 84,
 ENGEL 88. On the basis of the MUTO 89 matrix element, the limit will be < 1.3 eV.
- 52 BELLOTTI 89 gives model-dependent upper bounds on Majorana neutrino masses and in the admixture of right-handed lepton-number-violating currents.

- on the admixture of right-handed lepton-number-violating currents.

 53 DANEVICH 80 uses calculations of GROTZ 86.

 54 CALDWELL 87 least stringent limit (using HAXTON 84) is listed. Limits given using other nuclear matrix element calculations are 1.5 eV and 0.7 eV.

 5 HUBERT 85 limit is obtained from analysis of data using theoretical calculations by HAXTON 81, HAXTON 82.

Limits on Lepton-Number Violating (V+A) Current Admixture

For reasons given in the discussion at the beginning of this section, we list only results from 1989 and later. $\langle \lambda \rangle = \lambda \sum U_{IJ} V_{IJ}$ and $\langle \eta \rangle = \eta \sum U_{IJ} V_{IJ}$, where the sum is over the number of neutrino generations. This sum vanishes for massless or unmixed neutrinos.

$\langle \lambda \rangle$ (10 $^-$	6) CL%	$\langle \eta \rangle$ (10 ⁻⁸) CL%	ISOTOPE	METHOD	DOCUMENT ID

- 60 BRITTON 92B is from a search for additional peaks in the e^+ spectrum from π^+ ightarrow $e^+\nu_a$ decay at TRIUMF. See also BRITTON 92.
- 61 BRYMAN 838 obtain upper limits from both direct peak search and analysis of B(π o $e\nu)/B(\pi\to\mu\nu).$ Latter limits are not listed, except for this entry (i.e. — we list the most stringent limits for given mass). 62 Analysis of $(\pi^+\to e^+\nu_e)/(\pi^+\to \mu^+\nu_\mu)$ and $(K^+\to e^+\nu_e)/(K^+\to \mu^+\nu_\mu)$
- decay ratios.
- ⁶³ Analysis of $(K^+ \rightarrow e^+ \nu_e)$ spectrum.

Lepton Particle Listings

Massive Neutrinos and Lepton Mixing

Kink search in nuclear β decay

High-sensitivity follow-up experiments show that indications for a neutrino with mass 17 keV (Simpson, Hime, and others) were not valid. Accordingly, we no longer list the experiments by these authors and some others which made positive claims of 17 keV neutrino emission. Complete listings are given in the 1994 edition (Physical Review **D50** 1173 (1994)). Limits on $|U_{1j}|^2$ as a function of m_{ν_j} .

- 64 In the beta spectrum from tritium eta decay nonvanishing or mixed $m_{\overline{
 u}_1}$ state in the mass region 0.01–4 keV. For $m_{
 u_j}$ <1 keV, their upper limit on $|U_{1j}|^2$ becomes less
- 65 BERMAN 93 uses an iron-free intermediate-image magnetic spectrometer to measure 35 S $_{\beta}$ decay over a large portion of the spectrum. Paper reports (0.01 \pm 0.15)%; above result revised by author on basis of analysis refinements.
- 66 KALBFLEISCH 93 extends the 17 keV neutrino search of BAHRAN 92, using an improved proportional chamber to which a small amount of 3H is added. Systematics are significantly reduced, allowing for an improved upper limit. The authors give a 99% confidence limit on $|U_1j|^2$ as a function of m_{ν_j} in the range from 13.5 keV to 17.5 keV. Typical upper limit. Typical upper limits are listed above. They report that this experiment in combination with BAHRAN 92 gives an upper limit of 2.4×10^{-3} at the 99% CL. See also the related papers BAHRAN 93, BAHRAN 938, and BAHRAN 95 on theoretical aspects of beta spectra and fitting methods for heavy neutrinos.
- beta spectra and fitting methods for neavy neutrinos.

 67 MORTARA 93 limit is from study using a high-resolution solid-state detector with a superconducting solenoid. The authors note that "The sensitivity to neutrino mass is verified by measurement with a mixed source of ³⁵S and ¹⁴C, which artificially produces a distortion in the beta spectrum similar to that expected from the massive neutrino."
- $^{68}\,\text{OHSHIMA}$ 93 is the full data analysis from this experiment. The above limit on the mixing strength for a 17 keV neutrino is obtained from the measurement $|U_{1\,j}|^2=$ $(-0.11\pm0.33\pm0.30)\times10^{-3}$ by taking zero as the best estimate and ignoring physical boundaries; see discussion in HOLZSCHUH 92s for a comparison of methods. An earlier report of this experiment was given in KAWAKAMI 92.
- 69 WIETFELDT 93 is an extension of the NORMAN 91 experiment. However, whereas NORMAN 91 reported indications for the emission of a neutrino with mass $m_{\nu_j}=$ 121 ± 2 keV and coupling strength = 0.0085 \pm 0.0045, the present experiment states that "We find no evidence for emission of a neutrino in the mass range 5–25 keV. In particular, a 17 keV neutrino with $\sin^2\theta \left(|U_1|^2 \right)$ in our notation) = 0.008 is excluded at the 7σ level." The listed limits can be obtained from the paper's Fig. 4. The authors acknowledge that this conclusion contradicts the one reported in NORMAN 91, based on a smaller data sample. In further tests, WIETFELDT 95 have shown that "the observed discretion are most likely covered by experiments effect. distortion was most likely caused by systematic effects... A new measurement with a smaller data sample shows no sign of this distortion." $\frac{1}{2} \left(\frac{1}{2} \right) \left(\frac{1$
- 70 CHEN 92 is a continuation and improvement of the Boehm et al. Caltech iron-free magnetic spectrometer experiment searching for emission of massive neutrinos in 35 S decay (MARKEY 85). The upper limit on $|U_{1j}|^2$ for $m_{\nu_j}=$ 17 keV comes from the measurement $|U_{1j}|^2=(-0.5\pm 1.4)\times 10^{-3}$. The authors state that their results "rule out, at the 6σ level, a 17 keV neutrino admixed at 0.85% (i.e. with $|U_{1\,i}|^2=$ 0.85×10^{-2} ." the level claimed by Hime and Jelly in HIME 91. They also state that "our data show no evidence for a heavy neutrino with a mass between 12 and 22 keV"

- with substantial admixture in the weak admixture in the weak eigenstate $u_{m{e}}$; see their Fig. 4 for a graphical set of measured values of $|U_{1\,i}|^2$ for various hypothetical values of $m_{
 u_i}$ in this range.
- 71 KAWAKAMI 92 experiment final results are given in OHSHIMA 93. The upper limit is improved to 0.73×10^{-3} , based on $|U_{1\,f}|^2=(-0.11\pm0.33\pm0.30)\times 10^{-3}.$ Ohshima notes that the result is 22 σ away from the value $|\mathit{U}_{1j}|^2=1\%$.
- 72 BORGE 86 results originally presented as evidence against the SIMPSON 85 claim of a 17 keV antineutrino emitted with $|U_{1f}|^2=0.03$ in $^3{\rm H}$ decay.
- 73 This limit was taken from the figure 3 of APALIKOV 85; the text gives a more restrictive limit of 1.7 \times 10^{-3} at CL = 90%. 74 SCHRECKENBACH 83 is a combined measurement of the β^+ and β^- spectrum.

- 78 BARANOV 93 is a search for neutrino decays into $e^+e^-\,\nu_e$ using a beam dump experiment at the 70 GeV Serpukhov proton synchrotron. The limits are not as good as those achieved earlier by BERGSMA 83 and BERNARDI 86, BERNARDI 88.
- 79 BURCHAT 90 includes the analyses reported in JUNG 90, ABRAMS 89c, and WENDT 87. 80 OBERAUER 87 bounds from search for $\nu \rightarrow \nu' ee$ decay mode using reactor (anti)neutrinos.
- (anti-neutrinos.) 81 COOPER-SARKAR 85 also give limits based on model-dependent assumptions for ν_{τ} flux. We do not list these. Note that for this bound to be nontrivial, j is not equal to 3, i.e. ν_{I} cannot be the dominant mass eigenstate in ν_{τ} since $m_{\nu_{3}}$ <70 MeV to 3, i.e. ν_i cannot be the dominant mass eigenstate in $\nu_{ au}$ since $m_{
 u_3}$
- (ALBRECHT 851). Also, of course, J is not equal to 1 or 2, so a fourth generation would be required for this bound to be nontrivial. ⁸² BERGSMA 838 also quote limits on $|U_{13}|^2$ where the index 3 refers to the mass eigenstate dominantly coupled to the τ . Those limits were based on assumptions about the D_S mass and $D_S \rightarrow \tau \nu_{\tau}$ branching ratio which are no longer valid. See COOPERSARKAR 85.

SOLAR NEUTRINOS

(by K. Nakamura, KEK, National Laboratory for High-Energy Physics, Japan)

The Sun is a main-sequence star at a stage of stable hydrogen burning. It produces an intense flux of electron neutrinos as a consequence of nuclear fusion reactions which generate solar energy, and whose combined effect is

$$4p + 2e^- \rightarrow {}^{4}\text{He} + 2\nu_e + 26.73 \text{ MeV} - E_{\nu}$$
, (1)

where E_{ν} represents the energy taken away by neutrinos, with an average value being $\langle E_{\nu} \rangle \sim 0.6$ MeV. Each neutrino-producing reaction and the resulting flux predicted by the two recent standard solar model (SSM) calculations [1,2] are listed in Table 1. Figure 1 shows the energy spectra of solar neutrinos from these reactions quoted from the SSM calculation by Bahcall and Ulrich [3]. All SSM calculations give essentially the same results for the same input parameters and physics. The Bahcall and Pinsonneault model [1] and the Turck-Chièze and Lopes model [2] listed in Table 1 differ primarily in that Bahcall and Pinsonneault include helium diffusion [4].

Observations of solar neutrinos directly addresses the SSM and, more generally, the theory of stellar structure and evolution which is the basis of the SSM. The Sun as a well defined neutrino source also provides extremely important opportunities to investigate nontrivial neutrino properties such as nonzero mass and mixing, because of the wide range of matter density and the very long distance from the Sun to the Earth. In fact, the currently available solar-neutrino data seem to require such neutrino properties, if one tries to understand them consistently.

At present, four solar-neutrino experiments are taking data. Three of them are radiochemical experiments using $^{37}{\rm Cl}$ (Homestake in USA) or $^{71}{\rm Ga}$ (GALLEX at Gran Sasso in Italy and SAGE at Baksan in Russia) to capture neutrinos: $^{37}{\rm Cl}~\nu_e \rightarrow ^{37}{\rm Ar}~e^-$ (threshold 814 keV) or $^{71}{\rm Ga}~\nu_e \rightarrow ^{71}{\rm Ge}~e^-$

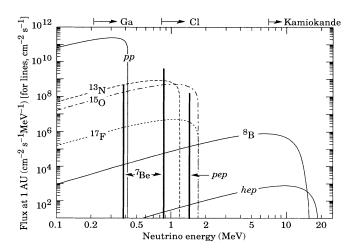

Figure 1: The solar neutrino spectrum predicted by the standard solar model. The neutrino fluxes from continuum sources are given in units of number $cm^{-2}s^{-1}MeV^{-1}$ at one astronomical unit, and the line fluxes are given in number $cm^{-2}s^{-1}$. Spectra for the pp chain are shown by solid lines, and those for the CNO chain by dotted or dashed lines. (Courtesy of J.N. Bahcall, 1995.)

Table 1: Neutrino-producing reactions in the Sun (the first column) and their abbreviations (second column). The neutrino fluxes predicted by Bahcall and Pinsonneault (B-P) [1] and by Turck-Chièze and Lopes (T-C-L) [2] are listed in the third and fourth columns, respectively. The errors associated with the B-P calculation are "theoretical" 3 standard deviations according to the authors.

Reaction	Abbr.	В-Р	T-C-L
$\frac{1}{pp \to d e^+ \nu}$	pp	$6.00(1 \pm 0.02)$ E10	6.02E10
$pe^-p \rightarrow d\nu$	pep	$1.43(1 \pm 0.04)$ E8	1.3E8

$^{8}\mathrm{B} \rightarrow {^{8}\mathrm{B}^{*}} \ e^{+}\nu$	$^8\mathrm{B}$	$5.69(1 \pm 0.43)$ E6	4.43E9
$^{13}\mathrm{N} ightharpoonup ^{13}\mathrm{C}~e^{+} u$	$^{13}\mathrm{N}$	$4.92(1 \pm 0.51)E8$	3.83E8
$^{15}{\rm O} \to ^{15}{\rm N}~e^+\nu$	$^{15}\mathrm{O}$	$4.26(1 \pm 0.58)$ E8	3.15 E8
$^{17}\mathrm{F} \rightarrow ^{17}\mathrm{O}~e^+ \nu$	$^{17}\mathrm{F}$	$5.39(1 \pm 0.48)$ E6	

(threshold 233 keV). The produced $^{37}\mathrm{Ar}$ and $^{71}\mathrm{Ge}$ are both radioactive nuclei with half lives $(\tau_{1/2})$ of 34.8 days and 11.43 days, respectively. After an exposure of the detector for two to three times $\tau_{1/2}$, the reaction products are extracted and introduced into a low-background proportional counter, and are counted for a sufficiently long period to determine the exponentially decaying signal and a constant background. In the chlorine experiment, the dominant contribution comes from $^8\mathrm{B}$ neutrinos, but $^7\mathrm{Be}$, pep, $^{13}\mathrm{N}$, and $^{15}\mathrm{O}$ neutrinos also contribute. At present, the most abundant pp neutrinos can be detected

Lepton Particle Listings Massive Neutrinos and Lepton Mixing

only in gallium experiments. Even so, almost half of the capture rate in these experiments is due to other solar neutrinos.

The fourth is a real-time experiment utilizing νe scattering in a large water-Čerenkov detector (Kamiokande in Japan). This experiment takes advantage of the directional correlation between the incoming neutrino and the recoil electron. This feature greatly helps the clear separation of the solar-neutrino signal from the background. Due to its high threshold (7 MeV at present), Kamiokande observes pure ⁸B solar neutrinos (hep neutrinos have too small a flux to be observed in the present generation of solar neutrino experiments.)

Solar neutrinos were first observed in the Homestake chlorine experiment around 1970. From the very beginning, it was recognized that the observed capture rate was significantly smaller than the SSM prediction. This deficit has been called "the solar-neutrino problem." The Kamiokande-II Collaboration started observing the ⁸B solar neutrinos at the beginning of 1987. Because of the strong directional correlation of νe scattering, this result gave the first direct evidence that the Sun emits neutrinos (no directional information is available in radiochemical solar-neutrino experiments.) The observed solarneutrino flux was also significantly less than the SSM prediction. In addition, Kamiokande-II obtained the energy spectrum of recoil electrons and the fluxes separately measured in the day time and nighttime. GALLEX presented the first evidence of pp solar-neutrino observation in 1992. Here also, the observed capture rate is significantly less than the SSM prediction. SAGE, after initial confusion which is ascribed to statistics by the group, observes a similar capture rate to that of GALLEX. The most recent results on the average capture rates or flux from these experiments [5-8] are compared with the recent SSM calculations [1,2] in Table 2.

Table 2: Recent results from the four solar-neutrino experiments. For Homestake [5], GALLEX [6], and SAGE [7], the data are capture rates given in SNU (Solar Neutrino Units; $1~\mathrm{SNU}=10^{-36}$ capture per atom per second). For Kamiokande [8], the datum is $^8\mathrm{B}$ solar-neutrino flux given in units of $10^6~\mathrm{cm}^{-2}~\mathrm{s}^{-1}$. The first errors are statistical and the second errors are systematic. The SSM predictions by Bahcall and Pinsonneault (B-P) [1] and by Turck-Chièze and Lopes (T-C-L) [2] are listed in the third and fourth columns, respectively. The errors associated with the B-P calculation are "theoretical" 3 standard deviations according to the authors.

Experiment	Data	В-Р	T-C-L
Homestake	$2.55 \pm 0.17 \pm 0.18$	8.0 ± 3.0	6.4

SAGE	73^{+18+5}_{-16-7}	131.5_{-17}^{+21}	122.5
Kamiokande	$2.89^{+0.22}_{-0.21} \pm 0.35$	5.7 ± 2.4	4.4

There was a controversy concerning whether the ³⁷Cl capture rate showed time variation, anticorrelated with the sunspot numbers which represent the 11-year solar-activity cycle. However, more than 7 years of the Kamiokande-II solar-neutrino observation does not show evidence for a statistically significant

correlation or anticorrelation between the solar-neutrino flux and sunspot number.

All results from the present solar-neutrino experiments indicate significantly less flux than expected from the SSM calculations. Is there any possible consistent explanation of all the results of solar-neutrino observations in the framework of the standard solar model? This is difficult because the Homestake result and the Kamiokande result, taken at face value, are mutually inconsistent if one assumes standard neutrino spectra. That is, with the reduction factor of the ⁸B solar-neutrino flux as determined from the Kamiokande result, the Homestake ³⁷Cl capture rate would be oversaturated, and there would be no room to accommodate the ⁷Be solar neutrinos. Several authors made more elaborate analyses using the constraint of observed solar luminosity, and found that not only the SSM but also nonstandard solar models are incompatible with the observed data. Now it is a common understanding that the solar-neutrino problem is not only the deficit of the ⁸B solar-neutrino flux, but also the deficit of ⁷Be solar-neutrino flux. The latter problem stems from the incompatibility between the Homestake and Kamiokande results and this makes astrophysical solutions untenable. There is another solar-neutrino problem concerning the low gallium capture rate observed by GALLEX and SAGE.

In view of the above situation, it is attractive to invoke nontrivial neutrino properties. Neutrino oscillation in matter (MSW mechanism) is particularly attractive in explaining all the experimental data on the average solar-neutrino flux consistently, without any a priori assumptions or fine tuning. Several authors made extensive MSW analyses using all the existing data and ended up with similar results. For example, Hata and Langacker [9] analyzed the solar-neutrino data as of mid-1993. They obtained solutions for various standard and nonstandard solar models taking the Earth effect and the Kamiokande daynight data into account. Assuming the Bahcall-Pinsonneault SSM [1], the small-mixing solution $(\Delta m^2 \sim 6 \times 10^{-6} \ {\rm eV}^2$ and $\sin^2 2\theta \sim 7 \times 10^{-3})$ gives an excellent fit to the data, but the large-mixing solution $(\Delta m^2 \sim 9 \times 10^{-6} \ {\rm eV}^2$ and $\sin^2 2\theta \sim 0.6)$ is marginally allowed at 90% confidence level.

Assuming that the solution to the solar-neutrino problem be provided by some nontrivial neutrino properties, how can one discriminate various scenarios? There are at least two very important things to do experimentally. One is the measurement of energy spectrum of the solar neutrinos and the other is the measurement of the solar-neutrino flux by utilizing neutral-current reactions. Two high-statistics solar-neutrino experiments which are under construction, SuperKamiokande and Sudbury Neutrino Observatory (SNO) are expected to provide such results within a few years. A 50 kton water-Čerenkov detector, SuperKamiokande is sensitive to the solar-neutrino spectrum through measurement of recoil electron energy. SNO will use 1,000 tons of heavy water (D₂O) to measure solar neutrinos through both inverse beta decay ($\nu_e d \rightarrow e^- pp$) and neutral current interactions ($\nu_x d \rightarrow \nu_x pn$). In addition, νe scattering events will also be measured. The Borexino experiment with 300 tons of ultra-pure liquid scintillator is approved for the Gran Sasso. The primary purpose of this experiment is

Lepton Particle Listings

Massive Neutrinos and Lepton Mixing

the measurement of the ⁷Be solar neutrino flux, where possible deficit is now a key question, by lowering the detection threshold for the recoil electrons to 250 keV. It is hoped that these experiments will finally provide the key to solving the solar-neutrino problem.

See also the reviews by BAHCALL 92, DAVIS 89, and ACKER 94. The latter rules out neutrino decay as a solution to the solar neutrino problem at better than 98% using the existing solar neutrino as of mid-1993.

 98 ANSELMANN 95B result is for a total of 39 completed runs (GALLEX I and GALLEX II combined), which updates the ANSELMANN 94 result. The total run data, covering the period 14 May 1991 through 22 June 1994, are consistent with a 71 Ge production rate constant in time. The results are strengthened by a calibration run using a strong 51Cr source (ANSELMANN 95), where the (measured)/(expected) Cr-induced ⁷¹Ge rate was

found to be 1.04 \pm 0.12. 99 ABDURASHITOV 94 result is for a total of 15 runs from January 1990 through May 1992, using 30 tons of metallic gallium for the first 7 runs, increased to 57 tons for the rest of 8 runs. The first 5 runs in 1990 yielded $40 + \frac{31+5}{38-7}$ SNU which updates the

ABAZOV 91B result.

 $_{\rm ABAZOV}$ 918 result.
100 HIRATA 90 data consists of 1040 days with threshold $E_{\rm g} > 9.3$ MeV (first 450 days) or $E_{\rm g} > 7.5$ MeV. "The total data sample is also analyzed for short-term variations; within the statistical error, no significant variation is observed." The flux is scaled by the value relative to the standard solar model (SSM) prediction. A theoretical flux of $(5.8 \pm 2.1) \times 10^6 \, {\rm cm}^{-2} \, {\rm s}^{-1}$ is cited, with the central value corresponding to 7.9 SNU $^{3.5}$ for ³⁷Cl experiment (but see TURCK-CHIEZE 93B and other theoretical calculations.)

- The analysis is more fully reported in HIRATA 91B. Earlier analyses were reported by
- HIRATA 91 and HIRATA 90B.

 101 DAVIS 89 is the average from the ³⁷CL experiment at the Homestake Mine (HOME) from 1970–1988. Earlier averages are given in the references therein.
- 102 ACKER 94 rules out neutrino decay as a solution to the solar neutrino problem at better than 98% CL, using the existing solar neutrino data as of mid-1993.
- 103 BAHCALL 94 argues that there are really two solar neutrino problems: (1) incompatibility of the chlorine (Homestake) and Kamiokande experiments, (2) deficiency of the observed
- solar neutrino flux in the gallium experiments.

 104 BAHCALL 93 is a study of 1000 solar models in which each input parameter is chosen from a normal distribution with the appropriate mean and error. It is concluded that "Even if one abuses the solar models by artifically imposing consistency with the Kamlokande experiment, the resulting predictions of all 1000 of the 'fudged' solar models are inconsistency with the security of the experiment. are inconsistent with the result of the chlorine experiment.
- 105 HAMPEL 93, by a member of the GALLEX collaboration, is a discussion of possible scenarios to explain the combined solar neutrino experimental data.
- 106 TURCK-CHIEZE 93B proposes new results on the solar neutrino predictions and acoustic mode frequencies. See also TURCK-CHIEZE 93 for an extensive review (233 pages, 524 references) concerning the solar interior. Table 17 provides a particularly useful comparison of experiment and theory as of mid-1993.
- 107 BAHCALL 92 is an extensive discussion of theoretical neutrino flux calculations with predicted event rates for various different solar neutrino detectors. "The quoted errors represent the total theoretical range and include the effects on the model predictions of 3σ errors in measured input parameters." 108 GARCIA 91 reports a new study of 3^{7} Ca β decays, with the result that the BAHCALL 88 SSM prediction for 3^{7} Cl should be increased from 7.9 to 8.1 SNU.
- 109 HIRATA 91 reports a search for day-night and semi-annual variations in the solar neutrino flux observed in the Kamiokandel I Detector. The sample is the same 1040 day counting period used for HIRATA 90 and HIRATA 90s. "Within statistical error, no such short-time variations were observed." This result was used to constrain neutrino socillation parameters, in the framework of oscillations between two mass eigenstates. "A region defined by $\sin^2 2\theta > 0.02$ and 2×10^{-6} eV $^2 < \Delta(m^2) < 1\times 10^{-5}$ eV 2 is excluded at the 90% CL without any assumptions on the absolute value of the expected solar
- at the 90% CL without any assumptions on the absolute value of the expected solar neutrino flux."

 110 In a later unbiased analysis, FILIPPONE 90 show that the hypothesis of a time-independent ³⁷Cl neutrino capture rate is marginally rejected, having only 2% probability. However, it is disturbing that we are not able to find a simple hypothesis of time variation that would describe the data well. A capture rate anticorrelated with sunspot number, although more probable than the constant rate hypothesis, has a probability of only 6%. One possible explanation of these results is simply the poor statistics of the
- $^{111}\mathrm{HIRATA}$ 90B gives an analysis of the implications of these data for allowed values of $\Delta(m^2)$ and $\sin^2 2 heta$ describing neutrino mixing between two mass eigenstates, in the model of resonant (MSW) neutrino oscillations. The possibility of regeneration as the neutrinos pass through the earth is neglected. Two limits are given, the first from the measured event rate alone, and the second from the combination of the measured event rate and the recoil electron energy spectrum. The latter "disfavor the region of adiabatic solutions $\Delta(m^2)\sim 1.3\times 10^{-4}~\text{eV}^2$ and $7.2\times 10^{-4}~<\sin^22\theta~<6.3\times 10^{-3}$ at 90%CL." The allowed regions in $\sin^2 2\theta$ vs. $\Delta(m^2)$ are given graphically; see Figs. 2(a) and 2(b) in the paper.
- 112 BAHCALL 88 "total theoretical range is calculated by evaluating the 3σ uncertainties for all measured input parameters and using the full spread in calculated values for input quantitites that cannot be measured; the uncertainties from different quantities are combined quadratically." (Quotation from BAHCALL 89, p. 301.)
- 113 BAHCALL 82 quotes "effective 3σ errors." First extensive discussion of formal uncertainties in the problem.

(F) Astrophysical neutrino observations

Neutrinos and antineutrinos produced in the atmosphere induce $\mu\text{-like}$ and e-like events in underground detectors. The ratio of the numbers of the two kinds of events is defined as μ/e . It has the advantage that that systematic effects, such as flux uncertainty, tend to cancel, for both experimental and $% \left(1\right) =\left(1\right) \left(1$ theoretical values of the ratio. The "ratio of the ratios" of experimental to theoretical μ/e , $R(\mu/e)$, is reported below. If the actual value is not unity, the value obtained in a given experiment may depend on the experimental

$R(\mu/e) = (Measured Ratio \mu/e) / (Expected Ratio \mu/e)$

$R(\mu/\epsilon) = (\text{vicusured Ratio } \mu/\epsilon) / (\text{Expected Ratio } \mu/\epsilon)$

< 0.14	68	¹⁴⁸ VIDYAKIN	87		$\overline{\nu}_e p \rightarrow e^+ n$
< 0.21	90	¹⁴⁹ ZACEK	86		$\overline{\nu}_e p \rightarrow e^+ n$
< 0.19	90	¹⁵⁰ ZACEK	85		Gösgen reactor
< 0.16	90	¹⁵¹ GABATHULE	R 84		$\overline{\nu}_e p \rightarrow e^+ n$

- 144 ACHKAR 95 bound is from data for L=15, 40, and 95 m distance from the Bugey reactor.
- 145 The VYRODOV 95 bound is from data for L=15 m distance from the Bugey-5 reactor.
 146 The VIDYAKIN 94 bound is from data for L=57.0 m, 57.6 m, and 231.4 m from three reactors in the Krasnoyark Reactor complex.
- 147 Several different methods of data analysis are used in AFONIN 88. We quote the most stringent limits. Different upper limits on $\sin^2 2\theta$ apply at intermediate values of $\Delta(m^2)$. Supersedes AFONIN 87, AFONIN 85, and BELENKII 83.
- 148 VIDYAKIN 87 bound is for L=32.8 and 92.3 m distance from two reactors. 149 This bound is from data for L=37.9 m, 45.9 m, and 64.7 m distance from Gosgen reactor.
- 150 ZACEK 85 gives two sets of bounds depending on what assumptions are used in the data analysis. The bounds in figure 3(a) of ZACEK 85 are progressively poorer for large $\Delta(m^2)$ whereas those of figure 3(b) approach a constant. We list the latter. Both sets of bounds use combination of data from 37.9, 45.9, and 64.7m distance from reactor. ZACEK 85 states "Our experiment excludes this area (the oscillation parameter region allowed by the Bugey data, CAVAIGNAC 84) almost completely, thus disproving the indications of neutrino oscillations of CAVAIGNAC 84 with a high degree of confidence."
- 151 This bound comes from a combination of the VUILLEUMIER 82 data at distance 37.9m from Gosgen reactor and new data at 45.9m.

$$----\nu_e \rightarrow (\overline{\nu}_e)_L$$

This is a limit on lepton family-number violation and total lepton-number violation. $(\overline{\nu}_e)_L$ denotes a hypothetical left-handed $\overline{\nu}_e$. The bound is quoted in terms of Δ (m^2) , $\sin(2\theta)$, and α , where α denotes the fractional admixture of (V+A) charged current.

Massive Neutrinos and Lepton Mixing

```
187 This bound applies for a wide range of \Delta(m^2) > 7 \text{ eV}^2. For some values of \Delta(m^2), the value is less stringent; the least restrictive, nontrivial bound occurs approximately at \Delta(m^2) = 300 \text{ eV}^2 where \sin^2(2\theta) < 0.13 at \text{CL} = 90\%.

188 This bound applies for \Delta(m^2) = 1.-10. \text{eV}^2. Less stringent bounds apply for other \Delta(m^2); these are nontrivial for 0.23 < \Delta(m^2) < 90 \text{ eV}^2.

189 This bound applies for \Delta(m^2) = 110 \text{ eV}^2. Less stringent bounds apply for other \Delta(m^2); these are nontrivial for 13 < \Delta(m^2) < 1500 \text{ eV}^2.

190 Bound holds for \Delta(m^2) = 20-1000 \text{ eV}^2.

\overline{\nu_{\mu} \neq \overline{\nu_{\mu}}}
\Delta(m^2) \text{ for } \sin^2(2\theta) = 1
\frac{\Delta(M^2)}{\sqrt{7}} \text{ for } \sin^2(2\theta) = 1
\frac{\Delta(M^2)}{\sqrt{7}} \text{ for } 190 \text{ eV}^2 < \Delta(m^2) < 320 \text{ eV}^2
\frac{\Delta(M^2)}{\sqrt{24UE}} \text{ for } 190 \text{ eV}^2 < \Delta(m^2) < 320 \text{ eV}^2

(by A. Manohar, University of California, San Diego)

A. Introduction

This note discusses some of the theoretical issues involved in the determination of quark masses. Unlike the leptons, quarks are confined inside hadrons and are not observed as physical particles. Quark masses cannot be measured directly, but must be determined indirectly through their influence on hadron properties. As a result, the values of the quark masses depend on precisely how they are defined; there is no one definition that is the obvious choice. Though one often speaks loosely of quark masses as one would of the electron or muon mass, any careful statement of a quark mass value must make reference to a particular computational scheme that is used to extract the mass from observations. It is important to keep this scheme dependence in mind when using the quark mass values tabulated in the data listings.

The simplest way to define the mass of a quark is by making a fit of the hadron mass spectrum to a nonrelativistic quark model. The quark masses are defined as the values obtained from the fit. The resulting masses only make sense in the limited context of a particular quark model. They depend on the phenomenological potential used, and on how relativistic effects are modelled. The quark masses used in potential models also cannot be connected with the quark mass parameters in the QCD Lagrangian. Fortunately, there exist other definitions of the quark mass that have a more general significance, though they also depend on the method of calculation. The purpose of this review is to explain the most important such definitions and their interrelations.

B. Mass parameters and the QCD Lagrangian

The QCD Lagrangian for N_F quark flavors is

$$\mathcal{L} = \sum_{k=1}^{N_F} \overline{q}_k (i \not\!\!\!D - m_k) q_k - \frac{1}{4} G_{\mu\nu} G^{\mu\nu} , \qquad (1)$$

where $\not D = (\partial_\mu - igA_\mu)\,\gamma^\mu$ is the gauge covariant derivative, A_μ is the gluon field, $G_{\mu\nu}$ is the gluon field strength, m_k is the mass parameter of the $k^{\rm th}$ quark, and q_k is the quark Dirac field. The QCD Lagrangian Eq. (1) gives finite scattering amplitudes after renormalization, a procedure that invokes a subtraction scheme to render the amplitudes finite, and requires the introduction of a dimensionful scale parameter μ . The mass parameters in the QCD Lagrangian Eq. (1) depend on the renormalization scheme used to define the theory, and also on the scale parameter μ . The most commonly used renormalization scheme for QCD perturbation theory is the $\overline{\rm MS}$ scheme.

The QCD Lagrangian has a chiral symmetry in the limit that the quark masses vanish. This symmetry is spontaneously broken by dynamical chiral symmetry breaking, and explicitly broken by the quark masses. The nonperturbative scale of dynamical chiral symmetry breaking, Λ_{χ} , is around 1 GeV. It is conventional to call quarks heavy if $m > \Lambda_{\chi}$, so that explicit chiral symmetry breaking dominates, and light if $m < \Lambda_{\chi}$, so that spontaneous chiral symmetry breaking dominates. The c, b, and t quarks are heavy, and the u, d and s quarks are light. The computations for light quarks involve an expansion in m_q/Λ_{χ} about the limit $m_q=0$, whereas for heavy quarks, they involve an expansion in Λ_{χ}/m_q about $m_q=\infty$. The corrections are largest for the s and c quarks, which are the heaviest light quark and the lightest heavy quark, respectively.

At high energies or short distances, nonperturbative effects such as chiral symmetry breaking are unimportant, and one can in principle analyze mass-dependent effects using QCD perturbation theory to extract the quark mass values. The QCD computations are conventionally performed using the $\overline{\rm MS}$ scheme at a scale $\mu\gg \Lambda\chi$, and give the $\overline{\rm MS}$ "running" mass $\overline{m}(\mu)$. The μ dependence of $\overline{m}(\mu)$ at short distances can be calculated using the renormalization group equations.

For heavy quarks, one can obtain useful information on the quark masses by studying the spectrum and decays of hadrons containing heavy quarks. One method of calculation uses the heavy quark effective theory (HQET), which defines a HQET quark mass m_Q . Other commonly used definitions of heavy quark masses such as the pole mass are discussed in Sec. C. QCD perturbation theory at the heavy quark scale $\mu=m_Q$ can be used to relate the various heavy quark masses to the $\overline{\rm MS}$ mass $\overline{m}(\mu)$, and to each other.

For light quarks, one can obtain useful information on the quark mass ratios by studying the properties of the light pseudoscalar mesons using chiral perturbation theory, which utilizes the symmetries of the QCD Lagrangian Eq. (1). The quark mass ratios determined using chiral perturbation theory are those in a subtraction scheme that is independent of the quark masses themselves, such as the $\overline{\rm MS}$ scheme.

A more detailed discussion of the masses for heavy and light quarks is given in the next two sections. The $\overline{\rm MS}$ scheme applies to both heavy and light quarks. It is also commonly used for predictions of quark masses in unified theories, and for computing radiative corrections in the Standard Model. For this reason, we use the $\overline{\rm MS}$ scheme as the standard scheme in reporting quark masses. One can easily convert the $\overline{\rm MS}$ masses into other schemes using the formulæ given in this review.

C. Heavy quarks

The commonly used definitions of the quark mass for heavy quarks are the pole mass, the $\overline{\rm MS}$ mass, the Georgi-Politzer mass, the potential model mass used in ψ and Υ spectroscopy, and the HQET mass.

The strong interaction coupling constant at the heavy quark scale is small, and one can compute the heavy quark propagator using QCD perturbation theory. For an observable particle such as the electron, the position of the pole in the propagator is the definition of the particle mass. In QCD this definition of the quark mass is known as the pole mass m_P , and is

Quarks

independent of the renormalization scheme used. It is known that the on-shell quark propagator has no infrared divergences in perturbation theory [1], so this provides a perturbative definition of the quark mass. The pole mass cannot be used to arbitrarily high accuracy because of nonperturbative infrared effects in QCD. The full quark propagator has no pole because the quarks are confined, so that the pole mass cannot be defined outside of perturbation theory.

The $\overline{\rm MS}$ running mass $\overline{m}(\mu)$ is defined by regulating the QCD theory using dimensional regularization, and subtracting the divergences using the modified minimal subtraction scheme. The $\overline{\rm MS}$ scheme is particularly convenient for Feynman diagram computations, and is the most commonly used subtraction scheme.

The Georgi-Politzer mass \widehat{m} is defined using the momentum space subtraction scheme at the spacelike point $-p^2 = \widehat{m}^2$ [2]. A generalization of the Georgi-Politzer mass that is often used in computations involving QCD sum rules [3] is $\widehat{m}(\xi)$, defined at the subtraction point $p^2 = -(\xi + 1)m_P^2$. QCD sum rules are discussed in more detail in the next section on light quark masses.

Lattice gauge theory calculations can be used to obtain heavy quark masses from ψ and Υ spectroscopy. The quark masses are obtained by comparing a nonperturbative computation of the meson spectrum with the experimental data. The lattice quark mass values can then be converted into quark mass values in the continuum QCD Lagrangian Eq. (1) using lattice perturbation theory at a scale given by the inverse lattice spacing. A recent computation determines the *b*-quark pole mass to be 5.0 ± 0.2 GeV, and the $\overline{\rm MS}$ mass to be 4.0 ± 0.1 GeV [4].

Potential model calculations of the hadron spectrum also involve the heavy quark mass. There is no way to relate the quark mass as defined in a potential model to the quark mass parameter of the QCD Lagrangian, or to the pole mass. Even in the heavy quark limit, the two masses can differ by nonperturbative effects of order $\Lambda_{\rm QCD}$. There is also no reason why the potential model quark mass should be independent of the particular form of the potential used.

Recent work on the heavy quark effective theory [5-9] has provided a definition of the quark mass for a heavy quark that is valid when one includes nonperturbative effects and will be called the HQET mass m_Q . The HQET mass is particularly useful in the analysis of the $1/m_Q$ corrections in HQET. The HQET mass agrees with the pole mass to all orders in perturbation theory when only one quark flavor is present, but differs from the pole mass at order α_s^2 when there are additional flavors [10]. Physical quantities such as hadron masses can in principle be computed in the heavy quark effective theory in terms of the HQET mass m_Q . The computations cannot be done analytically in practice because of nonperturbative effects in QCD, which also prevent a direct extraction of the quark masses from the original QCD Lagrangian, Eq. (1). Nevertheless, for heavy quarks, it is possible to parametrize the nonperturbative effects to a given order in the $1/m_Q$ expansion in terms of a few unknown constants that can be obtained from experiment. For example, the B and D meson masses in the heavy quark effective theory are given in terms of a single nonperturbative parameter $\overline{\Lambda}$,

$$M(B) = m_b + \overline{\Lambda} + \mathcal{O}\left(\frac{\overline{\Lambda}^2}{m_b}\right) ,$$

$$M(D) = m_c + \overline{\Lambda} + \mathcal{O}\left(\frac{\overline{\Lambda}^2}{m_c}\right) .$$
(2)

This allows one to determine the mass difference $m_b - m_c =$ M(B) - M(D) = 3.4 GeV up to corrections of order $\overline{\Lambda}^2/m_b - M(B) = 3.4 \text{ GeV}$ $\overline{\Lambda}^2/m_c$. The extraction of the individual quark masses m_b and m_c requires some knowledge of $\overline{\Lambda}$. An estimate of $\overline{\Lambda}$ using QCD sum rules gives $\overline{\Lambda} = 0.57 \pm 0.07$ GeV [11]. The HQET masses with this value of $\overline{\Lambda}$ are $m_b = 4.74 \pm 0.14$ GeV and $m_c = 1.4 \pm 0.2$ GeV, where the spin averaged meson masses $(3M(B^*) + M(B))/4$ and $(3M(D^*) + M(D))/4$ have been used to eliminate the spin-dependent $\mathcal{O}(\overline{\Lambda}^2/m_Q)$ correction terms. The errors reflect the uncertainty in $\overline{\Lambda}$ and the unknown spinaveraged $\mathcal{O}(\overline{\Lambda}^2/m_Q)$ correction. The errors do not include any theoretical uncertainty in the QCD sum rules, which could be large. A quark model estimate suggests that $\overline{\Lambda}$ is the constituent quark mass (≈ 350 MeV), which differs significantly from the sum rule estimate. In HQET, the $1/m_Q$ corrections to heavy meson decay form-factors are also given in terms of $\overline{\Lambda}$. Thus an accurate enough measurement of these form-factors could be used to extract $\overline{\Lambda}$ directly from experiment, which then determines the quark masses up to corrections of order $1/m_Q$.

The quark mass m_Q of HQET can be related to other quark mass parameters using QCD perturbation theory at the scale m_Q . The relation between m_Q and $\widehat{m}(\xi)$ at one loop is [12]

$$m_Q = \widehat{m}(\xi) \left[1 + \frac{\widehat{\alpha}_s(\xi)}{\pi} \frac{\xi + 2}{\xi + 1} \log(\xi + 2) \right], \tag{3}$$

where $\widehat{\alpha}_s(\xi)$ is the strong interaction coupling constant in the momentum space subtraction scheme. The relation between m_O and the $\overline{\text{MS}}$ mass \overline{m} is known to two loops [13],

$$m_Q = \overline{m}(m_Q) \left[1 + \frac{4\overline{\alpha}_s(m_Q)}{3\pi} + \left(16.11 - 1.04 \sum_k \left(1 - \frac{m_{Q_k}}{m_Q} \right) \right) \left(\frac{\overline{\alpha}_s(m_Q)}{\pi} \right)^2 \right], \quad (4)$$

where $\overline{\alpha}_s(\mu)$ is the strong interaction coupling constants in the $\overline{\text{MS}}$ scheme, and the sum on k extends over all flavors Q_k lighter than Q. For the b-quark, Eq. (4) reads

$$m_b = \overline{m}_b (m_b) [1 + 0.09 + 0.06],$$
 (5)

where the contributions from the different orders in α_s are shown explicitly. The two loop correction is comparable in size and has the same sign as the one loop term. There is

presumably an error of order 0.05 in the relation between m_b and $\overline{m}_b(m_b)$ from the uncalculated higher order terms.

D. Light quarks

For light quarks, one can use the techniques of chiral perturbation theory to extract quark mass ratios. The light quark part of the QCD Lagrangian Eq. (1) has a chiral symmetry in the limit that the light quark masses are set to zero, under which left- and right-handed quarks transform independently. The mass term explicitly breaks the chiral symmetry, since it couples the left- and right-handed quarks to each other. A systematic analysis of this explicit chiral symmetry breaking provides some information on the light quark masses.

It is convenient to think of the three light quarks u, d and s as a three component column vector Ψ , and to write the mass term for the light quarks as

$$\overline{\Psi}M\Psi = \overline{\Psi}_L M\Psi_R + \overline{\Psi}_R M\Psi_L, \tag{6}$$

where M is the quark mass matrix M,

$$M = \begin{pmatrix} m_u & 0 & 0 \\ 0 & m_d & 0 \\ 0 & 0 & m_s \end{pmatrix}. \tag{7}$$

The mass term $\overline{\Psi}M\Psi$ is the only term in the QCD Lagrangian that mixes left- and right-handed quarks. In the limit that $M\to 0$, there is an independent SU(3) flavor symmetry for the left- and right-handed quarks. This $G\chi=\mathrm{SU}(3)_L\times\mathrm{SU}(3)_R$ chiral symmetry of the QCD Lagrangian is spontaneously broken, which leads to eight massless Goldstone bosons, the π 's, K's, and η , in the limit $M\to 0$. The symmetry $G\chi$ is only an approximate symmetry, since it is explicitly broken by the quark mass matrix M. The Goldstone bosons acquire masses which can be computed in a systematic expansion in M in terms of certain unknown nonperturbative parameters of the theory. For example, to first order in M one finds that [14,15]

$$m_{\pi^0}^2 = B (m_u + m_d) ,$$

$$m_{\pi^{\pm}}^2 = B (m_u + m_d) + \Delta_{em} ,$$

$$m_{K^0}^2 = m_{\overline{K}^0}^2 = B (m_d + m_s) ,$$

$$m_{K^{\pm}}^2 = B (m_u + m_s) + \Delta_{em} ,$$

$$m_{\eta}^2 = \frac{1}{3} B (m_u + m_d + 4m_s) ,$$
(8)

with two unknown parameters B and Δ_{em} , the electromagnetic mass difference. From Eq. (8), one can determine the quark mass ratios [14]

$$\frac{m_u}{m_d} = \frac{2m_{\pi^0}^2 - m_{\pi^+}^2 + m_{K^+}^2 - m_{K^0}^2}{m_{K^0}^2 - m_{K^+}^2 + m_{\pi^+}^2} = 0.56 ,
\frac{m_s}{m_d} = \frac{m_{K^0}^2 + m_{K^+}^2 - m_{\pi^+}^2}{m_{K^0}^2 + m_{\pi^+}^2 - m_{K^+}^2} = 20.1 ,$$
(9)

to lowest order in chiral perturbation theory. The error on these numbers is the size of the second-order corrections, which are discussed at the end of this section. Chiral perturbation theory cannot determine the overall scale of the quark masses, since it uses only the symmetry properties of M, and any multiple of M has the same G_{χ} transformation law as M. This can be seen from Eq. (8), where all quark masses occur only in the form Bm, so that B and m cannot be determined separately.

The mass parameters in the QCD Lagrangian have a scale dependence due to radiative corrections, and are renormalization scheme dependent. Since the mass ratios extracted using chiral perturbation theory use the symmetry transformation property of M under the chiral symmetry G_X , it is important to use a renormalization scheme for QCD that does not change this transformation law. Any quark mass independent subtraction scheme such as $\overline{\rm MS}$ is suitable. The ratios of quark masses are scale independent in such a scheme.

The absolute normalization of the quark masses can be determined by using methods that go beyond chiral perturbation theory, such as QCD sum rules [3]. Typically, one writes a sum rule for a quantity such as B in terms of a spectral integral over all states with certain quantum numbers. This spectral integral is then evaluated by assuming it is dominated by one (or two) of the lowest resonances, and using the experimentally measured resonance parameters [16]. There are many subtleties involved, which cannot be discussed here [16].

Another method for determining the absolute normalization of the quark masses, is to assume that the strange quark mass is equal to the SU(3) mass splitting in the baryon multiplets [14,16]. There is an uncertainty in this method since in the baryon octet one can use either the Σ -N or the Λ -N mass difference, which differ by about 75 MeV, to estimate the strange quark mass. But more importantly, there is no way to relate this normalization to any more fundamental definition of quark masses.

One can extend the chiral perturbation expansion Eq. (8) to second order in the quark masses M to get a more accurate determination of the quark mass ratios. There is a subtlety that arises at second order [17], because

$$M\left(M^{\dagger}M\right)^{-1}\det M^{\dagger} \tag{10}$$

transforms in the same way under $G\chi$ as M. One can make the replacement $M\to M(\lambda)=M+\lambda M\left(M^\dagger M\right)^{-1}\det M^\dagger$ in all formulæ,

$$M(\lambda) = \operatorname{diag}(m_u(\lambda), m_d(\lambda), m_s(\lambda))$$

$$= \operatorname{diag}(m_u + \lambda m_d m_s, \ m_d + \lambda m_u m_s, \ m_s + \lambda m_u m_d), (11)$$

so it is not possible to determine λ by fitting to data. One can only determine the ratios $m_i(\lambda)/m_j(\lambda)$ using second-order chiral perturbation theory, not the desired ratios $m_i/m_j = m_i(\lambda = 0)/m_j(\lambda = 0)$.

Dimensional analysis can be used to estimate [18] that second-order corrections in chiral perturbation theory due to the

Quarks

strange quark mass are of order $\lambda m_s \sim 0.25$. The ambiguity due to the redefinition Eq. (11) (which corresponds to a second-order correction) can produce a sizeable uncertainty in the ratio m_u/m_d . The lowest-order value $m_u/m_d = 0.56$ gets corrections of order $\lambda m_s(m_d/m_u - m_u/m_d) \sim 30\%$, whereas m_s/m_d gets a smaller correction of order $\lambda m_s(m_u/m_d - m_u m_d/m_s^2) \sim 15\%$. A more quantitative discussion of second-order effects can be found in Refs. 17,19,20. Since the second-order terms have a single parameter ambiguity, the value of m_u/m_d is related to the value of m_s/m_d .

The ratio m_u/m_d is of great interest since there is no strong CP problem if $m_u=0$. To determine m_u/m_d requires fixing λ in the mass redefinition Eq. (11). There has been considerable effort to determine the chiral Lagrangian parameters accurately enough to determine m_u/m_d , for example from the analysis of the decays $\psi' \to \psi + \pi^0, \eta$, the decay $\eta \to 3\pi$, using sum rules, and from the heavy meson mass spectrum [16,21–24]. A recent paper giving a critique of these estimates is Ref. 25.

Eventually, lattice gauge theory methods will be accurate enough to be able to compute meson masses directly from the QCD Lagrangian Eq. (1), and thus determine the light quark masses. For a reliable determination of quark masses, these computations will have to be done with dynamical fermions, and with a small enough lattice spacing that one can accurately compute the relation between lattice and continuum Lagrangians.

The quark masses for light quarks discussed so far are often referred to as current quark masses. Nonrelativistic quark models use constituent quark masses, which are of order 350 MeV for the u and d quarks. Constituent quark masses model the effects of dynamical chiral symmetry breaking, and are not related to the quark mass parameters m_k of the QCD Lagrangian Eq. (1). Constituent masses are only defined in the context of a particular hadronic model.

E. Numerical values and caveats

The quark masses in the particle data listings have been obtained by using the wide variety of theoretical methods outlined above. Each method involves its own set of approximations and errors. In most cases, the errors are a best guess at the size of neglected higher-order corrections. The expansion parameter for the approximations is not much smaller than unity (for example it is $m_K^2/\Lambda_\chi^2 \approx 0.25$ for the chiral expansion), so an unexpectedly large coefficient in a neglected higher-order term could significantly alter the results. It is also important to note that the quark mass values can be significantly different in the different schemes. For example, assuming that the b-quark pole mass is 5.0 GeV, and $\overline{\alpha}_s(m_b) \approx 0.22$ gives the $\overline{\rm MS}$ b-quark mass $\overline{m}_b(\mu = m_b) = 4.6$ GeV using the one-loop term in Eq. (4), and $\overline{m}_b(\mu=m_b)=4.3$ GeV including the one-loop and two-loop terms. The heavy quark masses obtained using HQET, QCD sum rules, or lattice gauge theory are consistent with each other if they are all converted into the same scheme. When using the data listings, it is important to remember that

the numerical value for a quark mass is meaningless without specifying the particular scheme in which it was obtained. All non- $\overline{\rm MS}$ quark masses have been converted to $\overline{\rm MS}$ values in the data listings using one-loop formulæ, unless an explicit two-loop conversion is given by the authors in the original article.

u-QUARK MASS

The u-, d-, and s-quark masses are estimates of so-called "current-quark masses," in a mass-independent subtraction scheme such as $\overline{\rm MS}$ at a scale $\mu \approx 1$ GeV. The ratios m_u/m_d and m_s/m_d are extracted from pion and kaon masses using chiral symmetry. The estimates of d and u masses are not without controversy and remain under active investigation. Within the literature there are even suggestions that the u quark could be essentially massless. The s-quark mass is estimated from SU(3) splittings in hadron masses.

- 10 BIJNENS 95 determines $m_{\overline{u}} + m_{\overline{d}}$ (1 GeV) = 12 \pm 2.5 MeV using finite energy sum
- rules. 11 JAMIN 95 uses QCD sum rules at next-to-leading order.
- 12 NARISON 95C determines the $\overline{\rm MS}$ mass at 1 GeV. 13 ADAMI 93 obtain $m_d-m_u{=}3\pm1$ MeV at $\mu{=}0.5$ GeV using isospin-violating effects in QCD sum rules.

- 14 NEFKENS 92 results for m_d-m_u are 3.1 \pm 0.4 MeV from meson masses and 3.6 \pm 0.4 MeV from baryon masses.
- 15 BARDUCCI 88 renormalized quark mass at 1 GeV. Uses a calculation of the effective potential for $\overline{\psi}\psi$ in QCD, and estimates for $\Sigma(\rho^2)$.
- 16 DOMINGUEZ 87 uses QCD sum rules to obtain $m_u + m_d = 15.5 \pm 2.0$ MeV and m_d $m_{\,U}=6\pm 1.5$ MeV.
- 17 KREMER 84 obtain $m_u + m_d = 21 \pm 2$ MeV at $Q^2 = 1~{\rm GeV^2}$ using SVZ values for quark condensates; they obtain $m_U+m_d=35\pm3$ MeV at $Q^2=1$ GeV using factorization values for quark condensates.
- 18 GASSER 82 uses chiral perturbation theory for the mass ratios, and uses QCD sum rules to extract the absolute values. The renormalization scale is 1 GeV. 19 PAGELS 80 uses lowest-order chiral perturbation theory plus an estimate of $\langle \overline{q} \, q \rangle$.
- $^{20}\,\text{PAGELS}$ 80 uses lowest-order chiral perturbation theory plus an estimate of $\langle \overline{q}\,q\,\overline{q}\,q\rangle$
- correlation function.

 21 WEINBERG 77 assumes that the baryon SU(3) splittings are equal to m_{ς} .
- $^{\rm 22}\,{\rm GASSER}$ 75 uses inelastic electron scattering and SU(6).

c-QUARK MASS

The c-quark mass is estimated from charmonium and D masses. It corresponds to the "running" mass in the MS scheme. We have converted masses in other schemes to the $\overline{\text{MS}}$ scheme using one-loop QCD pertubation theory with $\alpha_s(\mu=m_C)=0.39$. The range 1.0–1.6 GeV for the $\overline{\rm MS}$ mass corresponds to 1.2–1.9 GeV for the pole mass (see the "Note on Quark Masses").

b-QUARK MASS

The b-quark mass is estimated from bottomonium and B masses. It corresponds to the "running" mass in the $\overline{\rm MS}$ scheme. We have converted masses in other schemes to the $\overline{\rm MS}$ scheme using one-loop QCD pertubation theory with $\alpha_{\rm S}(\mu{=}m_b)=0.22$. The range 4.1–4.5 GeV for the $\overline{\rm MS}$ mass corresponds to 4.5–4.9 GeV for the pole mass (see the "Note on Quark Masses").

- 1 NARISON 958 uses finite energy sum rules to two-loop accuracy to determine a b-quark pole mass of 4.61 \pm 0.05 GeV. 2 VOLOSHIN 95 result was converted from a pole mass of 4827 \pm 7 MeV using the one-loop formula. Pole mass was extracted using moments of the total cross section for $e^+e^- \rightarrow b$ hadrons.

- 3 DAVIES 94 uses lattice computation of $^{\gamma}$ spectroscopy. They also quote a value of 5.0 \pm 0.2 GeV for the b-quark pole mass. The numerical computation includes quark vacuum polarization (unquenched); they find that the masses are independent of n_f to within their errors. Their error for the pole mass is larger than the error for the $\overline{\rm MS}$ mass, because both are computed from the bare lattice quark mass, and the conversion for the pole mass is less accurate.
- ⁴ LIGETI 94 computes lower bound of 4.66 GeV on pole mass using HQET, and experimental data on inclusive B and D decays.
- ⁵ LUKE 94 computes lower bound of 4.60 GeV on pole mass using HQET, and experimental data on inclusive B and D decays.
- 6 NARISON 94 uses spectral sum rules to two loops, and $J/\psi(1S)$ and Υ systems.
- 7 TITARD 94 uses one-loop computation of the quark potential with nonperturbative gluon condensate effects to fit $J/\psi(1S)$ and \varUpsilon states.
- ⁸ DOMINGUEZ 92 determines pole mass to be 4.72 \pm 0.05 using next-to-leading order in 1/m in moment sum rule.
- 9 NARISON 89 determines the Georgi-Politzer mass at $\rho^2\!=\!-m^2$ to be 4.23 \pm 0.05 GeV using QCD sum rules.
- 10 REINDERS 88 determines the Georgi-Politzer mass at $p^2=-m^2$ to be 4.17 \pm 0.02 using moments of $\overline{b}\gamma^\mu b$. This technique leads to a value for the mass of the B meson of 5.25 \pm 0.15 GeV.
- 11 NARISON 87 determines the pole mass to be 4.70 \pm 0.14 using QCD sum rules, with $\Lambda(\overline{\text{MS}})=180\pm80$ MeV.
- 12 GASSER 82 uses SVZ sum rules. The renormalization point is $\mu=$ quark mass.

$m_b - m_c$ MASS DIFFERENCE

The mass difference m_b-m_c in the HQET scheme is 3.4 \pm 0.2 GeV (see the "Note on Quark Masses").

THE TOP QUARK

(by M. Mangano at CERN and T. Trippe at LBNL)

A. Introduction: The top quark is the Q = 2/3, $T_3 = +1/2$ member of the weak-isospin doublet containing the bottom quark (see our review on the "Standard Model of Electroweak Interactions" for more information). The existence of a sixth quark has been expected since the discovery of the bottom quark itself and has become an absolute theoretical necessity within the Standard Model (SM) after the measurement of the $T_3 = -1/2$ weak isospin of the bottom quark [1]. While models with additional quarks but quantum numbers different from the top quark have been constructed, the simplest hypothesis that the weak doublet containing the bottom be completed into a family structure similar to the first two generations has always been the most appealing. This idea has finally been confirmed with the recent announcement of the top discovery by the CDF and DØ experiments at the Fermilab 1.8 TeV Tevatron proton-antiproton collider.

We start this note by presenting a brief historical survey of top searches. Then we discuss in more detail the essential features of top production and decay properties which were exploited to perform the discovery. Finally, we discuss the experimental and theoretical issues involved in the determination of its parameters (mass, production cross section, decay branching ratios, *etc.*) and conclude with the prospects for future improvements.

B. Some history: The first expectations for the value of the top mass used a naive extrapolation of the up- to down-type quark mass ratios in the first two generations, leading to values in the range of 10–20 GeV. Direct searches for $t\bar{t}$ pair production in e^+e^- collisions in this mass range were performed beginning in the late 70's at DESY and SLAC (see the compilation of limits in our 1990 edition [2]). These searches looked for a sudden increase in the ratio $R = \sigma(e^+e^- \to \text{hadrons})/\sigma(e^+e^- \to \mu^+\mu^-)$ or for anomalies in the distributions of thrust and acoplanarity in hadronic events. The lower limit on the top mass was increased to 30 GeV and then to approximately 46 GeV between the end of the 80's and the beginning of the 90's, when the more powerful Tristan, SLC and LEP e^+e^- colliders began operations (see the t-Quark Particle Listings in the current edition).

In parallel to the searches in e^+e^- collisions, direct searches were performed during the 80's by the UA1 and UA2 experiments at the CERN $S\overline{p}pS$ proton-antiproton collider, $\sqrt{s}=630$ GeV. At this energy, and at the available luminosities, the CERN experiments were sensitive to top mass values not exceeding 70 GeV, the top quark being mostly produced via an intermediate on-shell W, decaying to $t\overline{b}$. A top quark with mass below the Wb threshold was then expected to undergo a 3-body weak decay to a $bf\overline{f}'$ final state, with $f\overline{f}'$ being a weak isospin doublet such as $\nu_\ell \overline{\ell}$ or $u\overline{d}$.

Because of the overwhelming QCD background to the detection of the purely hadronic final states, the experiments looked for final states including a high momentum isolated lepton, missing transverse energy (E_T) , and one or more jets. No evidence for top production was obtained (see the t-Quark Particle Listings in the current edition for the references): the 95% CL mass limits went from 41 GeV (UA1, 1988), to 60 GeV (UA1, 1990), to 69 GeV (UA2, 1990). The first limits from CDF at the Fermilab Tevatron also appeared in 1990: $m_t > 72$ GeV from searches in the $e\mu$ final states, and $m_t > 77$ GeV from searches in the e plus jets and missing E_T final states.

Further indications of a large top mass had come from the measurement of a significant B^0 – \overline{B}^0 mixing, performed in 1986 by UA1 and Argus.

Mass limits independent of the decay mode were also set in the range $m_t > 40$ GeV via the determination of the W boson width, from the measurement in hadronic collisions of the ratio $\sigma(W \to \ell \nu_\ell)/\sigma(Z \to \ell^+ \ell^-)$. With the advent of high-precision electroweak data (from deep-inelastic scattering, M_W , atomic parity violation and, most importantly, from the study of the Z-boson couplings at SLC and LEP), global fits of the SM parameters have become possible, and have provided significant indirect constraints on the value of the top mass, once more indicating a large value (see our review "Standard").

Model of Electroweak Interactions" in the current edition for more information).

In this edition we have shortened the Particle Listings of indirect top mass limits by omitting superseded limits and reviews published before 1994. For more complete listings see our 1994 edition [3].

C. Top quark searches at the Tevatron: The first direct limits on the top mass exceeding the threshold for the decay into real W and a bottom quark came in the early 90's from the Fermilab Tevatron collider: $m_t > 91$ GeV (CDF, 1992) and $m_t > 131$ GeV (D0, 1994).

At the Tevatron energy, 1.8 TeV, a top quark above the W mass is dominantly produced in pairs from pure QCD processes: $q\overline{q} \to t\overline{t}$ and $gg \to t\overline{t}$. For a top mass around 100 GeV, the production cross section is expected to be of the order of 100 pb and is evenly shared between the two above channels. At 150 (175, 200) GeV the cross section is about 10 (5, 2.5) pb, with approximately 80% (90%, 95%) of it due to the light quark annihilation.

For masses above the Wb threshold, and neglecting terms of order m_b^2/m_t^2 , the top quark decay width is predicted in the SM to be [4]:

$$\Gamma_t = \frac{G_F m_t^3}{8\pi\sqrt{2}} (1 - \frac{M_W^2}{m_t^2})^2 (1 + 2\frac{M_W^2}{m_t^2}) [1 - \frac{2\alpha_s}{3\pi} (\frac{2\pi^2}{3} - \frac{5}{2})].$$

The use of G_F in this equation accounts for the largest part of the 1-loop electroweak radiative corrections, providing an expression accurate to better than 2%. The width values increase from 302 MeV (for $m_t=120~{\rm GeV}$) to 1.04 GeV ($m_t=160~{\rm GeV}$) and 2.23 GeV ($m_t=200~{\rm GeV}$). With such a correspondingly short lifetime, the top quark is expected to decay before top-favoured hadrons or $t\bar{t}$ quarkonium bound states can form.

The top quark decay is expected to be largely dominated by the Wb final state. The Ws and Wd final states are suppressed relatively to Wb by the square of the CKM matrix elements V_{ts} and V_{td} , whose values can be estimated under the assumption of unitarity of the three-generation CKM matrix to be less than 0.046 and 0.014, respectively (see our review "The Cabibbo-Kobayashi-Maskawa Mixing Matrix" in the current edition for more information).

Typical final states therefore belong to three classes:

A.
$$t\bar{t} \to W b W \bar{b} \to q \bar{q}' b q'' \bar{q}''' \bar{b}$$
,

B.
$$t\bar{t} \to W b W \bar{b} \to q \bar{q}' b \ell \bar{\nu}_{\ell} \bar{b}$$
,

C.
$$t\bar{t} \to W b W \bar{b} \to \bar{\ell} \nu_{\ell} b \ell' \bar{\nu}_{\ell'} \bar{b}$$
.

The final state quarks emit radiation and evolve into jets of hadrons. The precise number of jets reconstructed by the detectors varies event by event, as it depends on the decay kinematics, as well as on the precise definition of jet used in the analysis. The neutrinos are reconstructed via the large imbalance in detected transverse momentum of the event (missing E_T).

The $t\bar{t}$ production signature is by itself quite clear in all possible decay channels, due to the many kinematical constraints

imposed by the sequential decay via a real W. However, the combination of the limited experimental resolution and of the large cross section for the production of 6 jets in the QCD continuum (several nb) make the search in the purely hadronic channel very difficult. Since the detection of τ leptons has small efficiency, studies have therefore mostly concentrated on final states where one (or both) W decays to either an electron or a muon. Potential physics backgrounds still exist, mainly due to associated production of one (or two) W and several jets, with the W decaying leptonically. The gain in the S/B ratio is by an approximate factor of 10 for each W which is required to decay leptonically.

The theoretical estimates of the physics backgrounds have large uncertainties, since only leading order QCD calculations are available for most of the relevant processes (W+3 and 4 jets, or WW+2 jets). While this limitation is known to affect the estimates of the overall production rates, it is believed that the LO determination of the event kinematics and of the fraction of W plus multi-jet events containing b quarks is rather accurate. In particular, one expects the E_T spectrum of these jets to fall rather steeply, the jet direction to point preferentially at small angles from the beams, and the fraction of events with b quarks to be of the order of few percent. In the case of the top signal, vice versa, the b fraction is $\sim 100\%$ and the jets are rather energetic, since they come from the decay of a massive object. It is therefore possible to improve the S/B ratio by either requiring the presence of a b quark, or by selecting very energetic and central kinematical configurations.

A detailed study of control samples with features similar to those of the relevant backgrounds, but free from possible top contamination (e.g., a sample of Z plus multi-jet events), is required to provide a reliable check on the background estimates.

D. Top observation at CDF and DØ: The CDF experiment and the DØ experiment independently observed the production and decay of the top quark at the Fermilab Tevatron collider in $p\bar{p}$ collisions at $\sqrt{s} = 1.8$ TeV.

The CDF experiment published the first direct experimental evidence for the top quark in 1994 [5]. They found 12 events consistent with top, containing 6 silicon vertex tags, 7 low- p_T lepton tags, and 3 dilepton events (these categories are discussed below in more detail) with estimated backgrounds of 2.3 ± 0.3 , 3.1 ± 0.3 , and $0.56^{+0.25}_{-0.13}$ respectively. The combined excess signal was inconsistent with backgrounds by $2.8~\sigma$, not enough to firmly establish the existence of the top quark. Interpreting the excess events as top, they found a $t\bar{t}$ production cross section of $13.9^{+6.1}_{-4.8}$ pb, larger than the expected QCD cross section discussed below. A mass analysis of seven of these events yielded $m_t = 174 \pm 10^{+13}_{-12}$ GeV. A sample of events selected according to the expected kinematical properties of top provided additional support for the top interpretation [6].

The DØ experiment [7] found nine top candidates in their data taken during the same Tevatron run with an estimated

background of 3.8 ± 0.9 . They found a probability of 2.7% that this yield was consistent with backgrounds, corresponding to a 1.9 σ effect. If they assumed that the observed excess was top production, they obtained a $t\bar{t}$ production cross section of 8.2 ± 5.1 pb at $m_t = 180$ GeV.

After accumulating more than three times the amount of data, both CDF and DØ reported in 1995 [8,9] that they had conclusively observed the top quark.

The CDF experiment [8] observed top signals in two classes of events: $\ell\ell + jets$ events, which have two high- p_T leptons (e or μ) of opposite charge, large missing E_T , and at least two jets; and $\ell + jets/b$ -tag events, which have one high- p_T lepton, large missing E_T , and at least three jets, of which at least one is tagged as a b jet. They tagged b jets by finding secondary vertices from b-quark decay with their silicon vertex detector or by finding low- p_T leptons from semileptonic b decay.

In 67 pb⁻¹ integrated luminosity, CDF observed 37 ℓ + jets/b-tag) events containing 27 secondary vertex b tags and 23 low- p_T lepton b tags with estimated backgrounds of 6.7 ± 2.1 and 15.4 ± 2.0 respectively. They also observed 6 $\ell\ell$ events with an estimated background of 1.3 ± 0.3 events. The combined excess signal observed in these three categories is inconsistent with the background prediction by $4.8 \ \sigma$.

In an integrated luminosity of approximately 50 pb⁻¹ DØ observed 3 $\ell\ell$ + jets events, 8 ℓ + jets events, and 6 ℓ + jets/b-tag events, a total of 17 top candidates. The total estimated background in these events is 3.8 ± 0.6 events. The excess signal is inconsistent with the background prediction by $4.6 \ \sigma$.

E. Measured top properties: CDF and DØ both measured the top mass using single lepton events with four or more jets. Each event was subjected to a two-constraint kinematic fit to the hypothesis $t\bar{t} \to W^+ b W^- \bar{b} \to \ell \nu_\ell q \bar{q}' b \bar{b}$, assuming that the four highest E_T jets were the $t\bar{t}$ daughters. All permutations of these jets were tried, with the restriction that b-tagged jets were assigned to b quarks in the fit.

CDF found that of their 37 $\ell + jets/b$ -tag events, 19 events had four or more jets. Of these 19, $6.9^{+2.5}_{-1.9}$ were expected to be background. A fit to the mass distribution of the 19 events by the sum of the expected distributions for the W + jets background and a top quark yielded $m_t = 176 \pm 8 \pm 10$ GeV where the second error is the estimated systematic uncertainty.

DØ found that of their $14 \ \ell + jets$ (with and without b-tags) events, 11 had four or more jets and passed the fit. To increase the statistics and reduce mass biases, the H_T requirement was removed, yielding $27 \ \ell + 4jets$ events, of which 24 passed the fit. A fit of the mass distribution to top and background contributions yielded $m_t = 199^{+19}_{-21} \pm 22$ GeV, where the second error is the estimated systematic error.

Preliminary results for the top mass based on the full (Run Ia+Ib) data set have been presented by CDF and DØ at conferences in early 1996 and are given in Table 1. Since these are preliminary results, we do not average them or include them in the data listings or summary tables.

Table 1: Preliminary top masses presented at conferences in early 1996. See for example Ref. 10 for CDF results and Ref. 11 for DØ results.

top quark mass	Expt.	Channel
$175.6 \pm 5.7 \pm 7.1 \text{ GeV}$	CDF	lepton + jets
$159^{+24}_{-22} \pm 17 \text{ GeV}$	CDF	dilepton
$187 \pm 8 \pm 12 \text{ GeV}$	CDF	hadronic
$170\pm15\pm10~\mathrm{GeV}$	DØ	lepton + jets
$158 \pm 24 \pm 10~\mathrm{GeV}$	DØ	$e\mu$

The current average of the CDF and DØ published results is $m_t = 180 \pm 12$ GeV, where statistical and systematic errors have been combined in quadrature and where CDF and DØ systematic errors have been assumed to be independent.

Given the experimental technique used to extract the top mass, this value should be taken as representing the top *pole mass* (see our review "Note on Quark Masses" in the current edition).

The extraction of the value of the top mass from the analyses described requires, in addition to an understanding of the absolute energy calibration and resolution of the detectors, also an a priori knowledge of the structure of the final state. Given the hardness of a $t\bar{t}$ production process, jets can in fact arise not only from the top decays, but also from the initial state gluon radiation. Furthermore, quarks from the top decays can radiate additional jets. The presence of these additional jets will affect the shape of the mass spectrum, depending on the details of how the samples used for the mass determination were defined. QCD calculations used to model top production and decay are expected to be rather reliable, but residual uncertainties remain and are accounted for in the overall systematic error on the top mass.

CDF [8] and DØ [9] determined the $t\bar{t}$ cross section in $p\bar{p}$ collisions at $\sqrt{s}=1.8$ TeV from their numbers of top candidates, their estimated background, their $t\bar{t}$ acceptance, and their integrated luminosity. The evaluation was done under the assumption of SM decays $t\to Wb$, with unity branching ratio. Based on their number of secondary-vertex b-tagged events, CDF determined the $t\bar{t}$ cross section to be $6.8^{+3.6}_{-2.4}$ pb at $m_t=175$ GeV. The next-to-leading-order QCD prediction [12],

t

allowing for a variation of the renormalization and factorization scales μ in the range $0.5 < \mu/m_t < 2$ and using the MRSA set of parton densities [13], gives $4.3 < \sigma_{t\bar{t}}(\mathrm{pb}) < 5.0$ at $m_t = 175$ GeV

Based on their 17 top candidates, DØ determined the $t\bar{t}$ cross section to be 6.4 ± 2.2 pb at their central mass value of 199 GeV or 8.2 ± 2.9 pb at 180 GeV. The QCD predictions are: $2.0 < \sigma_{t\bar{t}}(\text{pb}) < 2.4$ ($m_t = 199$ GeV), and $3.6 < \sigma_{t\bar{t}}(\text{pb}) < 4.3$ ($m_t = 180$ GeV).

More recent preliminary values of the $t\bar{t}$ cross section were given at early 1996 conferences CDF found $7.5^{+1.9}_{-1.7}$ pb at 175 GeV [14] and DØ found 5.2 ± 1.8 pb at 170 GeV [15].

The measurement of other properties of the top quark has just started. CDF reported the first direct measurement of the $t \to Wb$ branching ratio [16]. Their preliminary result, obtained by comparing the number of events with 1 and 2 tagged-b jets and using the known tagging efficiency, is: $R = \mathrm{B}(t \to Wb)/\sum_{q=d,s,b} \mathrm{B}(t \to Wq) = 0.87^{+0.13}_{-0.30}^{+0.13}^{+0.13}$

F. The future: With the discovery of the top quark, future studies will follow two main tracks. Theoretically, it is hoped that the large top mass, and the tantalizing coincidence between its current value and the fundamental scale of the electroweak symmetry breaking, will lead to some understanding of the structure of fermion masses and of the symmetry breaking mechanism itself. Experimentally, the work will concentrate on reducing the errors on the mass and cross section determinations and on the measurement of more specific properties of the top quark, namely its decay branching ratios and its couplings. With a smaller error on the top mass, and with yet improved measurements of the electroweak parameters, it will be possible to get important constraints on the value of the Higgs mass. Current global fits performed within the SM and its minimal supersymmetric extension, provide indications for a relatively light Higgs (see the " H^0 Indirect Mass Limits from Electroweak Analysis" in the Particle Listings of the current edition), possibly within the range of the upcoming LEP2 experiments.

The current Tevatron data, once fully analysed, should allow the first determination of limits on rare top decay modes, such as $t \to \gamma c$ or $t \to Zc$. Studies of the decay angular distributions will allow a first direct analysis of the V-A nature of the Wtb coupling, as well as providing direct information on the relative coupling of longitudinal and transverse W bosons to the top. In the SM, the fraction of decays to transversely polarized W bosons is expected to be $1/(1+m_t^2/2M_W^2)$ (29% for $m_t=180~{\rm GeV}$). Deviations from this value would challenge the Higgs mechanism of spontaneous symmetry breaking.

Over the longer term, a direct measurement of the Wtb coupling constant will be possible when enough data will be accumulated to detect the less frequent single-top production processes, such as $q\bar{q}' \to W^* \to t\bar{b}$ and $qb \to q't$ via W exchange.

A precise determination of the top production cross section will test the current theoretical understanding of the production mechanisms. The current state of the art amounts to complete calculations at the next-to-leading order in QCD [12], as well as efforts to resum classes of potentially large logarithmic corrections coming from multiple soft gluon emission in the intial state [17]. A precise understanding of top production at the Tevatron is important for the extrapolation to the higher energies of future colliders, like the LHC, where the expected large cross section will enable more extensive studies.

Discrepancies in rate between theory and data, on the other hand, would be more exciting and might indicate the presence of exotic production channels, as predicted in some models. In this case, one should also expect a modification of kinematical distributions such as the invariant mass of the top pair or the top quark transverse momentum.

As discussed in the previous sections, some of the current uncertainty in the determination of the top mass from the reconstruction of its final state jets arises from theoretical uncertainties in the modeling of the radiation in these very hard events. The current data, once fully analyzed, will presumably help improve our theoretical understanding. At the same time, the larger samples that will become available in the future will allow more strict selection criteria, leading to purer samples of top quarks. For example, requesting the presence of two secondary-vertex b tags in the event, in addition to two and only two central jets of high- E_T , should largely reduce the possibility of erroneously including jets not coming from the top decays into the mass reconstruction. This will significantly improve the mass resolution and will make it less sensitive to the theoretical uncertainties.

Finally, the large mass of the top quark leaves open the possibility of top decays into yet unobserved particles beyond the SM. For example, current limits on the masses of a charged Higgs (H^+) or of a supersymmetric scalar top quark (\tilde{t}) and neutralino $(\tilde{\chi}^0)$, cannot exclude the existence of decays such as $t \to H^+ b$ or $t \to \tilde{t} \tilde{\chi}^0$. The first channel, in particular, has been used extensively in the past in direct top searches (see the Particle Listings in the current edition). Both these exotic modes are currently under investigation at CDF and DØ.

t-Quark Mass in pp Collisions

The t quark has now been observed. Its mass is sufficiently high that decay is expected to occur before hadronization.

Preliminary results for the top mass based on the full (Run la+lb) data set have been presented by CDF and DØ at conferences in early 1996:

$$\begin{split} m_t &= 175.6 \pm 5.7 \pm 7.1 \text{ GeV} & \text{CDF} & \text{ lepton + jets} \\ m_t &= 159 ^{+24}_{-22} \pm 17 \text{ GeV} & \text{CDF} & \text{ dilepton} \\ m_t &= 187 \pm 8 \pm 12 \text{ GeV} & \text{CDF} & \text{ hadronic} \\ \end{split}$$

$$m_t &= 170 \pm 15 \pm 10 \text{ GeV} & \text{DØ} & \text{ lepton + jets} \end{split}$$

 $m_{\,t}=$ 158 \pm 24 \pm 10 GeV Because of the high current interest, we mention these preliminary results here but do not average them or include them in the Listings or Tables. See the note on the top quark for references.

DØ

Search limits, which are now primarily of historical interest, are based on the assumption that no nonstandard decay modes such as $t \rightarrow bH^+$ are available, except as noted in the comments.

- ¹ ABACHI 95 search for $\ell\ell$ +jets ($e\mu$, ee, and $\mu\mu$) and ℓ +jets (ℓ =e or μ). The ℓ +jets search is done in two ways, using either topological cuts or requiring μ tagging. They observe 17 ($3\ell\ell$, 6ℓ -b-jets, and 8ℓ +jets topological) events with an expected background of 3.8 \pm 0.6. These seven analysis channels combine to give a 4.6 standard deviation effect. The mass fit is from 24 ℓ +4-jet events obtained with looser cuts.
- effect. The mass it is from 24.2+4-jet events obtained with noser cuts. 2 ABE 95F search for $\ell\ell$ (e.e. $e\mu$, and $\mu\mu$) final states and ℓ + b-jet final states. They find 37 ℓ + b-jet candidates containing 27 secondary vertex tags and 23 lepton tags with expected backgrounds of 6.7 \pm 2.1 and 15.4 \pm 2.0 respectively. They find 6 $\ell\ell$ events with an expected background of 1.3 \pm 0.3 These three observations combine to give a 4.8 standard deviation effect. The mass fit is from 19ℓ +4-jet events with a ℓ -tag. The shape of the mass distribution is consistant with top and this increases the significance of the effect to 5.0σ
- of the effect to 5.0 σ . 3 ABACH 195B searched for dilepton channels $e\mu+$ jets, ee+ jets, $\mu\mu+$ jets, and single-letpon channels e+ jets and $\mu+$ jets with and without b tagging. They found 9 events where 3.8 \pm 0.9 events are expected from background. Based on an integrated luminosity of 13.5 \pm 1.6 $\rm pb^{-1}$. These analyses combine to give a 1.9 standard deviation effect. Assuming that the observed excess signal is due to top quark production, the cross section is 8.2 \pm 5.1 $\rm pb$ for $m_t=$ 180 GeV.
- ABACH1 95F searched for dilepton channels $e\mu$ + jets, ee+ jets, $\mu\mu$ + jets, and single-lepton channels e+ jets and μ + jets with and without b tagging. The lower mass bound supersedes that of ABACH1 94 and is weaker as a result of a recalibration of the integrated luminosity. Assuming that the observed excess signal is due to top quark production, the cross section is 8.2 \pm 5.1 pb (9.2 \pm 5.7 pb) for m_t = 180 GeV (160 Ca).
- ⁵ABE 950 find evidence for top production in the jet $E_{\mathcal{T}}$ distributions of $W+\geq 3$ jet events, based on an integrated luminosity of 19,3pb $^{-1}$. The observed distributions are consistent with $m_t=170$ GeV. Supersed by ABE 95v.
- 6 ABE 95V find evidence for top production in the jet $E_{\mathcal{T}}$ distributions of $W+\geq 3$ jet events, based on an integrated luminosity of $67pb^{-1}$.
- ⁷ABE,F 95 compared the total transverse energy distribution of the $W+\geq 4$ -jet data with that expected from all known backgrounds and found 3.8 σ deviation in the shape. The distribution agrees well with a linear combination of background and $t\,\bar{t}$ events, the agreement being best for $m_{ extbf{\emph{t}}}=$ 180 GeV.
- ⁸ ABACHI 94 search for $e\mu$ + jets, ee + jets, e + jets, and μ + jets. Production cross section with soft-gluon resummation of LAENEN 94 is used. The limit decreases to >122 GeV if $\mathcal{O}(\alpha_s^{-3})$ cross section is employed for comparison with ABE 92. Superseded by ABACHI 95F.
- ABE 94E search for e.e., $e\mu$, and $\mu\mu$ dilepton final states and single lepton + b-jet final Table 94s search for ee, $e\mu$, and $\mu\mu$ dilepton final states and single lepton + b-jet final states. They observe a total of 15 top topology tags (12 events of which three are doubly tagged) with an expected background of $5.96^{+0.49}_{-0.44}$. The mass determination is from 7 single-lepton + b-jet events which have four jets. Their $\ell\ell$ limit uses the production cross section with soft gluon resummation from LAENEN 94. Superseded by ABE 95F. 10 ABE 944 searched for $t \to bH^+$, $H^+ \to \tau^+\nu_\tau$ with τ decaying hadronically. The search was done in the region $45\,\mathrm{GeV} < m_{H^+} < m_\ell - m_b$ and $55\,\mathrm{GeV} < m_t < m_{H^+} < m_\ell - m_b$ and $55\,\mathrm{GeV} < m_t < m_t$
- search was done in the region 45 GeV $< m_{H^+} < m_t m_b$ and 55 GeV $< m_t < m_{W^+} + m_b$. See their Fig. 3 for the 95% CL excluded regions in the (m_{H^+}, m_t) plane for ${\rm B}(H^+ \to ~ \tau^+ \, \nu_{ au}) =$ 1, 0.75, and 0.5.
- 11 ABE 94) searched for $t\to bH^+, H^+\to \tau^+\nu_\tau, \tau^+\to \ell^+\nu_\ell\bar{\nu}_\tau$. The search was done in the region 45 GeV $< m_{H^+} < m_t m_b$ and 62 GeV $< m_t < 110$ GeV. See their Fig. 2 for the 95% CL excluded regions in the (m_{H^+}, m_t) plane for ${\rm B}(H^+ \to ~ \tau^+ \nu_{ au})$ = 1, 0.75, and 0.5. The entire region of the plane is excluded for B($H^+
 ightarrow au^+
 u_ au$)
- $^{-12}$ ABE 92 search for e.e., e.g., $\mu\mu$ dilepton final states and (e or μ) plus a b-quark jet. The bjet is tagged by a soft muon. The 90%CL limit is 95 GeV. Superseded by ABE 94E $\ell\ell$
- ¹³ALITTI 92F search for $t o bH^+$, $H^+ o au^+
 u_ au$ with au^+ decaying hadronically. m_t between 50 and 70 GeV is excluded if $m_t-m_{H^+}=m_b+(\lesssim$ a few–10 GeV). See their Figs. 5,6 for the excluded region for B(H $^+ \rightarrow \stackrel{\prime\prime}{\tau}^+ \nu_{\tau}) =$ 1, 0.5.
- 14 ALBAJAR 91B searched for the decay $t
 ightarrow H^+ b$ using single muon and dimuon events and assuming B($H^+ \to \tau^+ \nu$) \geq 0.95. The limit holds for $m_{H^+} \lesssim m_t - m_b$ – (3-6) GeV.
- 15 BAER 918 argue that a top quark as light as 60 GeV (65 GeV, if the minimal SUSY framework is assumed) may have escaped detection at CDF if a supersymmetric decay mode is open.
- 16 ABE 90B exclude the region 28-72 GeV.
- 17 ABE 90C cannot exclude $m_{\tilde{t}} < 40$ GeV, but this region is ruled out by other experiments. They study events with an energetic electron, missing transverse energy and two or more jets. Only the $t\bar{t}$ contribution (not $W \to tb$) is relevant for these masses. See also
- ABE 91. 18 AKESSON 90 searched for events having an electron with $p_T>12$ GeV, missing momentum > 15 GeV, and a jet with $E_T>10$ GeV, $|\eta|<2.2$, and excluded m_t between 30 and 69 GeV. 19 BARGER 90E claim that ABE 90C data exclude most regions of two-Higgs-doublet models
- with $m_t < 80$ GeV even if $t \to bH^+$ decay is allowed.
- 20 ALBAJAR 88 value quoted here is revised using the full $O(lpha_s^3)$ cross section of ALTARELLI 88. Superseded by ALBAJAR 90B.

Indirect t-Quark Mass from Standard Model Electroweak Fit

'OUR EVALUATION" below is from the fit to electroweak data described in the "Standard Model of Electroweak Interactions" section of this Review. This fit result does not include direct measurements of m_t . The second error corresponds to m_H =300 $^+_-$ 2400.

The RVUE values are based on the data described in the footnotes. RVUE's published before 1994 and superseded analyses are now omitted. For more complete listings of earlier results, see the 1994 edition (Physical Review D50 1173 (1994)).

- ²¹ ERLER 95 result is from fit with free m_t and $\alpha_s(m_Z)$, yielding $\alpha_s(m_Z) = 0.127(5)(2)$. 22 MATSUMOTO 95 result is from fit with free m_t to Z parameters, M_W , and low-energy neutral-current data. The second error is for $m_H=300^{+700}_{-240}$ GeV, the third error is for $\alpha_s(m_Z)=0.116\pm0.005$, the fourth error is for $\delta\alpha_{\rm had}=0.0283\pm0.0007$.
- $\alpha_s(m_Z) = 0.116 \pm 0.005$, the locality close is to sequence $\alpha_s(m_Z) = 0.016 \pm 0.005$. The second error corresponds to $m_H = 300 + 700$ GeV.
- 24 ACCIARRI 94 value is for $\alpha_{\rm S}(m_Z)$ constrained to 0.124 \pm 0.006. The second error corresponds to $m_H=300^{+700}_{-240}$ GeV.
- $^{25}\,\mathrm{AKERS}$ 94 result is from fit with free $\alpha_\mathrm{S}.$ The second error corresponds to $m_{H}\!\!=\!\!300\,^{+\,700}_{-\,240}$ GeV. The 95%CL limit is m_{t} <210 GeV.
- ²⁶ ARROYO 94 measures the ratio of the neutral-current and charged-current deep inelastic scattering of u_{μ} on an iron target. By assuming the SM electroweak correction, they obtain $1-m_W^2/m_Z^2=0.2218\pm0.0059$, yielding the quoted m_t value. The second error corresponds to $m_H = 300 + 700 \text{ GeV}$.
- 27 BUSKULIC 94 result is from fit with free $\alpha_{\rm S}$. The second error is from $m_{H}{=}300^{+700}_{-240}$
- GeV. 28 ELLIS 94B result is fit to electroweak data available in spring 1994, including the 1994 A_{LR} data from SLD. m_t and m_H are two free parameters of the fit for $\alpha_s(m_Z)=0.118\pm0.007$ yielding m_t above, and $m_H=35^{+70}_{-22}$ GeV. ELLIS 94B also give results for fits including constraints from CDF's direct measurement of m_t and CDF's and DØ's production cross-section measurements. Fits excluding the A_{LR} data from SLD are also given
- ²⁹ GURTU 94 result is from fit with free m_t and $\alpha_s(m_Z)$, yielding m_t above and $\alpha_s(m_Z)$ = $0.125\pm0.005^{+0.003}_{-0.001}$ The second errors correspond to $m_H=300^{+700}_{-240}$ GeV. Uses LEP, M_W , ν N, and SLD electroweak data available in spring 1994.
- ³⁰ MONTAGNA 94 result is from fit with free m_t and $\alpha_s(m_Z)$, yielding m_t above and $\alpha_S(m_Z)=0.124$. The second errors correspond to $m_H=300^{+700}_{-240}$ GeV. Errors in $\alpha(m_Z)$ and m_B are taken into account in the fit. Uses LEP, SLC, and M_W/M_Z data available in spring 1994. ³¹ NOVIKOV 948 result is from fit with free m_t and $\alpha_S(m_Z)$, yielding m_t above and
- $lpha_{
 m S}(m_Z)=$ 0.125 \pm 0.005 \pm 0.002. The second errors correspond to $m_H=$ 300 $^{+700}_{-240}$
- GeV. Uses LEP and CDF electroweak data available in spring 1994. 32 ALITTI 928 assume $m_H=$ 100 GeV. The 95%CL limit is $m_t<$ 250 GeV for $m_H<$

MASS LIMITS for t Quark or Hadron Independent of t Decay Mode

These limits are derived from $\Gamma(W)$ values shown in the W width section. Independent of the top decay mode, any W decay to $t\overline{b}$ would increase the total width of the Wboson. Since the discovery of top, this section is of historical interest only.

- 41 ADRIANI 93G search for vector quarkonium states near Z and give limit on quarkonium–Z mixing parameter $\delta m^2 < (10{\text -}30) \; \text{GeV}^2$ (95%CL) for the mass 88–94.5 GeV. Using Richardson potential, a 15 toponium state is excluded for the mass range 87.9–88.7, 89.1–94.3 GeV. This range is very sensitive to the potential choice.
- 42 Search was near the Z peak at LEP. 43 Assumed $m_{H^+} < m_t 6$ GeV.
- 44 Superseded by ABREU 91F.

ı

- 45 AKRAWY 90B search was restricted to data near the Z peak at $E_{
 m cm}=91.26$ GeV at LEP. The excluded region is between 23.4 and 44.5 GeV if no H^+ decays exist.
- ⁴⁶AKRAWY 908 limit applies for any H^+ branching ratio B($c\bar{s}$). Limit increases to 45.2 GeV if B($c\bar{s}$) = 1. The lower end of the excluded region is m_{H^+} + 5 GeV.
- 47 The ABRAMS 89C limit from an isolated track search is 40.0 GeV. 48 ADACHI 89C search was at $E_{\rm cm}=56.5$ –60.8 GeV at TRISTAN using multi-hadron events accompanying muons.
- events accompanying muons. 49 ENO 89 search at $E_{\rm cm} = 50$ –60.8 GeV at TRISTAN. 50 ADACHI 88 set limit $\sigma({\rm top}) < 8.2$ pb at CL=95% for top-flavored-hadron production from event shape analyses at $E_{\rm cm} = 52$ GeV. By using the quark-parton model cross-section formula with first-order QCD corrections near the threshold, the above limit leads to a lower mass limit of 25.8 GeV at 95% confidence level for top quarks.
- 51 [GARASHI188 searches for leptons in low-thrust events and gives $\Delta R(t) < 0.15$ (95% CL) at $E_{\rm cm} = 50$ –52 GeV.
- 52 SAGAWA 88 set limit $\sigma(\text{top}) < 6.1$ pb at CL=95% for top-flavored hadron production from event shape analyses at $E_{\text{cm}} = 52$ GeV. By using the quark parton model cross-section formula near threshold, the above limit leads to lower mass bounds of 25.9 GeV for charge 2/3 quarks.
- 53 ABE 87 set limit $\sigma(\text{top}) <$ 16 pb at CL=95% for top-flavored hadron production, which
- 93 ABE 87 set limit \(\sigma(\text{top}) < 16 \) pb at CL=95% for top-flavored hadron production, which should be compared with the full top-quark production cross section of 45.9 pb.</p>
 54 YOSHIDA 87 set limit \(\sigma(\text{top}) < 17 \) pb at CL=95% for top-flavored hadron production from event shape analyses at \(E_{cm} = 52 \) GeV. This limit should be compared with the full top-quark production cross section of 34 pb, which takes into account the effect of weak neutral current but neglects its axial-vector coupling contribution expected to be suppressed near threshold. After considering the radiative effects, top quarks of mass below 25.5 GeV can be excluded by the above limit.</p>

>34	95	⁶ ALBAJAR	88	UA1	e or μ + jets

- 1 ABE 92 dilepton analysis limit of >85 GeV at CL=95% also applies to b^\prime quarks, as discussed in ABE 908. 2 MUKHOPADHYAYA 93 analyze CDF dilepton data of ABE 92G in terms of a new
- quark decaying via flavor-changing neutral current. The above limit assumes B(b^\prime $b\ell^+\ell^-)=1\%$. For an exotic quark decaying only via virtual Z [B($b\ell^+\ell^-$) = 3%], the limit is 85 GeV.
- 3 ABE 90B exclude the region 28-72 GeV.
- 4 AKESSON 90 searched for events having an electron with $p_{\mathcal{T}}>12$ GeV, missing momentum >15 GeV, and a jet with $E_{\mathcal{T}}>10$ GeV, $|\eta|<2.2$, and excluded $m_{b'}$
- between 30 and 69 GeV.

 For the reduction of the limit due to non-charged-current decay modes, see Fig. 19 of ALBATAR 90B.
- ALBAJAR 908. $^6 \text{ALBAJAR 88 study events at } E_{\text{cm}} = 546 \text{ and } 630 \text{ GeV} \text{ with a muon or isolated electron,} \\ \text{accompanied by one or more jets and find agreement with Monte Carlo predictions for the production of charm and bottom, without the need for a new quark. The lower mass limit is obtained by using a conservative estimate for the <math display="inline">b'\overline{b'}$ production cross section and by assuming that it cannot be produced in W decays. The value quoted here is revised using the full $O(\alpha_3^2)$ cross section of ALTARELLI 88.

MASS LIMITS for b' (4th Generation) Quark or Hadron in e^+e^- Collisions

Search for hadrons containing a fourth-generation -1/3 quark denoted b'.

The last column specifies the assumption for the decay mode (C C denotes the conventional charged-current decay) and the event signature which is looked for

- ⁷ DECAMP 90F looked for isolated charged particles, for isolated photons, and for four-jet final states. The modes $b'\to bg$ for B $(b'\to bg)>65\%$ $b'\to b\gamma$ for B $(b'\to b\gamma)>5\%$ are excluded. Charged Higgs decay were not discussed.
- A ADRIANI 93G search for vector quarkonium states near Z and give limit on quarkonium-Z mixing parameter $\delta m^2 < (10-30) \text{ GeV}^2$ (95%CL) for the mass 88–94.5 GeV. Using Richardson potential, a 1S $(b' \, \overline{b'})$ state is excluded for the mass range 87.7–94.7 GeV. This range depends on the potential choice.
- 9 ABREU 90D assumed $m_{H^{-}} < m_{b^{\prime}} 3$ GeV.
- $^{10}\,\mathrm{Superseded}$ by ABREU 91F.
- LEP. The excluded region is between 23.6 and 41.4 GeV if no H^\pm decays exist. For charged Higgs decays the excluded regions are between $(m_{H^\pm} + 1.5 \text{ GeV})$ and 45.5
- GeV. 12 AKRAWY 90J search for isolated photons in hadronic Z decay and derive B($Z \rightarrow b' \overline{b}'$)·B($b' \rightarrow \gamma X$)/B($Z \rightarrow hadrons$) < 2.2×10^{-3} . Mass limit assumes $B(b' \rightarrow \gamma X) > 10\%$.
- 13 ABE 89s search at $E_{\rm cm}=$ 56–57 GeV at TRISTAN for multihadron events with a spherical shape (using thrust and acoplanarity) or containing isolated leptons.
- $^{14}\,\mathrm{ABE}$ 89G search was at $E_\mathrm{cm}=$ 55–60.8 GeV at TRISTAN.
- 15 if the photonic decay mode is large (B($b'\to b\gamma$) > 25%), the ABRAMS 89C limit is 45.4 GeV. The limit for for Higgs decay ($b'\to cH^-, H^-\to \overline{c}s$) is 45.2 GeV.
- $^{16}\,\mathrm{ADACHI}$ 89c search was at $E_{\mathrm{CM}}=56.5\text{--}60.8$ GeV at TRISTAN using multi-hadron events accompanying muons.
- The ENO 89 search at $E_{\rm cm} = 50$ –60.8 at TRISTAN.
- ¹⁹ ENO 89 considers arbitrary mixture of the charged current, bg, and $b\gamma$ decays.
- 20 IGARASHI 88 searches for leptons in low-thrust events and gives $\Delta R(b') < 0.26$ (95% CL) assuming charged current decay, which translates to $m_{b'} > 24.4$ GeV.
- ²¹ SAGAWA 88 set limit $\sigma(\text{top}) < 6.1$ pb at CL=95% for top-flavored hadron production from event shape analyses at $E_{\text{cm}} = 52$ GeV. By using the quark parton model cross-section formula near threshold, the above limit leads to lower mass bounds of 23.8 GeV for charge -1/3 quarks.
- for charge -1/3 quarks. 22 ADEVA 86 give 95%CL upper bound on an excess of the normalized cross section, ΔR , as a function of the minimum c.m. energy (see their figure 3). Production of a pair of 1/3 charge quarks is excluded up to $E_{\rm cm}=45.4$ GeV. 2^3 ALTHOFF 84c narrow state search sets limit $\Gamma(e^+e^-)$ B(hadrons) <2.4 keV CL = 95% and heavy charge 1/3 quark pair production m>21 GeV, CL = 95%. 2^4 ALTHOFF 84i exclude heavy quark pair production for 7 < m < 19 GeV (1/3 charge) using aplanarity distributions (CL = 95%).

Free Quark Searches

FREE QUARK SEARCHES

The basis for much of the theory of particle scattering and hadron spectroscopy is the construction of the hadrons from a set of fractionally charged constituents (quarks). A central but unproven hypothesis of this theory, Quantum Chromodynamics, is that quarks cannot be observed as free particles but are confined to mesons and baryons.

Experiments show that it is at best difficult to "unglue" quarks. Accelerator searches at increasing energies have produced no evidence for free quarks, while only a few cosmic-ray and matter searches have produced uncorroborated events.

This compilation is only a guide to the literature, since the quoted experimental limits are often only indicative. Reviews can be found in Refs. 1-3.

Quark Flux — Accelerator Searches

The definition of FLUX depends on the experiment

- (a) is the ratio of measured free quarks to predicted free quarks if there is no "con-
- (b) is the probability of fractional charge on nuclear fragments.
- (c) is the 90%CL upper limit on fractionally-charged particles produced per interaction.
- (d) is quarks per collision.
- (e) is inclusive quark-production cross-section ratio to $\sigma(e^+e^- \to \mu^+\mu^-)$.
- (f) is quark flux per charged particle.
- (g) is the flux per ν -event.
- (h) is quark yield per π^- yield.
- (i) is 2-body exclusive quark-production cross-section ratio to $\sigma(e^+\,e^-\,\rightarrow$ $\mu^+\mu^-$).

	$\mu^+\mu^-$).

- ²¹ Distribution in celestial sphere was described as anisotropic. ²² With telescope axis at zenith angle 40° to the south.

- ²⁴ Urith telescope and 3.1 = 2.3 Leptonic quarks. 2.4 Lifetime $> 10^{-8}$ s; charge ± 0.70 , 0.68, 0.42; and mass >4.4, 4.8, and 20 GeV, respectively. tively.

 25 Time delayed air shower search.
- 26 Prompt air shower search. 27 Also e/4 and e/6 charges.
- 28 No events in subsequent experiments.

PSEUDOSCALAR-MESON DECAY CONSTANTS

(by M. Suzuki, LBNL)

Charged mesons

The decay constant f_P for a charged pseudoscalar meson P is defined by

$$\langle 0|A_{\mu}(0)|P(\mathbf{q})\rangle = if_P q_{\mu}$$
,

where A_{μ} is the axial-vector part of the charged weak current after a Cabibbo-Kobayashi-Maskawa mixing-matrix element $V_{qq'}$ has been removed. The state vector is normalized by $\langle P(\mathbf{q})|P(\mathbf{q'})\rangle=(2\pi)^3$ $2E_q$ $\delta(\mathbf{q}-\mathbf{q'})$, and its phase is chosen to make f_P real and positive. Note, however, that in many theoretical papers our $f_P/\sqrt{2}$ is denoted by f_P .

In determining f_P experimentally, radiative corrections must be taken into account. Since the photon-loop correction introduces an infrared divergence that is canceled by soft-photon emission, we can determine f_P only from the combined rate for $P^{\pm} \to \ell^{\pm} \nu_{\ell}$ and $P^{\pm} \to \ell^{\pm} \nu_{\ell} \gamma$. This rate is given by

$$\begin{split} &\Gamma\left(P \to \ell \nu_{\ell} + \ell \nu_{\ell} \gamma\right) = \\ &\frac{G_F^2 |V_{qq'}|^2}{8\pi} f_P^2 \; m_{\ell}^2 \; m_P \left(1 - \frac{m_{\ell}^2}{m_P^2}\right)^2 \left[1 + \mathscr{O}(\alpha)\right] \; . \end{split}$$

Radiative corrections include inner bremsstrahlung, which is independent of the structure of the meson [1–3], and also a structure-dependent term [4,5]. After radiative corrections are made, there are ambiguities in extracting f_P from experimental measurements. In fact, the definition of f_P is no longer unique.

It is desirable to define f_P such that it depends only on the properties of the pseudoscalar meson, not on the final decay products. The short-distance corrections to the fundamental electroweak constants like $G_F|V_{qq'}|$ should be separated out. Following Marciano and Sirlin [6], we define f_P with the following form for the $\mathcal{O}(\alpha)$ corrections:

$$\begin{split} &1 + \mathcal{O}(\alpha) = \left[1 + \frac{2\alpha}{\pi} \ln\!\left(\frac{m_Z}{m_\rho}\right)\right] \left[1 + \frac{\alpha}{\pi} F(x)\right] \\ &\times \left\{1 - \frac{\alpha}{\pi} \left[\frac{3}{2} \ln\!\left(\frac{m_\rho}{m_P}\right) + C_1 + C_2 \frac{m_\ell^2}{m_\rho^2} \ln\left(\frac{m_\rho^2}{m_\ell^2}\right) + C_3 \frac{m_\ell^2}{m_\rho^2} + \ldots\right]\right\} \;. \end{split}$$

Here

$$F(x) = 3 \ln x + \frac{13 - 19x^2}{8(1 - x^2)} - \frac{8 - 5x^2}{2(1 - x^2)^2} x^2 \ln x$$
$$-2\left(\frac{1 + x^2}{1 - x^2} \ln x + 1\right) \ln(1 - x^2) + 2\left(\frac{1 + x^2}{1 - x^2}\right) L(1 - x^2) ,$$

with

$$x \equiv m_\ell/m_P \; , \;\;\;\; L(z) \equiv \int_0^z rac{\ln(1-t)}{t} \; dt \; .$$

The first bracket in the expression for $1+\mathscr{O}(\alpha)$ is the short-distance electroweak correction. The QCD correction reduces this factor by 0.00033. The second bracket together with the term $-(3\alpha/2\pi)\ln(m_\rho/m_P)$ in the third bracket corresponds to the radiative corrections to the point-like pion decay ($\Lambda_{\rm cutoff} \approx m_\rho$) [2]. The rest of the corrections in the third bracket are expanded in powers of m_ℓ/m_ρ . The expansion coefficients C_1 , C_2 , and C_3 depend on the hadronic structure of the pseudoscalar meson and in most cases cannot be computed accurately. In particular, C_1 absorbs the uncertainty in the matching energy scale between short- and long-distance strong interactions and thus is the main source of uncertainty in determining f_{π^+} accurately.

With the experimental value for the decay $\pi \to \mu \nu_{\mu} + \mu \nu_{\mu} \gamma$, one obtains

$$f_{\pi^+} = 130.7 \pm 0.1 \pm 0.36 \text{ MeV}$$
,

where the first error comes from the experimental uncertainty on $|V_{ud}|$ and the second comes from the uncertainty on C_1 (= 0 ± 0.24) [6]. Similarly, one obtains from the decay $K \to \mu\nu_{\mu} + \mu\nu_{\mu}\gamma$ the decay constant

$$f_{K^+} = 159.8 \pm 1.4 \pm 0.44 \text{ MeV}$$
,

where the first error is due to the uncertainty on $|V_{us}|$.

For the heavy pseudoscalar mesons, uncertainties in the experimental values for the decay rates are much larger than the radiative corrections. For the D^+ , only an upper bound can be obtained from the published data:

$$f_{D^+} < 310~{
m MeV}~({
m CL} = 90\%)$$
 .

Three groups have measured the $D_s^+ \to \mu^+ \nu_\mu$ branching fraction, leading to the following values of the decay constant:

$$f_{D^{+}} = 232 \pm 45 \pm 20 \pm 48 \text{ MeV}$$
 [7],

$$f_{D^{\pm}} = 344 \pm 37 \pm 52 \pm 42 \text{ MeV [8]}$$
 ,

$$f_{D_s^+} = 430^{+150}_{-130} \pm 40 \text{ MeV}$$
 [9]

where the first errors are statistical, the second errors are systematic, and the third errors are uncertainties involved in extracting the branching fraction $\mathrm{B}(D_s^+ \to \mu^+ \nu_\mu)$. We must wait for more data before drawing a conclusion on $f_{D_s^+}$.

There have been many attempts to extract f_P from spectroscopy and nonleptonic decays using theoretical models. Since it is difficult to estimate uncertainties for them, we have listed here only values of decay constants that are obtained directly from the observation of $P^\pm \to \ell^\pm \nu_\ell$.

 π^{\pm}

Light neutral mesons

The decay constants for the light neutral pseudoscalar mesons π^0 , η , and η' are defined by

$$\langle 0|A_{\mu}(0)|P^{0}(\mathbf{q})\rangle = \mathrm{i}(f_{P}/\sqrt{2})q_{\mu}$$

where A_{μ} is a neutral axial-vector current of octet or singlet. Values of f_{P} can be obtained from the two-photon decay $P^{0} \rightarrow \gamma \gamma$, since in the $m_{P}=0$ limit the decay matrix element is determined by the Adler-Bell-Jackiw anomaly [10,11]. However, large uncertainties enter values of f_{P} through extrapolation to the physical mass and, in the case of η and η' , through the mixing angle, too.

The CELLO Collaboration has obtained the values [12]

$$f_{\pi^0} = 119 \pm 4 \text{ MeV}$$

$$f_{\eta} = 133 \pm 10 \text{ MeV}$$

$$f_{\eta'} = 126 \pm 7 \text{ MeV}$$
,

while the TPC/2 γ Collaboration has obtained [13]

$$f_n = 129 \pm 8 \text{ MeV}$$

$$f_{n'} = 110 \pm 7 \text{ MeV}$$
.

(We have multiplied the published values by $\sqrt{2}$ to be in accord with our definition of f_P .)

We have omitted some results that have been superseded by later experiments. The omitted results may be found in our 1988 edition Physics Letters **B204** (1988).

π^{\pm} MASS

The most accurate charged pion mass measurements are based upon x-ray wavelength measurements for transitions in π^- -mesonic atoms. The observed line is the blend of three components, corresponding to different K-shell occupancies. JECKELMANN 94 revisits the occupancy question, with the conclusion that two sets of occupancy ratios, resulting in two different pion masses (Solutions A and B), are equally probable. We choose the higher Solution B since only this solution is consistent with a positive mass-squared for the muon neutrino, given the precise muon momentum measurements now available (DAUM 91, ASSAMAGAN 94, and ASSAMAGAN 96) for the decay of pions at rest. Earlier mass determinations with pi-mesonic atoms may have used incorrect K-shell screening corrections.

Measurements with an error of > 0.005 MeV have been omitted from this Lieting

- 1 JECKELMANN 94 Solution B (dominant 2-electron K-shell occupancy), chosen for consistency with positive $m_{\nu_n}^2$.
- ² ASSAMAGAN 96 measures the μ^+ momentum p_μ in $\pi^+ \to \mu^+ \nu_\mu$ decay at rest to be 29.79200 \pm 0.00011 MeV/c. Combined with the μ^+ mass and the assumption m_{ν_μ} = 0, this gives the π^+ mass above; if m_{ν_μ} > 0, m_{π^+} given above is a lower limit.
- Combined instead with m_μ and (assuming *CPT*) the π^- mass of JECKELMANN 94, ρ_μ gives an upper limit on m_{ν_μ} (see the ν_μ).
- 3 JECKELMANN 94 Solution A (small 2-electron K-shell occupancy) in combination with either the DAUM 91 or ASSAMAGAN 94 pion decay muon momentum measurement yields a significantly negative $m_{\nu_{\perp}}^2$. It is accordingly not used in our fits.
- 4 The DAUM 91 value includes the ABELA 84 result. The value is based on a measurement of the μ^+ momentum for π^+ decay at rest, $\rho_\mu=29.79179\pm0.00053$ MeV, uses $m_\mu=105.658389\pm0.000034$ MeV, and assumes that $m_{\nu_\mu}=0$. The last assumption means that in fact the value is a lower limit.
- that in fact the value is a lower limit. $^{-\mu}$ SIECKELMANN 86B gives $m_{\pi}/m_e = 273.12677(71)$. We use $m_e = 0.51099906(15)$ MeV from COHEN 87. The authors note that two solutions for the probability distribution of K-shell occupancy fit equally well, and use other data to choose the lower of the two possible π^{\pm} masses.
- These values are scaled with a new wavelength-energy conversion factor $V\lambda = 1.23984244(37) \times 10^{-6}$ eV m from COHEN 87. The LU 80 screening correction relies upon a theoretical calculation of inner-shell refilling rates.
- 7 This MARUSHENKO 76 value used at the authors' request to use the accepted set of calibration γ energies. Error increased from 0.0017 MeV to include QED calculation error of 0.0017 MeV (12 ppm).

$$m_{\pi^+} - m_{\mu^+}$$

Measurements with an error $> 0.05 \; \text{MeV}$ have been omitted from this Listing.

- [a] Measurements of $\Gamma(e^+\nu_e)/\Gamma(\mu^+\nu_\mu)$ always include decays with γ 's, and measurements of $\Gamma(e^+\nu_e\gamma)$ and $\Gamma(\mu^+\nu_\mu\gamma)$ never include low-energy γ 's. Therefore, since no clean separation is possible, we consider the modes with γ 's to be subreactions of the modes without them, and let $[\Gamma(e^+ \nu_e)$ $+ \Gamma(\mu^+ \nu_\mu)]/\Gamma_{\text{total}} = 100\%.$
- [b] See the Particle Listings below for the energy limits used in this measurement; low-energy $\gamma \ensuremath{^{\prime}} \ensuremath{\mathrm{s}}$ are not included.
- [c] Derived from an analysis of neutrino-oscillation experiments.

 $\pi^{\pm} \to \ell^{\pm} \nu \gamma$ AND $K^{\pm} \to \ell^{\pm} \nu \gamma$ FORM FACTORS (by H.S. Pruys, Zürich University)

In the radiative decays $\pi^{\pm} \to \ell^{\pm}\nu\gamma$ and $K^{\pm} \to \ell^{\pm}\nu\gamma$, where ℓ is an e or a μ and γ is a real or virtual photon $(e^+e^-$ pair), both the vector and the axial-vector weak hadronic currents contribute to the decay amplitude. Each current gives a structure-dependent term $(\mathrm{SD}_V \text{ and } \mathrm{SD}_A)$ from virtual hadronic states, and the axial-vector current also gives a contribution from inner bremsstrahlung (IB) from the lepton and meson. The IB amplitudes are determined by the meson decay constants f_π and f_K [1]. The SD_V and SD_A amplitudes are parameterized in terms of the vector form factor F_V and the axial-vector form factors F_A and R [1–4]:

$$M(\mathrm{SD}_V) = \frac{-eG_F\,V_{qq'}}{\sqrt{2}\,m_P} \epsilon^\mu\,\ell^\nu\,F_V\,\epsilon_{\mu\nu\sigma\tau}\,k^\sigma\,q^\tau \;,$$

$$M({\rm SD}_A) = \frac{-ie\, G_F V_{qq'}}{\sqrt{2} \ m_P} \, \epsilon^\mu \, \ell^\nu \left\{ F_A \left[(s-t) g_{\mu\nu} - q_\mu \, k_\nu \right] + R \, t \, g_{\mu\nu} \right\} \; . \label{eq:MSDA}$$

Here $V_{qq'}$ is the Cabibbo-Kobayashi-Maskawa mixing-matrix element; ϵ^{μ} is the polarization vector of the photon (or the effective vertex, $\epsilon^{\mu}=(e/t)\overline{u}(p_{-})\gamma^{\mu}v(p_{+})$, of the $e^{+}e^{-}$ pair); $\ell^{\nu}=\overline{u}(p_{\nu})\gamma^{\nu}(1-\gamma_{5})v(p_{\ell})$ is the lepton-neutrino current; q and k are the meson and photon four-momenta, with $s=q\cdot k$ and $t=k^{2}(=(p_{+}+p_{-})^{2})$; and P stands for π or K. In the analysis of data, the s and t dependence of the form factors is neglected, which is a good approximation for pions [2] but not for kaons [4]. The pion vector form factor F_{V}^{π} is related via CVC to the π^{0} lifetime, $|F_{V}^{\pi}|=(1/\alpha)\sqrt{2\Gamma_{\pi^{0}}/\pi m_{\pi^{0}}}$ [1]. PCAC relates R to the electromagnetic radius of the meson [2,4], $R^{P}=\frac{1}{3}m_{P}f_{P}\langle r_{P}^{2}\rangle$. The calculation of the other form factors, F_{A}^{π} , F_{V}^{K} , and F_{A}^{K} , is model dependent [1,4].

When the photon is real, the partial decay rate can be given analytically [1,5]:

$$\frac{d^2\Gamma_{P\rightarrow\ell\nu\gamma}}{dxdy} = \frac{d^2\left(\Gamma_{\rm IB} + \Gamma_{\rm SD} + \Gamma_{\rm INT}\right)}{dxdy} \; , \label{eq:delta-de$$

where Γ_{IB} , Γ_{SD} , and Γ_{INT} are the contributions from inner bremsstrahlung, structure-dependent radiation, and their interference, and the Γ_{SD} term is given by

$$\frac{d^2\Gamma_{\rm SD}}{dxdy} = \frac{\alpha}{8\pi} \Gamma_{P \to \ell\nu} \frac{1}{r(1-r)^2} \left(\frac{m_P}{f_P}\right)^2 \times \left[(F_V + F_A)^2 \, \text{SD}^+ + (F_V - F_A)^2 \, \text{SD}^- \right] .$$

Here

$$SD^{+} = (x + y - 1 - r) [(x + y - 1)(1 - x) - r] ,$$

$$SD^{-} = (1 - y + r) [(1 - x)(1 - y) + r] ,$$

where $x = 2E_{\gamma}/m_P$, $y = 2E_{\ell}/m_P$, and $r = (m_{\ell}/m_P)^2$.

In $\pi^\pm\to e^\pm\nu\gamma$ and $K^\pm\to e^\pm\nu\gamma$ decays, the interference terms are small, and thus only the absolute values $|F_A+F_V|$ and $|F_A-F_V|$ can be obtained. In $K^\pm\to\mu^\pm\nu\gamma$ decay, the interference term is important, and thus the signs of F_V and F_A can be obtained. In $\pi^\pm\to\mu^\pm\nu\gamma$ decay, bremsstrahlung completely dominates. In $\pi^\pm\to e^\pm\nu e^+e^-$ and $K^\pm\to\ell^\pm\nu e^+e^-$ decays, all three form factors, F_V , F_A , and R, can be determined.

We give the π^{\pm} form factors F_V , F_A , and R in the Listings below. In the K^{\pm} Listings, we give the sum $F_A + F_V$ and difference $F_A - F_V$.

The electroweak decays of the pseudoscalar mesons are investigated to learn something about the unknown hadronic structure of these mesons, assuming a standard V-A structure of the weak leptonic current. The experiments are quite difficult, and it is not meaningful to analyse the results using parameters for both the hadronic structure (decay constants, form factors) and the leptonic weak current (e.g., to add pseudoscalar or tensor couplings to the V-A coupling). Deviations from the V-A interactions are much better studied in purely leptonic systems such as muon decay.

CONSTRAINED FIT INFORMATION

An overall fit to 2 branching ratios uses 4 measurements and one constraint to determine 3 parameters. The overall fit has a χ^2 = 1.9 for 2 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\mathsf{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

$\pi^{\rm 0}$ ELECTROMAGNETIC FORM FACTOR

The amplitude for the process $\pi^0 \to e^+ e^- \gamma$ contains a form factor F(x) at the $\pi^0\gamma\gamma$ vertex, where $x=[m_{e^+e^-}/m_{\pi^0}]^2$. The parameter a in the linear expansion ${\sf F}(x)=1+ax$ is listed below.

All the measurements except that of BEHREND 91 are in the time-like region of momentum transfer.

 $^{^{14}}$ BEHREND 91 estimates that their systematic error is of the same order of magnitude as their statistical error, and so we have included a systematic error of this magnitude. The value of a is obtained by extrapolation from the region of large space-like momentum transfer assuming vector dominance.

- [a] See the "Note on the Decay Width $\Gamma(\eta \to \gamma \gamma)$ " in our 1994 edition, Phys. Rev. **D50**, 1 August 1994, Part I, p. 1451.
- [b] C parity forbids this to occur as a single-photon process.

¹⁵ TUPPER 83 is a theoretical analysis of FISCHER 78 including 2-photon exchange in the

corrections.

16 The FISCHER 78 error is statistical only. The result without radiation corrections is

CONSTRAINED FIT INFORMATION

An overall fit to a decay rate and 15 branching ratios uses 43 measurements and one constraint to determine 9 parameters. The overall fit has a $\chi^2=33.2$ for 35 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j),$ in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}.$ The fit constrains the x_i whose labels appear in this array to sum to one

 $^{^1}$ BEMPORAD 67 gives $\Gamma(2\gamma)=1.21\pm0.26$ keV assuming $\Gamma(2\gamma)/\Gamma(\text{total})=0.314$. Bemporad private communication gives $\Gamma(2\gamma)^2/\Gamma(\text{total})=0.380\pm0.083$. We evaluate this using $\Gamma(2\gamma)/\Gamma(\text{total})=0.38\pm0.01$. Not included in average because the uncertainty resulting from the separation of the coulomb and nuclear amplitudes has apparently been underestimated.

⁴ These experiments are not used in the averages as they do not separate clearly $\eta \to \pi^+\pi^-\pi^0$ and $\eta \to \pi^+\pi^-\gamma$ from each other. The reported values thus probably contain some unknown fraction of $\eta \to \pi^+\pi^-\gamma$.

 $^{^7}$ The authors don't believe this indicates D-wave because the dependence of β on the γ energy is inconsistent with theoretical prediction. A $\cos^2\theta$ dependence may also come from P- and F-wave interference.

ENERGY DEPENDENCE OF $\eta \to ~\pi^+\pi^-\pi^0$ DALITZ PLOT

See the "Note on η Decay Parameters" in our 1994 edition, Phys. Rev. **D50**, 1 August 1994, Part I, p. 1454. The following experiments fit to one or more of the coefficients a, b, c, d, or e for $|\text{matrix element}|^2 = 1 + ay + by^2 + cx + dx^2 + exy$.

a, b, c, d, or e for matrix el	$ ement ^2 = 1 + ay$	y + t	$by^2 + cx + dx^2 + exy$.

 $\rho(770)$

$$\rho$$
(770)

 $I^{G}(J^{PC}) = 1^{+}(1^{-})$

THE $\rho(770)$

Because of its large width, determination of the parameters of the $\rho(770)$ is beset with many difficulties. In physicalregion fits, the line shape does not correspond to a relativistic Breit-Wigner function with a P-wave width, but requires some additional shape parameter. This dependence on parametrization was demonstrated long ago by PISUT 68, who showed that the mass was consistent with values between 761 MeV and 783 MeV to within two standard deviations. When mass values are quoted, as below, with one-standard-deviation errors, the conflicts between them are evident.

The same model dependence afflicts any other source of the resonance parameters, such as the energy dependence of the phase shift δ_1^1 or the pole position. It is therefore not surprising that a recent study of $\rho(770)$ dominance in the decays of the η and η' reveals the need for specific dynamical effects in addition to the $\rho(770)$ pole (BENAYOUN 93).

Recently LAFFERTY 93 has demonstrated that Bose-Einstein correlations are another source of shifts in the $\rho(770)$ line shape.

ρ(770) MASS

We no longer list S-wave Breit-Wigner fits, or data with high combinatorial background.

[a] The e^+e^- branching fraction is from $e^+e^- \to \pi^+\pi^-$ experiments only. The $\omega \rho$ interference is then due to $\omega \rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \to \mu^+ \mu^-) = \Gamma(\rho^0 \to e^+ e^-)$ \times 0.99785.

CONSTRAINED FIT INFORMATION

An overall fit to the total width and a partial width uses 9 measurements and one constraint to determine 3 parameters. The overall fit has a $\chi^2=10.2$ for 7 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left<\delta\rho_i\delta\rho_j\right>/(\delta\rho_i\cdot\delta\rho_j)\text{, in percent, from the fit to parameters }\rho_i\text{, including the branch-}$ ing fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

²⁵ Solution corresponding to constructive ω - ρ interference. The quark model predicts a relative decay phase of zero. Also much favored by the ALDE 93 model-independent measurement of B($\omega \to \eta \gamma$).

²⁶ Solution corresponding to destructive ρ - ω interference.

CONSTRAINED FIT INFORMATION

An overall fit to the total width, a partial width, 2 combinations of partial widths obtained from integrated cross section, and 16 branching ratios uses 45 measurements and one constraint to determine 7 parameters. The overall fit has a $\chi^2=33.4$ for 39 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta \rho_i \delta \rho_j \right\rangle / (\delta \rho_i \cdot \delta \rho_j)$, in percent, from the fit to parameters ρ_i , including the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

$\eta'(958) \; \Gamma(i)\Gamma(\gamma\gamma)/\Gamma(total)$

This combination of a partial width with the partial width into $\gamma\gamma$ and with the total width is obtained from the integrated cross section into channel(i) in the $\gamma\gamma$ annihilation.

1 At high t				

- ² At low |t|.
- 3 On sheet II in a 4-pole solution, the other poles are found on sheet III at (953–55/) MeV and on sheet IV at (938–35/) MeV.
- Combined fit of ALDE 95B, ANISOVICH 94, AMSLER 94D.
- 5 On sheet II in a 2 pole solution. The other pole is found on sheet III at (996–103f) MeV.
 6 On sheet II in a 2 pole solution. The other pole is found on sheet III at (797–185f) MeV
- and can be interpreted as a shadow pole.

 On sheet II in a 2 pole solution. The other pole is found on sheet III at (978–28/) MeV.
- ⁸ From invariant mass fit. ⁹ From coupled channel analysis.
- 10 Coupled channel analysis with finite width corrections.
- 11 Included in AGUILAR-BENITEZ 78 fit.

f₀(980) WIDTH

Width determination very model dependent. Peak width is about 50 MeV, but decay width can be much larger.

Γ_4	e^+e^-	< 3 × 10	₀ -7 90%

CONSTRAINED FIT INFORMATION

An overall fit to a branching ratio uses 3 measurements and one constraint to determine 2 parameters. The overall fit has a χ^2 = 2.0 for 2 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

$$x_2$$
 -100 x_1

CONSTRAINED FIT INFORMATION

An overall fit to the total width, a partial width, and 9 branching ratios uses 43 measurements and one constraint to determine 6 parameters. The overall fit has a $\chi^2=28.9$ for 38 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left<\delta p_i \delta p_j \right>/(\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

	Mode	Rate (MeV)	Scale factor
Γ_1	K ⁺ K ⁻	2.18 ±0.04	1.1
Γ_2	$K_L^0 K_S^0$	1.510 ± 0.029	1.1
Γ ₃ Γ ₄	$ ho\pi$	0.570 ± 0.030	
Γ_4	$\pi^{+}\pi^{-}\pi^{0}$	0.12 ± 0.04	1.1
Γ_5	$\eta\gamma$	0.0561 ± 0.0025	1.1

 $^{^1}$ Weighted and scaled average of 12 measurements of DIJKSTRA 86. 2 PELLINEN 82 review includes AKERLOF 77, DAUM 81, BALDI 77, AYRES 74, DESCRIPTION 10 PROPERTY OF THE PROPERTY OF THE

GROOT 74.

3 Systematic errors not evaluated.

⁴ Mass errors enlarged by us to Γ/\sqrt{N} ; see the note with the $K^*(892)$ mass.

⁶ Systematic errors not evaluated.

$$a_1(1260)$$

$$I^{G}(J^{PC}) = 1^{-}(1^{+})$$

THE $a_1(1260)$

The main experimental data on the $a_1(1260)$ may be grouped into two classes:

(1) Hadronic production: This comprises diffractive production with incident π^- (DAUM 80, 81B) and charge-exchange production with low-energy π^- (DANKOWYCH 81, ANDO 92). The 1980's experiments explain the $I^GLJ^P = 1^+S0^+$ data using a phenomenological amplitude consisting of a rescattered Deck amplitude plus a direct resonance-production term. They agree on an $a_1(1260)$ mass of about 1270 MeV and a width of 300-380 MeV. ANDO 92 finds rather lower values for the mass (1121 MeV) and width (239 MeV) in a partial-wave analysis based on the isobar model of the $\pi^+\pi^-\pi^0$ system. However, in this analysis, only Breit-Wigner terms were considered.

(2) τ decay: Five experiments have reported good data on $\tau \to a_1(1260)\nu_{\tau} \to \rho\pi\nu_{\tau}$ (RUCKSTUHL 86, SCHMIDKE 86, ALBRECHT 86B, BAND 87, and AKERS 95P). They are somewhat inconsistent concerning the $a_1(1260)$ mass, which can, however, be attributed to model-dependent systematic uncertainties (BOWLER 86, ALBRECHT 93C, AKERS 95P). They all find a width greater than 400 MeV.

The discrepancies between the early hadronic and τ decay results have stimulated several reanalyses. BOWLER 86, TORNQVIST 87, ISGUR 89, and IVANOV 91 have studied the process $\tau \to 3\pi\nu_{\tau}$. Despite quite different approaches, they all found a good overall description of the τ decay data with an $a_1(1260)$ mass near 1230 MeV, consistent with the hadronic data. However, their widths remain significantly higher (400-600 MeV) than those extracted from diffractive-hadronic data. This is also the case with the later OPAL experiment (AKERS 95P).

BOWLER 88 showed that good fits to both the hadronic and the τ -decay data could be obtained with a width of about 400 MeV. However, applying the same type of analysis to the ANDO 92 data, the low mass and narrow width they obtained with the Breit-Wigner PWA do not change appreciably.

CONDO 93 found no evidence for charge-exchange photoproduction of the $a_1(1260)$ (but found a clear signal of $a_2(1320)$ photoproduction). They show that this is consistent with either an extremely large $a_1(1260)$ hadronic width or with a small radiative width to $\pi\gamma$, which could be accommodated if the a_1 mass is somewhat below 1260 MeV.

CONSTRAINED FIT INFORMATION

An overall fit to the total width, 4 partial widths, a combination of partial widths obtained from integrated cross sections, and 6 branching ratios uses 38 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2 = 69.8$ for 31 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta p_i \delta p_j \rangle / (\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

 $\Gamma(\gamma\gamma)$ Γ_7 The value of this width depends on the theoretical model used. Unitarised models with scalars give values clustering around \simeq 2.6; without an S-wave contribution, values are systematically higher (typically around 3). Since it is used to average results obtained with variety of models, we prefer to quote our own estimate.

CONSTRAINED FIT INFORMATION

An overall fit to 7 branching ratios uses 13 measurements and one constraint to determine 6 parameters. The overall fit has a χ^2 = 11.4 for 8 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left<\delta x_i \delta x_j \right>/(\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{
m total}$. The fit constrains the x_i whose labels appear in this array to sum to

$f_1(1285) \Gamma(i)\Gamma(\gamma\gamma)/\Gamma(total)$

$\Gamma(\eta \pi \pi) \times \Gamma(\gamma \gamma) / \Gamma_{\text{total}}$					$\Gamma_6\Gamma_{14}/\Gamma = (\Gamma_7 + \Gamma_8)\Gamma_{14}/\Gamma$

CONSTRAINED FIT INFORMATION

An overall fit to 5 branching ratios uses 18 measurements and one constraint to determine 4 parameters. The overall fit has a $\chi^2 =$ 9.3 for 15 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\mathrm{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

$$\begin{array}{c|ccccc} x_2 & & 10 & & \\ x_3 & & -89 & -46 & & \\ x_4 & & -1 & -2 & -24 \\ \hline & x_1 & x_2 & x_3 & & \end{array}$$

NOTE ON SCALAR MESONS

The analysis of the scalar resonances in the $\pi\pi$ S-wave is notoriously difficult. In other partial waves, a resonance may be identified by the behavior of a single dominant channel across a mass range of a few hundred MeV. In contrast, the scalar waves couple strongly to more than one channel, and have overlapping and interfering broad resonances, often extending over more than 1 GeV. In addition, the $K\overline{K}$ and $\eta\eta$ thresholds produce sharp cusps in the partial waves. Thus, given experimental results in one channel, one can derive conclusions affecting the other scalar resonances. For this reason we discuss in this one Note all light scalars, organized in the Listings under the entries $f_0(400\text{-}1200)$, $f_0(980)$, $f_0(1370)$, $f_0(1500)$, $a_0(980)$, $a_0(1450)$, and $K_0^*(1430)$. This list is "minimal:" it does not necessarily exhaust the list of actual resonances.

The I=0 states and the $\pi\pi$ S-wave: From the $\pi\pi$ threshold to about 1500 MeV, the claimed isoscalar resonances are found under four separate entries: $f_0(400\text{-}1200)$, $f_0(980)$, $f_0(1370)$, and $f_0(1500)$. The data are obtained from resonance decays into the channels $\pi\pi$, $K\overline{K}$, $\eta\eta$, $\eta\eta'$, and 4π .

Below 1100 MeV, the essential contributions come from $\pi\pi$ and $K\overline{K}$ final states. The $\pi\pi$ phase shift δ^0_0 is well known to rise smoothly (GRAYER 74, ROSSELET 77) to 90° at around 900 MeV (HYAMS 73, CASON 76), then shows a rapid step of 180° near the $K\overline{K}$ threshold, due to the $f_0(980)$ resonance, which is superimposed over a large background. Above 1 GeV, the $\pi\pi$ phase shift continues to grow slowly, as expected for a very broad resonance. The $\pi\pi$ S-wave inelasticity is not accurately known, and the reported $\pi\pi \to K\overline{K}$ cross sections (WETZEL 76, POLYCHRONAKOS 79, COHEN 80, ETKIN 82B) may have large uncertainties.

In our editions from 1976 to 1994, this behavior of the phase shift was thought to be due mainly to the narrow $f_0(980)$ and the broad $f_0(1370)$, the latter variously named in earlier editions the $\epsilon(1200)$ and the $f_0(1300\text{-}1400)$. It was, however, always uncertain whether there also exists a very

broad structure mostly called σ in the literature. Before 1974, when the phase shift was known only up to about 900 MeV, one generally believed in a light σ (also called ϵ or η_{0+}) with a very large and uncertain width.

BECKER 79B excluded a narrow resonance behavior for δ_0^0 in their $\pi^- p$ (polarized) $\to \pi^+ \pi^- n$ data below 900 MeV. In contrast, SVEC 92, 96, using their data on $\pi^+ n$ (polarized) $\rightarrow \pi^+\pi^- p$ from 600 to 900 MeV, suggest a narrow scalar state at 750 MeV with a width of 100 to 200 MeV; the $f_0(980)$ was not included, which can explain the very narrow width obtained. Furthermore, the associated δ_0^0 values differ substantially from recent consensus and would reopen the old Up-Down ambiguity of the early 1970's (see our 1984 edition). Thus, the interpretation of SVEC 92 and others who claim a narrow σ must be treated with reservation, although, as SVEC 96 emphasize, the contribution from a_1 exchange in the $\pi N \to \pi \pi N$ processes has not been included in most analyses. New data resolving these important ambiguities would be most welcome. For further discussions of earlier analyses on the $\pi\pi$ S-wave, see our Notes in earlier editions and AU 87, MORGAN 93, and ZOU 93.

It has now become evident that the simplest understanding of the conventional $\pi\pi$ S-wave is obtained if one includes, in addition to the $f_0(980)$ and $f_0(1370)$ resonances, a very broad σ with a mass in the region 400-1200 MeV and a width exceeding 500 MeV (AU 87, MORGAN 93, ZOU 93, 94B, ACHASOV 94, TORNQVIST 95, 96, AMSLER 95B, AMSLER 95D, JANSSEN 95). The large spread in the resonance parameters obtained by these groups is due less to differences in the data used than to differences in the models employed. Important input in all analyses for the $f_0(400\text{-}1200)$ are the standard $\pi\pi$ phase shifts below 1200 MeV, the same for all groups.

As to the $f_0(1370)$, all analyses of $\pi\pi$ and $K\overline{K}$ data claim a mainly elastic resonance around 1400 MeV. This still depends strongly on the standard $\pi\pi$ phase shift solution above 1100 MeV, and in particular on the small inelasticity of that solution, as mentioned above.

Above 1300 MeV, there is also evidence for a scalarisoscalar resonance decaying to 4π . Whether this is the same resonance as the $f_0(1370)$ remains unsettled. There may be two resonances, one seen in elastic $\pi\pi$ scattering and coupling predominantly to $\pi\pi$, and another coupling mainly to 4π via $\rho\rho$ and two $\pi\pi$ S-waves. For now, we list both under the $f_0(1370)$. The 4π decay mode would, however, point to a large inelasticity. The information on the 4π channel comes mainly from the analysis of $\bar{p}n$ or $\bar{p}p \to 5\pi$ (GASPERO 93, ADAMO 93, AMSLER 94). AMSLER 94 finds a large production of a 0^{++} resonance decaying into 4π , mostly $\rho\rho$, with $M=1374\pm38$ MeV and $\Gamma=375\pm61$ MeV, and quotes a $4\pi:2\pi$ branching ratio of order 5:1.

Above the $f_0(1370)$ there is at least one resonance, the $f_0(1500)$, seen by the Crystal Barrel Collaboration (ANTINORI 95, AMSLER 95B, 95C). The $f_0(1590)$ of GAMS (BINON 83) in our 1994 edition is now listed under the same entry as the

$f_0(1370)$

 $f_0(1500)$. For the determination of the resonance parameters, we use only the analyses in terms of T-matrix poles. See also our Note on Non- $q\overline{q}$ Mesons.

The I=1 states: Two states are known, the $a_0(980)$ and the $a_0(1450)$ seen by the Crystal Barrel (AMSLER 94D). For a longer Note on the $a_0(980)$, see our 1994 edition, which includes comments on the nature of this resonance.

The most important fact about the $a_0(980)$ is that it lies very close to the $K\overline{K}$ threshold (like the $f_0(980)$); its shape, mass, and width are strongly distorted by this threshold. A naive Breit-Wigner fit to the resonance bump cannot reveal its true coupling constants to $\eta\pi$ and $K\overline{K}$. To obtain these, one must use a coupled-channel model with energy-dependent widths and mass-shift contributions. For the same reason, the branching ratios to $K\overline{K}$ and $\eta\pi$ are strongly energy dependent and one cannot use quoted width parameters in a naive way to determine the strength of the couplings.

Independently of any model about the nature of the $a_0(980)$ (or the $f_0(980)$), the $K\overline{K}$ component in the wave function of the state must be large. By general quantum mechanical arguments, any state (be it $q\overline{q}$ or whatever) that lies at the Swave $K\overline{K}$ threshold and to which it couples strongly must have significant mixing with the $K\overline{K}$ continuum. Therefore, one cannot discuss the $a_0(980)$ (or the $f_0(980)$) without taking into account this large continuum component, e.q. when calculating $\gamma\gamma$ widths. The $\gamma\gamma$ width will always be suppressed by the $K\overline{K}$ component of the state.

The I=1/2 sector: The $K_0^*(1430)$ (ASTON 88) is certainly the least controversial of the light scalar mesons. The phase shift rises smoothly from threshold, passes 90° at 1350 MeV, and then continues to rise to about 170° at 1600 MeV at the first important inelastic threshold, $K\eta'$. Thus, it behaves just as expected of a single broad, nearly elastic resonance. All analyses agree on a pole mass of about 1430 MeV and a width of about 300 MeV.

Interpretation of the nature of the scalars: Almost every model of the scalar states agrees that the $K_0^*(1430)$ is the 1^3P_0 quark model $s\overline{u}$ (or $s\overline{d}$) state. For the interpretation of the other light scalars, there are two main classes of models:

- (i) The two states near the $K\overline{K}$ threshold, the $f_0(980)$ and the $a_0(980)$, are $K\overline{K}$ bound states (WEINSTEIN 89). The $f_0(1370)$ is the 1^3P_0 $u\overline{u}+d\overline{d}$ state, the $a_0(1450)$ is the $u\overline{d}$ state, and the mainly $s\overline{s}$ is still missing. The last is perhaps the state reported by LASS at 1525 MeV (ASTON 88D) or the $f_J(1710)$. The $f_0(400-1200)$ is then left as a background structure. The $f_0(1500)$ is too light and too narrow to be the second radially excited $u\overline{u} + d\overline{d}$ state, and it is not the missing $s\overline{s}$ state, due to its small $K\overline{K}$ branching ratio. A non- $q\overline{q}$ (gluonium) interpretation seems likely (AMSLER 96); see our Note on Non- $q\overline{q}$ Mesons.
- (ii) Most, if not all, light scalars are different manifestations of the quark model ${}^{3}P_{0}$ $q\bar{q}$ states. The most economic model for this second alternative is that of TORNQVIST 82, 95,

and 96, who fits the $f_0(400-1200)$, $f_0(980)$, $f_0(1370)$, $a_0(980)$, $a_0(1450)$, and $K_0^*(1430)$, as unitarized remnants of $q\bar{q}$ 1^3P_0 states with six parameters and theoretical constraints including flavor symmetry, the OZI rule, the equal-spacing rule for bare $q\overline{q}$ states, Adler zeroes, unitarity, and analyticity. Here the $f_0(400-1200)$ is at the same time the $u\overline{u} + d\overline{d}$ state, the chiral partner of the π , and the Higgs boson of QCD. The $f_0(980)$ and the $f_0(1370)$ are two different manifestations of the unitarized $s\bar{s}$ state, while the $a_0(980)$ and the $a_0(1450)$ are two manifestations of $u\overline{d}$. The interpretation of $f_0(1500)$ is in this scheme an open

For other models and more details discussing the interpretations of the scalar resonances, see AU 87, MORGAN 93, ZOU 93, 94B, and JANSSEN 95.

 $f_1(1420)$

$$I^{G}(J^{PC}) = 0^{+}(1^{+})$$

See also minireview under non- $q\overline{q}$ candidates.

THE $f_1(1420)$

ı

This particle is the axial-vector component of the old puzzling E/ι , which has caused much trouble.

In hadron-induced reactions, the $f_1(1420)$ is observed in centrally produced $K\overline{K}\pi$ systems obtained with π and p beams (DIONISI 80, ARMSTRONG 84, 89). A Dalitz-plot analysis gives its quantum numbers and the dominant decay mode. For instance, ARMSTRONG 89 finds that the signal is totally consistent with being an 1++ state with a dominant quasitwo-body S-wave decay into $K^*(892)\overline{K}$; furthermore, no 0^{-+} or 1^{+-} waves are required to fit the data. A G parity of +1 is suggested by the positive interference between the two overlapping $K^*(892)$ (ARMSTRONG 84). No significant signals in the $\eta\pi\pi$ or 4π decay modes are found in centrally produced 4π systems (ARMSTRONG 89G). All of this is in line with the previous observations made in $\overline{p}p$ annihilations.

In $\gamma\gamma$ fusion from e^+e^- annihilations, a signal at about 1420 MeV is seen only in single-tag events (AIHARA 86C, GIDAL 87B, BEHREND 89, HILL 89), where one of the two photons is off the mass shell; by contrast, it is totally absent in the untagged events where both photons are real and hence they cannot produce a spin-1 meson, because of the Yang-Landau theorem. This clearly implies J=1 and C=+1. As for the parity, AIHARA 88B, 88C (same analysis as AIHARA 86C, with 25% more events) and BEHREND 89 all find angular distributions with positive parity preferred, but negative parity not excluded.

Although some uncertainties still remain, the state seen in hadronic interactions and that seen in spacelike virtual photon fusion from e^+e^- annihilations are often identified with

⁴ Using Crystal Barrel data

⁵ A general fit allowing S, D, and P waves (including m=0) is not done because of limited statistics.

one another since there are more similarities than differences. In particular, all experiments agree that this state appears only in $K^*(892)\overline{K}$. The same conclusions are obtained from partial wave analyses of $J/\psi(1S) \to \gamma K\overline{K}\pi$ (BAI 90C, AUGUSTIN 91).

BITYUKOV 88 studied the radiative decay $1^{++} \to \phi \gamma$. Since the ϕ is (almost) a pure $s\overline{s}$ state, the $\phi \gamma$ decay seems to be a good analyser to extract the $s\overline{s}$ component in the wave function of the decaying meson. Finding the $f_1(1285)$ but not the $f_1(1420)$, BITYUKOV 88 concludes that the $f_1(1420)$ cannot be the $s\overline{s}$ isoscalar member of the $q\overline{q}$ nonet containing the $f_1(1285)$. On the other hand, AIHARA 88C argues that, assuming they both belong to the same nonet and using several hypotheses, the octet-singlet mixing angle obtained is compatible with the $f_1(1420)$ being mostly $s\overline{s}$ and the $f_1(1285)$ being mostly $(u\overline{u}+d\overline{d})/\sqrt{2}$, although both require large admixtures of other $q\overline{q}$ components.

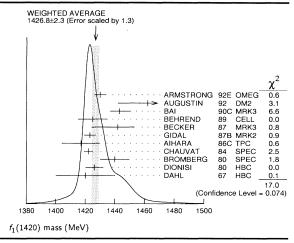

Arguments favoring the possibility the $f_1(1420)$ is a hybrid $q\bar{q}g$ meson or a four-quark state are put forward by ISHIDA 89 and by CALDWELL 90, respectively.

LONGACRE 90 argues that this particle is inconsistent with a QCD arrangement of quarks and gluons. He then develops a final-state rescattering mechanism with successive interactions between a K, a \overline{K} , and a π . The $f_1(1420)$ would then be a molecular state formed by the π orbiting in a P wave around an S-wave $K\overline{K}$ state.

$\eta(1440)$

$$I^{G}(J^{PC}) = 0^{+}(0^{-}+)$$

See also the mini-review under non- $q\overline{q}$ candidates. (See the index for the page number.)

THE $\eta(1440)$

The first observation of a meson with $I^G J^{PC} = 0^+0^{-+}$ in the 1400-MeV mass region was made in $p\bar{p} \to K\bar{K}3\pi$ annihilations at rest (BAILLON 67). The $\eta(1440)$ was reported to decay into $K\overline{K}\pi$, equally through $a_0(980)\pi$ and $K^*(892)\overline{K}$.

The $\eta(1440)$ has since also been seen in a partial-wave analysis of the $K\overline{K}\pi$ system (CHUNG 85, BIRMAN 88), in 6-GeV $p\bar{p}$ annihilations (REEVES 86), and in nonperipherally selected $\pi^- p \to K_S^0 K_S^0 \pi^0 n$ (RATH 89). RATH 89 favors two η resonances in the 1410-1480 MeV region. This is also observed at LEAR in $\overline{p}p \to K\overline{K}3\pi$ annihilations at rest (BERTIN 95).

In a partial-wave analysis of $\pi^- p \to \eta \pi^+ \pi^-$, FUKUI 91C confirms the decay $\eta(1440) \rightarrow a_0(980)\pi$. In $\bar{p}p \rightarrow \eta\pi\pi$ annihilations at rest, AMSLER 95F finds roughly equal contributions from $a_0(980)\pi$ and $\eta(\pi\pi)_S$.

Neither the $\eta(1440)$ nor the $f_1(1420)$ are observed in the $s\bar{s}$ -enriched peripheral reaction $K^-p\to K\overline{K}\pi\Lambda$ at 11 GeV/c (ASTON 87), which speaks against an $s\bar{s}$ interpretation of either state. ARMSTRONG 84, 89, studying $K\overline{K}\pi$ central production in $\pi^+p \to \pi^+(K\overline{K}\pi)p$ and $pp \to p(K\overline{K}\pi)p$ at 85 and 300 GeV/c, observed the $f_1(1420)$ but not the $\eta(1440)$.

The $\eta(1440)$ is also seen as a broad enhancement in $J/\psi(1S)$ radiative decay. BUGG 95 has reanalyzed the MARK-III data and finds a contribution to 4π in agreement with DM2 (BISELLO 89B). The $\eta \pi^+ \pi^-$ channel peaks near 1400 MeV (AUGUSTIN 90, BOLTON 92B), in agreement with observations in $\overline{p}p$ annihilation at rest (AMSLER 95F). It has been shown (TOKI 87, BAI 90C) that two pseudoscalar resonances at ≈ 1420 and ≈ 1490 MeV, together with a 1⁺⁺ around 1440 MeV, give a better description of the $K\overline{K}\pi$ data. These results, together with RATH 89 and BERTIN 95, suggest the existence of two overlapping pseudoscalar states, one around 1400 MeV

decaying into both $K\overline{K}\pi$ and $\eta\pi\pi$, the other one around 1480 MeV decaying only to $K\overline{K}\pi$.

We continue to list under the $\eta(1440)$ all the results on the 0^{-+} system in the 1380-1490 MeV region, but there is probably more than one resonance present in the observations. It is thus difficult to give reliable \overline{K}^*K or $a_0\pi$ branching ratios. The masses and widths are given separately according to the various decay modes. See also our Note on "Non- $q\bar{q}$ Mesons."

CONSTRAINED FIT INFORMATION

An overall fit to the total width, 2 partial widths, a combination of partial widths obtained from integrated cross sections, and 3 branching ratios uses 14 measurements and one constraint to determine 5 parameters. The overall fit has a $\chi^2=11.4$ for 10

The following off-diagonal array elements are the correlation coefficients $\langle \delta p_i \delta p_j \rangle / (\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

CONSTRAINED FIT INFORMATION

An overall fit to 4 branching ratios uses 6 measurements and one constraint to determine 4 parameters. The overall fit has a χ^2 = 1.9 for 3 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

$$\begin{array}{c|ccccc} x_3 & -53 & & \\ x_4 & -29 & -59 & & \\ x_5 & -8 & -21 & -9 & \\ \hline & x_2 & x_3 & x_4 & & \end{array}$$

CONSTRAINED FIT INFORMATION

An overall fit to 5 branching ratios uses 10 measurements and one constraint to determine 4 parameters. The overall fit has a $\chi^2=$ 14.7 for 7 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

THE $\rho(1450)$ AND THE $\rho(1700)$

In our 1988 edition, we replaced the $\rho(1600)$ entry with two new ones, the $\rho(1450)$ and the $\rho(1700)$, because there was emerging evidence that the 1600-MeV region actually contains two ρ -like resonances. ERKAL 86 had pointed out this possibility with a theoretical analysis on the consistency of 2π and 4π electromagnetic form factors and the $\pi\pi$ scattering length. DONNACHIE 87, with a full analysis of data in the annihilation reactions $e^+e^- \to \pi^+\pi^-$, $2\pi^+2\pi^-$, and $\pi^+\pi^-\pi^0\pi^0$, and in the photoproduction reactions $\gamma p \to \pi^+\pi^- p$, $2\pi^+2\pi^- p$, and $\pi^+\pi^-\pi^0\pi^0p$, had also argued that to obtain a consistent picture two resonances, whose masses and widths could be fixed reasonably well, were necessary. This picture was supported by the analysis of DONNACHIE 87B of $J^P = 1^- \eta \rho^0$ mass spectra obtained in photoproduction and in e^+e^- annihilations; the analysis showed the need for a contribution from a ρ meson with a mass of about 1470 MeV, but could say little about a higher-mass resonance (actually the data could be explained without it). Confirmation of the decay $\rho(1450) \rightarrow \omega \pi$, and a tight constraint on the mass due to strong interference with the $\rho(770)$ tail, was found by DONNACHIE 91 in an analysis of $e^+e^- \to \omega\pi$.

The analysis of DONNACHIE 87 was extended by CLEGG 88 to include new data on 4π systems produced in e^+e^- annihilation and in τ decay (4π τ decays and 4π annihilation reactions can be related by the Conserved Vector Current assumption). These systems were successfully analyzed using interfering contributions from two ρ -like states, and from the tail of the $\rho(770)$ decaying into two-body states. While specific conclusions on $\rho(1450) \rightarrow 4\pi$ were obtained, the quality of the data used by CLEGG 88 prevented any conclusion on $\rho(1700) \rightarrow 4\pi$ decay.

An analysis by CLEGG 90 of 6π mass spectra from $e^+e^$ annihilation and from diffractive photoproduction provides evidence for two ρ mesons, at about 2.1 and 1.8 GeV, that decay strongly into 6π states. While the former is a candidate for a new resonance, the latter could be a manifestation of the $\rho(1700)$ distorted by threshold effects.

Independent evidence for two 1⁻ states is provided by KILLIAN 80 in 4π electroproduction at $\langle Q^2 \rangle = 1 \ (\text{GeV}/c)^2$, and by FUKUI 88 in a high-statistics sample of the $\eta\pi\pi$ system in $\pi^- p$ charge exchange.

This picture with two overlapping resonances is supported by other data. BISELLO 89 measured the pion form factor in the interval 1.35-2.4 GeV with significant statistics (280 $e^+e^- \rightarrow$ $\pi^+\pi^-$ events with very low background). A deep minimum is observed around 1.6 GeV, and the best fit to the form factor is obtained with the hypothesis of ρ -like resonances at 1420 and 1770 MeV with widths of about 250 MeV. ANTONELLI 88 found that the $e^+e^- \rightarrow \eta \pi^+\pi^-$ cross section (using three different η decay modes) is better fitted with two fully interfering Breit-Wigners, with parameters in fair agreement with those of DONNACHIE 87 and BISELLO 89.

These results (although ANTONELLI 88 is statistically less significant than BISELLO 89) have also resolved the disagreement between DONNACHIE 87 and FUKUI 88 on the $\rho(1450)$ width in favor of the DONNACHIE 87 value. From this point of view, BISELLO 89 and ANTONELLI 88 can be considered as solid confirmation of the $\rho(1450)$. For the possibility that its $\phi\pi$ mode actually contains two independent vector states, see LANDSBERG 92.

Several observations on the $\omega\pi$ system in the 1200-MeV region (FRENKIEL 72, COSME 76, BARBER 80C, ASTON 80C, ATKINSON 84C, BRAU 88, AMSLER 93B) may be interpreted in terms of either $J^P = 1^- \rho(770) \rightarrow \pi \omega$ production (LAYSSAC 71) or $J^P = 1^+ b_1(1235)$ production (BRAU 88, AMSLER 93B). We argue that no special entry for a $\rho(1250)$ is needed. The LASS amplitude analysis (ASTON 91B) showing evidence for a $\rho(1270)$ is preliminary and needs confirmation. For completeness, these various observations are listed under the $\rho(1450)$.

$f_J(1710)$

 $I^G(J^{PC}) = 0^+(\text{even}^{++})$

THE $f_J(1710)$

The $f_J(1710)$ is seen in the gluon-rich radiative decay $J/\psi(1S) \to \gamma f_J(1710)$; therefore C=+1. It decays into 2η and $K_S^0K_S^0$, which implies $I^GJ^{PC}=0^+(\text{even})^{++}$. In an amplitude analysis of the $K\overline{K}$ and $\pi^+\pi^-$ systems produced in $J/\psi(1S)$ radiative decay, CHEN 91 finds a large spin-0 component for this particle, but ARMSTRONG 89D favors spin 2 in central production. The spin is thus uncertain. This resonance is also observed in $K\overline{K}$ systems recoiling against a ϕ or an ω in hadronic $J/\psi(1S)$ decay. However, according to FALVARD 88, $J/\psi(1S) \to \omega f_J(1710)$ is rather controversial. The $f_J(1710)$ is not seen by DM2 (BISELLO 89B) in $J/\psi(1S) \to \gamma \rho^0 \rho^0$,

in agreement with the indication from MARK III (BALTRU-SAITIS 86B) that the $\rho\rho$ enhancement in this region has $J^P=0^-$, and hence is unrelated to the $f_J(1710)$. However, a reanalysis (BUGG 95) of the 4π channel from MARK III, including now two $\pi\pi$ S-waves in addition to $\rho\rho$, finds 0^{++} .

Clear evidence is seen in 300-GeV/c pp central production in both K^+K^- and $K_S^0K_S^0$ (ARMSTRONG 89D). Mass and width determinations are complicated because the spectra are dominated by overlap with the $f_2'(1525)$. The apparent large disagreement between the widths found by ARMSTRONG 89D in the two channels (≈ 180 MeV in K^+K^- and ≈ 100 MeV in $K_S^0K_S^0$) can be explained by the arbitrariness of the polynomial-exponential background shape, which leads to a large systematic error for the width. ARMSTRONG 93C also sees in $\eta\eta$ a broad peak at 1747 MeV, which may be the $f_J(1710)$. This resonance is not observed in the hypercharge-exchange reactions $K^-p \to K_S^0K_S^0\Lambda$ (ASTON 88D) and $K^-p \to K_S^0K_S^0Y^*$ (BOLONKIN 86)

A partial-wave analysis of the $\pi^-p \to K_S^0 K_S^0$ system (BOLONKIN 88) finds a D_0 wave behavior ($J^{PC}=2^{++}$) near 1700 MeV, but the width (≈ 30 MeV) is much narrower than that observed in $J/\psi(1S)$ decays and in hadroproduction.

Note that in our 1992 edition this particle was named the $f_2(1710)$. See also our Note on "Non- $q\overline{q}$ Mesons."

OMITTED FROM SUMMARY TABLE

This state has been seen at SPEAR in the $K\overline{K}$ systems ($K^+K^$ and $K^0_S\,K^0_S)$ produced in the radiative decay of $J/\psi(1S)$. Seen in $\eta\eta'$ (ALDE 86B), in $K_0^SK_0^S$ (ASTON 88D), and in K^+K^- (ASTON 88F). Not seen in Υ radiative decays (BARU 89) nor in Binclusive decay (BEHRENDS 84). Not seen in $\overline{p}p \rightarrow K^+K^-$ formation experiment (BARDIN 87,SCULLI 87) and $\bar{p}p \to K_S^0 K_S^0$ formation experiment (BARNES 93). Not seen at DCI in either K^+K^- or $K_S^0 K_S^0$ systems (AUGUSTIN 88). Needs confirmation.

This high-mass region is covered nearly continuously with evidence for peaks of various widths and decay modes. As no satisfactory grouping into particles is yet possible, we list together in order of increasing mass all the Y=0 bumps above 1900 MeV that are coupled neither to $\overline{N}N$ nor to e^+e^- .

THE CHARGED KAON MASS

(by T.G. Trippe, Lawrence Berkeley National Laboratory)

The average of the six charged kaon mass measurements which we use in the Particle Listings is

$$m_{K^{\pm}} = 493.677 \pm 0.013 \text{ MeV (S} = 2.4),$$
 (1)

where the error has been increased by the scale factor S. The large scale factor indicates a serious disagreement between different input data. The average before scaling the error is

$$m_{K^{\pm}} = 493.677 \pm 0.005 \text{ MeV}$$
 , $\chi^2 = 22.9 \text{ for 5 D.F., Prob.} = 0.04\%$, (2)

where the high χ^2 and correspondingly low χ^2 probability further quantify the disagreement.

The main disagreement is between the two most recent and precise results,

$$m_{K^{\pm}} = 493.696 \pm 0.007 \text{ MeV}$$
 DENISOV 91
 $m_{K^{\pm}} = 493.636 \pm 0.011 \text{ MeV (S} = 1.5) \text{ GALL 88}$
Average $= 493.679 \pm 0.006 \text{ MeV}$

$$\chi^2 = 21.2$$
 for 1 D.F., Prob. = 0.0004\%, (3)

both of which are measurements of x-ray energies from kaonic atoms. Comparing the average in Eq. (3) with the overall average in Eq. (2), it is clear that DENISOV 91 and GALL 88 dominate the overall average, and that their disagreement is responsible for most of the high χ^2 .

The GALL 88 measurement was made using four different kaonic atom transitions, K^- Pb (9 \rightarrow 8), K^- Pb (11 \rightarrow 10), K^- W (9 \rightarrow 8), and K^- W (11 \rightarrow 10). The m_{K^\pm} values they obtain from each of these transitions is shown in the Particle Listings and in Fig. 1. Their K^- Pb (9 \rightarrow 8) m_{K^\pm} is below and somewhat inconsistent with their other three transitions. The average of their four measurements is

$$m_{K^\pm} = 493.636 \pm 0.007$$
 ,
$$\chi^2 = 7.0 \ \mbox{for 3 D.F., Prob.} \ = 7.2\% \ . \eqno(4)$$

This is a low but acceptable χ^2 probability so, to be conservative, GALL 88 scaled up the error on their average by S=1.5 to obtain their published error ± 0.011 shown in Eq. (3) above and used in the Particle Listings average.

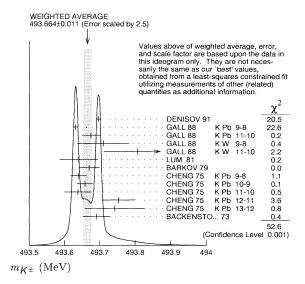

Figure 1: Ideogram of $m_{K^{\pm}}$ mass measurements. GALL 88 and CHENG 75 measurements are shown separately for each transition they measured.

The ideogram in Fig. 1 shows that the DENISOV 91 measurement and the GALL 88 K^- Pb (9 \to 8) measurement yield two well-separated peaks. One might suspect the GALL 88 K^- Pb (9 \to 8) measurement since it is responsible both for the internal inconsistency in the GALL 88 measurements and the disagreement with DENISOV 91.

To see if the disagreement could result from a systematic problem with the K^- Pb (9 \rightarrow 8) transition, we have separated the CHENG 75 data, which also used K^- Pb, into its separate transitions. Figure 1 shows that the CHENG 75 and GALL 88 K^- Pb (9 \rightarrow 8) values are consistent, suggesting the possibility of a common effect such as contaminant nuclear γ rays near the K^- Pb (9 \rightarrow 8) transition energy, although the CHENG 75 errors are too large to make a strong conclusion. The average of all 13 measurements has a χ^2 of 52.6 as shown in Fig. 1 and the first line of Table 1, yielding an unacceptable χ^2 probability of 0.00005%. The second line of Table 1 excludes both the GALL 88 and CHENG 75 measurements of the K^- Pb (9 \rightarrow 8) transition and yields a χ^2 probability of 43%. The third [fourth] line of Table 1 excludes only the GALL 88 K^- Pb (9 \rightarrow 8) [DENISOV 91] measurement and yields a χ^2 probability of 20% [8.6%]. Table 1 shows that removing both measurements of the K^- Pb (9 \rightarrow 8) transition produces the most consistent set of data, but that excluding only the GALL 88 K^- Pb (9 \rightarrow 8) transition or DENISOV 91 also produces acceptable probabilities.

Yu.M. Ivanov, representing DENISOV 91, has estimated corrections needed for the older experiments because of improved 192 Ir and 198 Au calibration γ -ray energies. He estimates

 \mathcal{K}^{\pm}

Table 1: $m_{K^{\pm}}$ averages for some combinations of Fig. 1 data.

$m_{K^{\pm}} \; (\mathrm{MeV})$	χ^2	D.F.	Prob. (9	%)	Measurements used
$\overline{493.664 \pm 0.004}$	52.6	12	0.00005	all	13 measurements
493.690 ± 0.006	10.1	10	43	no	$K^- \operatorname{Pb}(9 \rightarrow 8)$
493.687 ± 0.006	14.6	11	20	no	GALL 88 K^- Pb(9 \rightarrow 8)
493.642 ± 0.006	17.8	11	8.6	no	DENISOV 91

that CHENG 75 and BACKENSTOSS 73 m_{K^\pm} values could be raised by about 15 keV and 22 keV, respectively. With these estimated corrections, Table 1 becomes Table 2. The last line of Table 2 shows that if such corrections are assumed, then GALL 88 K^- Pb (9 \to 8) is inconsistent with the rest of the data even when DENISOV 91 is excluded. Yu.M. Ivanov warns that these are rough estimates. Accordingly, we do not use Table 2 to reject the GALL 88 K^- Pb (9 \to 8) transition, but we note that a future reanalysis of the CHENG 75 data could be useful because it might provide supporting evidence for such a rejection.

Table 2: $m_{K^{\pm}}$ averages for some combinations of Fig. 1 data after raising CHENG 75 and BACKENSTOSS 73 values by 0.015 and 0.022 MeV respectively.

$m_{K^{\pm}} \; (\mathrm{MeV})$	χ^2	D.F.	Prob. (%	6)	Measurements used
493.666 ± 0.004	53.9	12	0.00003	all	13 measurements
493.693 ± 0.006	9.0	10	53	no	$K^- \operatorname{Pb}(9 \rightarrow 8)$
493.690 ± 0.006	11.5	11	40	no	GALL 88 K^- Pb(9 \rightarrow 8)
493.645 ± 0.006	23.0	11	1.8	no	DENISOV 91

The GALL 88 measurement uses a Ge semiconductor spectrometer which has a resolution of about 1 keV, so they run the risk of some contaminant nuclear γ rays. Studies of γ rays following stopped π^- and Σ^- absorption in nucleii (unpublished) do not show any evidence for contaminants according to GALL 88 spokesperson, B.L. Roberts. The DENISOV 91 measurement uses a crystal diffraction spectrometer with a resolution of 6.3 eV for radiation at 22.1 keV to measure the 4f-3d transition in $K^{--12}{\rm C}$. The high resolution and the light nucleus reduce the probability for overlap by contaminant γ rays, compared with the measurement of GALL 88. The DENISOV 91 measurement is supported by their high-precision measurement of the 4d-2p transition energy in $\pi^{--12}{\rm C}$, which is good agreement with the calculated energy.

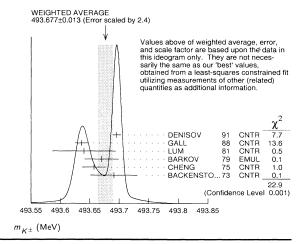

While we suspect that the GALL 88 K^- Pb (9 \rightarrow 8) measurements could be the problem, we are unable to find clear grounds for rejecting it. Therefore, we retain their measurement in the average and accept the large scale factor until further information can be obtained from new measurements and/or from reanalysis of GALL 88 and CHENG 75 data.

We thank B.L. Roberts (Boston Univ.) and Yu.M. Ivanov (Petersburg Nuclear Physics Inst.) for their extensive help in understanding this problem.

RARE KAON DECAYS

(by L. Littenberg, BNL and G. Valencia, Iowa State University)

- **A.** Introduction: There are several recent reviews on rare kaon decays and related topics [1–13]. The current activity in rare kaon decays can be divided roughly into four categories:
- 1. Searches for explicit violations of the Standard Model
- 2. Measurements of Standard Model parameters
- 3. Searches for ${\cal CP}$ violation
- 4. Studies of strong interactions at low energy.

The paradigm of Category 1 is the lepton flavor violating decay $K_L \to \mu e$. Category 2 includes processes such as $K^+ \to \pi^+ \nu \overline{\nu}$, which is sensitive to $|V_{td}|$. Much of the interest in Category 3 is focussed on the decays $K_L \to \pi^0 \ell \overline{\ell}$, where $\ell \equiv e, \mu, \nu$. Category 4 includes reactions like $K^+ \to \pi^+ \ell^+ \ell^-$ which constitute a testing ground for the ideas of chiral perturbation theory. Other reactions of this type are $K_L \to \pi^0 \gamma \gamma$, which also scales a CP-conserving background to CP violation in $K_L \to \pi^0 \ell^+ \ell^-$ and $K_L \to \gamma \ell^+ \ell^-$, which could possibly shed light on long distance contributions to $K_L \to \mu^+ \mu^-$.

B. Explicit violations of the Standard Model: Most of the activity here is in searches for lepton flavor violation (LFV). This is motivated by the fact that many extensions of the minimal Standard Model violate lepton flavor and by the potential to access very high scales. For example, the tree-level exchange of a LFV vector boson of mass M_X that couples to left-handed fermions with electroweak strength and without mixing angles yields $B(K_L \to \mu e) = 3.3 \times 10^{-11} (91 \text{ TeV}/M_X)^4$ [7]. This simple dimensional analysis may be used to read from Table 1 that the reaction $K_L \to \mu e$ is already probing scales of nearly 100 TeV. Table 1 summarizes the present experimental situation vis a vis LFV, along with the expected near-future progress. The decays $K_L \to \mu^\pm e^\mp$ and $K^+ \to \pi^+ e^\mp \mu^\pm$ (or $K_L \to \pi^0 e^\mp \mu^\pm$) provide complementary information on potential family number violating interactions since the former is sensitive to axial-vector (or pseudoscalar) couplings and the latter is sensitive to vector (or scalar) couplings.

Table 1: Searches for lepton flavor violation in K decay

Mode	90% CL upper limit	Exp't	Yr./Ref.	(Near-) future aim
$K^+ \to \pi^+ e \mu$	2.1E-10	BNL-777	90/14	3E-12 (BNL-865)
$K_L \rightarrow \mu e$	3.3E-11			2E-12 (BNL-871)
$K_L \! o \! \pi^0 \mu e$	3.5E-9	FNAL-799	94/16	E-11 (FNAL799II)

Another forbidden decay currently being pursued is $K^+ \to \pi^+ X^0$, where X^0 is a very light, noninteracting particle (e.g. hyperphoton, axion, familon, etc.). The published upper limit on this process [17] is 1.7×10^{-9} , but recently this has been improved to 5.2×10^{-10} [18]. Data already collected by BNL-787 are expected to yield another substantial factor in sensitivity to this process.

C. Measurements of Standard Model parameters: Until recently searches for $K^+ \to \pi^+ \nu \overline{\nu}$ have been motivated by the possibility of observing non-SM physics because the sensitivity attained was far short of the SM prediction for this decay [19] and long-distance contributions were known to be negligible [3,20]. However, BNL-787 is approaching the sensitivity at which the observation of an event could no longer be unambiguously attributed to non-SM physics. The published 90% c.l. upper limit [17] is 5.2×10^{-9} , but this has been recently improved to 2.4×10^{-9} [18], and extensive recent running with an upgraded beam and detector is expected to further improve this significantly. This reaction is now becoming interesting from the point of view of constraining SM parameters where the branching ratio is expected to be of order 10^{-10} , and can be written as [3]:

$$B(K^{+} \to \pi^{+} \nu \overline{\nu}) = \frac{\alpha^{2} B(K^{+} \to \pi^{o} e^{+} \nu)}{V_{us}^{2} 2\pi^{2} \sin^{4} \theta_{W}} \times \sum_{l=e,\mu,\tau} |V_{cs}^{*} V_{cd} X_{NL}^{\ell} + V_{ts}^{*} V_{td} X(m_{t})|^{2}$$
(1)

where $X(m_t)$ is of order 1, and X_{NL}^{ℓ} is several hundred times smaller. This form exhibits the strong dependence of this

 \mathcal{K}^{\pm}

branching ratio on $|V_{td}|$. It also makes manifest the fact that the *a priori* unknown hadronic matrix element drops out in the comparison to the very well-measured rate of K_{e3} decay. QCD corrections, which are contained in X_{NL}^{ℓ} , are relatively small and now known [21] to $\leq 10\%$. Evaluating the constants in Eq. (1) with $m_t = 175$ GeV, one can cast this result in terms of the CKM parameters A, ρ and η (see our Section on "The Cabibbo-Kobayashi-Maskawa mixing matrix") [21].

$$B(K^{+} \to \pi^{+} \nu \overline{\nu})$$

$$\approx 1.2 \times 10^{-10} A^{4} [\eta^{2} + \frac{2}{3} (\rho_{o}^{e} - \rho)^{2} + \frac{1}{3} (\rho_{o}^{\tau} - \rho)^{2}] \quad (2)$$

where $\rho_o^\ell \equiv 1 + \frac{X_{NL}^\ell}{A^2 \lambda^4 X(m_t)}$. Thus, $\mathrm{B}(K^+ \to \pi^+ \nu \overline{\nu})$ determines a circle in the ρ , η plane with center $(\rho_o,0)$; $\rho_o \equiv \frac{2}{3} \rho_o^e + \frac{1}{3} \rho_o^\tau \approx 1.4$, and radius $\approx \frac{1}{A^2} \sqrt{\frac{\mathrm{B}(K^+ \to \pi^+ \nu \overline{\nu})}{1.2 \times 10^{-10}}}$. The decay $K_L \to \mu^+ \mu^-$ also has a short distance contribu-

The decay $K_L \to \mu^+ \mu^-$ also has a short distance contribution sensitive to the CKM parameter ρ . For $m_t = 175$ GeV it is given by [21]:

$$B_{SD}(K_L \to \mu^+ \mu^-) \approx 1.9 \times 10^{-9} A^4 (\rho_o' - \rho)^2$$
 (3)

where ρ'_{o} depends on the charm quark mass and is around 1.2. This decay, however, is dominated by a long-distance contribution from a two-photon intermediate state. The absorptive (imaginary) part of the long-distance component is calculated in terms of the measured rate for $K_L \to \gamma \gamma$ to be $B_{abs}(K_L \to \gamma \gamma)$ $\mu^+\mu^-$) = $(6.8 \pm 0.3) \times 10^{-9}$; and it almost completely saturates the observed rate $B(K_L \to \mu^+ \mu^-) = (7.2 \pm 0.5) \times 10^{-9}$ listed in the current edition. The difference between the observed rate and the absorptive component can be attributed to the (coherent) sum of the short-distance amplitude and the real part of the long-distance amplitude. In order to use this mode to constrain ρ it is, therefore, necessary to know the real part of the long-distance contribution. Unlike the absorptive part, the real part of the long-distance contribution cannot be derived from the measured rate for $K_L \to \gamma \gamma$. At present, it is not possible to compute this long-distance component reliably and, therefore, it is not possible to constrain ρ from this mode. It is expected that studies of the reactions $K_L \to \ell^+\ell^-\gamma$, and $K_L \to \ell^+ \ell^- \ell'^+ \ell'^-$ for $\ell, \ell' = e$ or μ will improve our understanding of the long distance effects in $K_L \to \mu^+ \mu^-$ (the current data is parameterized in terms of α_K^* , discussed in the Form Factors section of the K_L^0 Particle Properties Listings).

D. Searches for CP violation: The mode $K_L \to \pi^0 \nu \overline{\nu}$ is dominantly CP-violating and free of hadronic uncertainties [3,22]. The Standard Model predicts a branching ratio of order 10^{-10} ; for $m_t=175$ GeV it is given approximately by [21]:

$$B(K_L \to \pi^0 \nu \overline{\nu}) \approx 5 \times 10^{-10} A^4 \eta^2 . \tag{4}$$

The current upper bound is $B(K_L \to \pi^0 \nu \overline{\nu}) \le 5.8 \times 10^{-5}$ [23] and FNAL799II (KTeV) is expected to place a bound of order 10^{-8} [24].

The decay $K_L \to \pi^0 e^+ e^-$ also has sensitivity to the product $A^4 \eta^2$. It has a direct CP-violating component that depends on the value of the top-quark mass, and that for $m_t = 175$ GeV is given by [25]:

$$B_{\rm dir}(K_L \to \pi^0 e^+ e^-) \approx 7 \times 10^{-11} A^4 \eta^2 \ .$$
 (5)

However, like $K_L \to \mu^+ \mu^-$ this mode suffers from large theoretical uncertainties due to long distance strong interaction effects. It has an indirect CP-violating component given by:

$$B_{\rm ind}(K_L \to \pi^0 e^+ e^-) = |\epsilon|^2 \frac{\tau_{K_L}}{\tau_{K_S}} B(K_S \to \pi^0 e^+ e^-) ,$$
 (6)

that has been estimated to be less than 10^{-12} [26], but that will not be known precisely until a measurement of $K_S \to \pi^0 e^+ e^-$ is available [6,27]. There is also a CP-conserving component dominated by a two-photon intermediate state that cannot be computed reliably at present. This component has an absorptive part that can be, in principle, determined from a detailed analysis of $K_L \to \pi^0 \gamma \gamma$.

An analysis of $K_L \to \pi^0 \gamma \gamma$ within chiral perturbation theory has been carried out in terms of a parameter a_V [28,29] that determines both the rate and the shape of the distribution $d\Gamma/dm_{\gamma\gamma}$. A fit to the distribution has given $-0.32 < a_V < 0.19$ [30]; a value that suggests that the absorptive part of the CP-conserving contribution to $K_L \to \pi^0 e^+ e^-$ is significantly smaller than the direct CP-violating component [30]. However, there remains some uncertainty in the interpretation of $K_L \to \pi^0 \gamma \gamma$ in terms of a_V . Analyses that go beyond chiral perturbation theory have found larger values of a_V , indicating a sizable CP-conserving component for $K_L \to \pi^0 e^+ e^-$. The real part of the CP-conserving contribution to $K_L \to \pi^0 e^+ e^-$ is also unknown.

Finally, BNL-845 observed a potential background to $K_L \to \pi^0 e^+ e^-$ from the decay $K_L \to \gamma \gamma e^+ e^-$ [31]. This was later confirmed with an order of magnitude larger sample by FNAL-799 [32], which measured additional kinematic quantities. It has been estimated that this background will enter at the level of 10^{-11} [33], comparable to the signal level. Because of this, the observation of $K_L \to \pi^0 e^+ e^-$ will depend on background subtraction with good statistics.

The current upper bound for the process $K_L \to \pi^0 e^+ e^-$ is 4.3×10^{-9} [34]. For the closely related muonic process, the upper bound is $B(K_L \to \pi^0 \mu^+ \mu^-) \leq 5.1 \times 10^{-9}$ [35]. FNAL799II expects to reach a sensitivity $\lesssim 10^{-11}$ for both reactions [36].

E. Other long distance dominated modes: The decays $K^+ \to \pi^+ \ell^+ \ell^-$ ($\ell = e$ or μ) are described by chiral perturbation theory in terms of one parameter, ω^+ [37]. This parameter determines both the rate and distribution $d\Gamma/dm_{\ell\ell}$ for these processes. A careful study of these two reactions can provide a measurement of ω^+ and a test of the chiral perturbation theory description. A simultaneous fit to the rate and spectrum of $K^+ \to \pi^+ e^+ e^-$ gives: $\omega^+ = 0.89^{+0.24}_{-0.14}$; $B(K^+ \to \pi^+ e^+ e^-) = (2.99 \pm 0.22) \times 10^{-7}$ [38]. These two results satisfy the prediction of chiral perturbation theory within

two standard deviations [6]. Improved statistics for this mode and a measurement of the mode $K^+ \to \pi^+ \mu^+ \mu^-$ are thus desired. BNL-787 has observed the process $K^+ \to \pi^+ \mu^+ \mu^-$ [39] at about the predicted level, but the result is not yet accurate enough to provide additional constraints.

\mathcal{K}^{\pm}

- [a] See the Particle Listings below for the energy limits used in this measure-
- [b] Most of this radiative mode, the low-momentum $\boldsymbol{\gamma}$ part, is also included in the parent mode listed without γ 's.
- [c] Direct-emission branching fraction.
- [d] Structure-dependent part.
- [e] Derived from an analysis of neutrino-oscillation experiments.

CONSTRAINED FIT INFORMATION

An overall fit to the mean life, 2 decay rate, and 20 branching ratios uses 60 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2=78.1$ for 53 degrees of

The following off-diagonal array elements are the correlation coefficients $\langle \delta \rho_i \delta \rho_j \rangle / (\delta \rho_i \cdot \delta \rho_j)$, in percent, from the fit to parameters ρ_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

 61 AOKI 94 measures $\xi P_{\mu} = -0.9996 \pm 0.0030 \pm 0.0048.$ The above limit is obtained by summing the statistical and systematic errors in quadrature, normalizing to the physically significant region ($\left|\xi P_{\mu}\right|<1$) and assuming that $\xi = 1$, its maximum value. 62 Assumes $\xi = 1$.

DALITZ PLOT PARAMETERS FOR $K \to 3\pi$ DECAYS

The Dalitz plot distribution for $K^\pm \to \pi^\pm \pi^\pm \pi^\mp$, $K^\pm \to \pi^0 \pi^0 \pi^\pm$, and $K_L^0 \to \pi^+ \pi^- \pi^0$ can be parameterized by a series expansion such as that introduced by Weinberg [1]. We use the form

$$\left| M \right|^2 \propto 1 + g \frac{(s_3 - s_0)}{a m_{\pi^+}^2} + h \left[\frac{s_3 - s_0}{m_{\pi^+}^2} \right]^2 + j \frac{(s_2 - s_1)}{m_{\pi^+}^2} + ak \left[\frac{s_2 - s_1}{m_{\pi^+}^2} \right]^2 + \cdots , \tag{1}$$

where $m_{\pi^+}^2$ has been introduced to make the coefficients g, h, j, and k dimensionless, and

$$s_i = (P_K - P_i)^2 = (m_K - m_i)^2 - 2m_K T_i , i = 1, 2, 3,$$

$$s_0 = \frac{1}{3} \sum_i s_i = \frac{1}{3} (m_K^2 + m_1^2 + m_2^2 + m_3^2)$$

Here the P_i are four-vectors, m_i and T_i are the mass and kinetic energy of the i^{th} pion, and the index 3 is used for the odd pion.

The coefficient q is a measure of the slope in the variable s_3 (or T_3) of the Dalitz plot, while h and k measure the quadratic dependence on s_3 and $(s_2 - s_1)$, respectively. The coefficient j is related to the asymmetry of the plot and must be zero if CPinvariance holds. Note also that if CP is good, g, h, and k must be the same for $K^+ \to \pi^+ \pi^+ \pi^-$ as for $K^- \to \pi^- \pi^- \pi^+$.

Since different experiments use different forms for M, in order to compare the experiments we have converted to g, h, j, and k whatever coefficients have been measured. Where such conversions have been done, the measured coefficient a_u , a_t , a_u , or a_v is given in the comment at the right. For definitions of these coefficients, details of this conversion, and discussion of the data, see the April 1982 version of this note [2].

$K_{\ell 3}^{\pm}$ AND $K_{\ell 3}^{0}$ FORM FACTORS

Assuming that only the vector current contributes to $K \to \pi \ell \nu$ decays, we write the matrix element as

$$M \propto f_{+}(t) \left[(P_K + P_{\pi})_{\mu} \overline{\ell} \gamma_{\mu} (1 + \gamma_5) \nu \right]$$

+ $f_{-}(t) \left[m_{\ell} \overline{\ell} (1 + \gamma_5) \nu \right] ,$ (1)

where P_K and P_{π} are the four-momenta of the K and π mesons, m_{ℓ} is the lepton mass, and f_+ and f_- are dimensionless form factors which can depend only on $t = (P_K - P_{\pi})^2$, the square of the four-momentum transfer to the leptons. If time-reversal invariance holds, f_+ and f_- are relatively real. $K_{\mu 3}$ experiments measure f_+ and f_- , while K_{e3} experiments are sensitive only

to f_+ because the small electron mass makes the f_- term negligible.

(a) $K_{\mu3}$ experiments. Analyses of $K_{\mu3}$ data frequently assume a linear dependence of f_+ and f_- on t, i.e.,

$$f_{\pm}(t) = f_{\pm}(0) \left[1 + \lambda_{\pm}(t/m_{\pi}^2) \right]$$
 (2)

Most $K_{\mu 3}$ data are adequately described by Eq. (2) for f_+ and a constant f_- (*i.e.*, $\lambda_-=0$). There are two equivalent parametrizations commonly used in these analyses:

(1) $\lambda_+, \xi(0)$ parametrization. Analyses of $K_{\mu 3}$ data often introduce the ratio of the two form factors

$$\xi(t) = f_{-}(t)/f_{+}(t)$$
.

The $K_{\mu 3}$ decay distribution is then described by the two parameters λ_+ and $\xi(0)$ (assuming time reversal invariance and $\lambda_- = 0$). These parameters can be determined by three different methods:

Method A. By studying the Dalitz plot or the pion spectrum of $K_{\mu 3}$ decay. The Dalitz plot density is (see, e.g., Chounet et al. [1]):

$$\rho(E_{\pi}, E_{\mu}) \propto f_{+}^{2}(t) \left[A + B\xi(t) + C\xi(t)^{2} \right] ,$$

where

$$\begin{split} A &= m_K \left(2 E_\mu E_\nu - m_K E_\pi' \right) + m_\mu^2 \left(\frac{1}{4} E_\pi' - E_\nu \right) \;, \\ B &= m_\mu^2 \left(E_\nu - \frac{1}{2} E_\pi' \right) \;, \\ C &= \frac{1}{4} m_\mu^2 E_\pi' \;, \\ E_\pi' &= E_\pi^{\rm max} - E_\pi = \left(m_K^2 + m_\pi^2 - m_\mu^2 \right) / 2 m_K - E_\pi \;. \end{split}$$

Here
$$E_{\pi}$$
, E_{μ} , and E_{ν} are, respectively, the pion, muon, and neutrino energies in the kaon center of mass. The density ρ is

fit to the data to determine the values of λ_+ , $\xi(0)$, and their correlation.

Method B. By measuring the $K_- a/K_-$ branching ratio

Method B. By measuring the $K_{\mu3}/K_{e3}$ branching ratio and comparing it with the theoretical ratio (see, e.g., Fearing et al. [2]) as given in terms of λ_+ and $\xi(0)$, assuming μ -e universality:

$$\begin{split} \Gamma(K_{\mu3}^{\pm})/\Gamma(K_{e3}^{\pm}) &= 0.6457 + 1.4115\lambda_{+} + 0.1264\xi(0) \\ &\quad + 0.0192\xi(0)^{2} + 0.0080\lambda_{+}\xi(0) \\ \Gamma(K_{\mu3}^{0})/\Gamma(K_{e3}^{0}) &= 0.6452 + 1.3162\lambda_{+} + 0.1264\xi(0) \\ &\quad + 0.0186\xi(0)^{2} + 0.0064\lambda_{+}\xi(0) \end{split}$$

This cannot determine λ_+ and $\xi(0)$ simultaneously but simply fixes a relationship between them.

Method C. By measuring the muon polarization in $K_{\mu 3}$ decay. In the rest frame of the K, the μ is expected to be

polarized in the direction **A** with $\mathbf{P} = \mathbf{A}/|\mathbf{A}|$, where **A** is given (Cabibbo and Maksymowicz [3]) by

$$\begin{split} \mathbf{A} &= a_1(\xi) \mathbf{p}_{\mu} \\ &- a_2(\xi) \left[\frac{\mathbf{p}_{\mu}}{m_{\mu}} \left(m_K - E_{\pi} + \frac{\mathbf{p}_{\pi} \cdot \mathbf{p}_{\mu}}{\left| \mathbf{p}_{\mu} \right|^2} (E_{\mu} - m_{\mu}) \right) + \mathbf{p}_{\pi} \right] \\ &+ m_K \mathrm{Im} \xi(t) (\mathbf{p}_{\pi} \times \mathbf{p}_{\mu}) \ .. \end{split}$$

If time-reversal invariance holds, ξ is real, and thus there is no polarization perpendicular to the K-decay plane. Polarization experiments measure the weighted average of $\xi(t)$ over the t range of the experiment, where the weighting accounts for the variation with t of the sensitivity to $\xi(t)$.

(2) λ_+, λ_0 parametrization. Most of the more recent $K_{\mu 3}$ analyses have parameterized in terms of the form factors f_{+} and f_0 which are associated with vector and scalar exchange, respectively, to the lepton pair. f_0 is related to f_+ and f_- by

$$f_0(t) = f_+(t) + \left[t/(m_K^2 - m_\pi^2)\right] f_-(t)$$
.

Here $f_0(0)$ must equal $f_+(0)$ unless $f_-(t)$ diverges at t=0. The earlier assumption that f_{+} is linear in t and f_{-} is constant leads to f_0 linear in t:

$$f_0(t) = f_0(0) \left[1 + \lambda_0(t/m_\pi^2) \right]$$
.

With the assumption that $f_0(0) = f_+(0)$, the two parametrizations, $(\lambda_+, \xi(0))$ and (λ_+, λ_0) are equivalent as long as correlation information is retained. (λ_+, λ_0) correlations tend to be less strong than $(\lambda_+, \xi(0))$ correlations.

The experimental results for $\xi(0)$ and its correlation with λ_{+} are listed in the K^{\pm} and K_{L}^{0} sections of the Particle Listings in section ξ_A , ξ_B , or ξ_C depending on whether method A, B, or C discussed above was used. The corresponding values of λ_{+} are also listed.

Because recent experiments tend to use the (λ_+, λ_0) parametrization, we include a subsection for λ_0 results. Wherever possible we have converted $\xi(0)$ results into λ_0 results and vice versa.

See the 1982 version of this note [4] for additional discussion of the $K_{\mu 3}^0$ parameters, correlations, and conversion between parametrizations, and also for a comparison of the experimental results.

(b) K_{e3} experiments. Analysis of K_{e3} data is simpler than that of $K_{\mu 3}$ because the second term of the matrix element assuming a pure vector current [Eq. (1) above] can be neglected. Here f_{+} is usually assumed to be linear in t, and the linear coefficient λ_+ of Eq. (2) is determined.

If we remove the assumption of a pure vector current, then the matrix element for the decay, in addition to the terms in Eq. (2), would contain

$$+2m_K f_S \bar{\ell}(1+\gamma_5)\nu$$

+
$$(2f_T/m_K)(P_K)_{\lambda}(P_{\pi})_{\mu} \bar{\ell} \sigma_{\lambda\mu}(1+\gamma_5)\nu ,$$

where f_S is the scalar form factor, and f_T is the tensor form factor. In the case of the K_{e3} decays where the f_- term can be neglected, experiments have yielded limits on $|f_S/f_+|$ and $|f_T/f_+|$.

KA FORM FACTORS

In the form factor comments, the following symbols are used.

f_ and f_ are form factors for the vector matrix element.

 f_{S} and f_{T} refer to the scalar and tensor term.

 $f_0 = f_+ + f_- t/(m_K^2 - m_\pi^2).$

 λ_+ , λ_- , and λ_0 are the linear expansion coefficients of f_+ , f_- , and f_0 . λ_+ refers to the $K_{\mu 3}^\pm$ value except in the K_{e3}^\pm sections.

 $d\xi(0)/d\lambda_+$ is the correlation between $\xi(0)$ and λ_+ in K_{u3}^{\pm} .

 $d\lambda_0/d\lambda_+$ is the correlation between λ_0 and λ_+ in K_{u3}^{\pm} .

t= momentum transfer to the π in units of m_π^2

DP = Dalitz plot analysis.

 $PI = \pi$ spectrum analysis.

 $MU = \mu$ spectrum analysis.

 $POL = \mu$ polarization analysis.

BR = $K_{\mu 3}^{\pm}/K_{e3}^{\pm}$ branching ratio analysis.

E = positron or electron spectrum analysis.

RC = radiative corrections

 $^{^{78}\,\}mathrm{ARNOLD}$ 74 figure 4 was used to obtain ξ_{A} and $d\xi(0)/d\lambda_{+}.$

$\xi_B = f_-/f_+$ (determined from $K_{\mu 3}^{\pm}/K_{e 3}^{\pm}$)

The $\kappa_{\mu3}^{\pm}/\kappa_{e3}^{\pm}$ branching ratio fixes a relationship between $\xi(0)$ and λ_{+} . We quote the author's $\xi(0)$ and associated λ_{+} but do not average because the λ_{+} values differ. The fit result and scale factor given below are not obtained from these ξ_B values. Instead they are obtained directly from the fitted $K_{\mu 3}^{\pm}/K_{e3}^{\pm}$ ratio $\Gamma(\pi^0\mu^+\nu_\mu)/\Gamma(\pi^0e^+\nu_e)$, with the exception of HEINTZE 77. The parameter $\hat{\epsilon}$ is redundant with λ_0 below and is not put into the Meson Summary Table.

 $^{^{87}\,\}mathrm{Calculated}$ by us from λ_0 and λ_+ given below.

$\xi_C = f_-/f_+$ (determined from μ polarization in $K^\pm_{\mu 2}$) The μ polarization is a measure of $\xi(t)$. No assumptions on λ_{+-} necessary, t (weighted

by sensitivity to $\xi(t)$) should be specified. In λ_+ , $\xi(0)$ parametrization this is $\xi(0)$ for λ_+ =0. $d\xi/d\lambda=\xi t$. For radiative correction to muon polarization in $K^\pm_{\mu3}$, see GINSBERG 71. The parameter ξ is redundant with λ_0 below and is not put into the Meson Summary Table.

 $^{^{79}\,\}mathrm{MERLAN}$ 74 figure 5 was used to obtain $d\xi(0)/d\lambda_{+}$.

⁸⁰ BRAUN 73c gives $\xi(t)=-0.34\pm0.20$, $d\xi(t)/d\lambda_{+}=-14$ for $\lambda_{+}=0.027$, t=6.6. We calculate above $\xi(0)$ and $d\xi(0)/d\lambda_{+}$ for their $\lambda_{+}=0.025\pm0.017$.

⁸¹ ANKENBRANDT 72 figure 3 was used to obtain $d\xi(0)/d\lambda_{+}$.

⁸² CHIANG 72 figure 10 was used to obtain $d\xi(0)/d\lambda_+$. Fit had $\lambda_-=\lambda_+$ but would not change for $\lambda_-=0$. L.Pondrom, (private communication 74).

⁸³ HAIDT 71 table 8 (Dalitz plot analysis) gives $d\xi(0)/d\lambda_{+} = (-1.1 + 0.5)/(0.050 - 0.029)$ = -29, error raised from 0.50 to agree with $d\xi(0) = 0.20$ for fixed λ_+ .

 $^{^{84}\,\}mathrm{KIJEWSKI}$ 69 figure 17 was used to obtain $d\xi(0)/d\lambda_{+}$ and errors.

⁸⁵ CALLAHAN 66 table 1 (π analysis) gives $d\xi(0)/d\lambda_+=(0.72-0.05)/(0-0.04)=-17$, error raised from 0.80 to agree with $d\xi(0)=0.37$ for fixed λ_+ . t unknown.

⁸⁶ JENSEN 64 gives $\lambda_+^\mu=\lambda_+^e=-$ 0.020 \pm 0.027. $d\xi$ (0)/ $d\lambda_+$ unknown. Includes SHAK-LEE 64 $\xi_B(K_{\mu 3}/K_{e3}^{\top})$.

⁸⁸ EICHTEN 68 has $\lambda_+=0.023\pm0.008$, t=4, independent of λ_- . Replaced by

 $^{^{89}}$ BOTTERILL 70 is re-evaluation of BOTTERILL 68B with different λ_+ .

 $^{^{91}}$ CUTTS 69 t=4.0 was calculated from figure 8. $d\xi(0)/d\lambda_{+}=\xi t=-0.95\times 4=-3.8.$

 $^{^{92}}$ BETTELS 68 $d\xi(0)/d\lambda_{+}=\xi t=-1.0 \times 4.9=-4.9.$

⁹³ MERLAN 74 polarization result (figure 5) not possible. See discussion of polarization experiments in note on " $K_{\ell 3}$ Form Factors" in the 1982 edition of this Review [Physics Letters **111B** (1982)].

 $^{^{94}\,}t$ value not given.

 $^{^{98}\}lambda_0$ value is for $\lambda_+=0.03$ calculated by us from $\xi(0)$ and $d\xi(0)/d\lambda_+$.

 $^{^{99}}$ MERLAN 74 λ_0 and $d\lambda_0/d\lambda_+$ were calculated by us from ξ_A , λ_+^μ , and $d\xi(0)/d\lambda_+$. Their figure 6 gives $\lambda_0 = -$ 0.025 \pm 0.012 and no $d\lambda_0/d\lambda_+.$

 $^{^{100}}$ This value and error are taken from BRAUN 75 but correspond to the BRAUN 73c λ_+^μ result. $d\lambda_0/d\lambda_+$ is from BRAUN 73C $d\xi(0)/d\lambda_+$ in ξ_A above.

 $^{^{101}\,\}lambda_0$ calculated by us from $\xi(0),\,\lambda_+^\mu,$ and $d\xi(0)/d\lambda_+.$

 $^{^{102}}$ BRAUN 74 is a combined $K_{\mu3}$, K_{e3} result. It is not independent of BRAUN 73C ($K_{\mu3}$) and BRAUN 73B (K_{e3}) form factor results.

0.866 ± 0.016		⁵ ALFF	66B	OSPK	
0.843 ± 0.013	5000	⁵ KIRSCH	66	HBC	

^{.843} ± 0.013 5000 First-H 66 HBC 1-CARITHERS 75 value is for $m_{\tilde{K}_L^0} - m_{\tilde{K}_S^0}$ $\Delta m = 0.5348 \pm 0.0021$. The Δm dependence of the total decay rate (inverse mean life) is $\Gamma(K_S^0) = [(1.122 \pm 0.004) + 0.16(\Delta m - 0.5348)/\Delta m] 10^{10}/s$. Value would not change significantly with our current $\Delta m = 0.5304 \pm 0.0014$. PHILL 68 has been changed by the authors from the published value (0.865 \pm 0.009) because of a correction in the shift due to η_{+-} . SKJEGGESTAD 72 and HILL 68 give detailed discussions of systematics encountered in this type of experiment. ARONSON 82 find that K_S^0 mean life may depend on the kaon energy.

- $^{
 m 4}\,{\sf FACKLER}$ 73 does not include systematic errors.
- ⁵ Pre-1971 experiments are excluded from the average because of disagreement with later more precise experiments.
- because of a correction in the shift due to η_{+-} . SKJEGGESTAD 72 and HILL 68 give detailed discussions of systematics encountered in this type of experiment.

- [a] See the Particle Listings below for the energy limits used in this measure-
- [b] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ 's.
- [c] Calculated from K^0_I semileptonic rates and the K^0_S lifetime assuming ΔS

CONSTRAINED FIT INFORMATION

An overall fit to 3 branching ratios uses 17 measurements and one constraint to determine 2 parameters. The overall fit has a χ^2 = 16.5 for 16 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\langle \delta x_i \delta x_j \rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv$ $\Gamma_i/\Gamma_{
m total}$. The fit constrains the x_i whose labels appear in this array to sum to

$$x_2 \quad \boxed{-100}{x_1}$$

 15 BARR 95B quotes this as the combined BARR 95B + BURKHARDT 87 result after rescaling BURKHARDT 87 to use same branching ratios and lifetimes as BARR 95B. 16 BARR 95B result is calculated using B($K_L \rightarrow \gamma \gamma$) = (5.86 \pm 0.17) \times 10 $^{-4}$.

<490 90 ¹⁹ BARMIN 85 HLBC <850 90 METCALF 72 ASPK

18 THOMSON 94 calculates this branching ratio from their measurements $|\rho_{+-0}| = 0.035^{+}_{-0.011} \pm 0.004$ and $\phi_{\rho} = (-59 \pm 48)^{\circ}$ where $|\rho_{+-0}| e^{i\phi_{\rho}} = A(K_S^0 \to \pi^+\pi^-\pi^0, 1 + 2)/A(K_L^0 \to \pi^+\pi^-\pi^0)$.

19 BARMIN 85 assumes that CP-allowed and CP-violating amplitudes are equally suppressed.

CP VIOLATION IN $K_S \rightarrow 3\pi$

(by T. Nakada, Paul Scherrer Institute and L. Wolfenstein, Carnegie-Mellon University)

The possible final states for the decay $K^0 \to \pi^+\pi^-\pi^0$ have isospin I=0, 1, 2, and 3. The I=0 and I=2 states have CP=+1 and K_S can decay into them without violating CP symmetry, but they are expected to be strongly suppressed by centrifugal barrier effects. The I=1 and I=3 states, which

have no centrifugal barrier, have CP = -1 so that the K_S decay to these requires CP violation.

In order to see CP violation in $K_S \to \pi^+\pi^-\pi^0$, it is necessary to observe the interference between K_S and K_L decay, which determines the amplitude ratio

$$\eta_{+-0} = \frac{A(K_S \to \pi^+ \pi^- \pi^0)}{A(K_L \to \pi^+ \pi^- \pi^0)}$$

ı

If η_{+-0} is obtained from an integration over the whole Dalitz plot, there is no contribution from the I=0 and I=2 final states and a nonzero value of η_{+-0} is entirely due to CP violation.

Only I=1 and I=3 states, which are CP=-1, are allowed for $K^0\to\pi^0\pi^0$ decays and the decay of K_S into $3\pi^0$ is an unambiguous sign of CP violation. Similarly to η_{+-0} , η_{000} is defined as

$$\eta_{000} = \frac{A(K_S \to \pi^0 \pi^0 \pi^0)}{A(K_L \to \pi^0 \pi^0 \pi^0)} \ .$$

If one assumes that CPT invariance holds and that there are no transitions to I=3 (or to nonsymmetric I=1 states), it can be shown that

$$\begin{split} \eta_{+-0} &= \eta_{000} \\ &= \epsilon + i \frac{\text{Im } a_1}{\text{Re } a_1} \ . \end{split}$$

With the Wu-Yang phase convention, a_1 is the weak decay amplitude for K^0 into I=1 final states; ϵ is determined from CP violation in $K_L \to 2\pi$ decays. The real parts of η_{+-0} and η_{000} are equal to $\mathrm{Re}(\epsilon)$. Since currently-known upper limits on $|\eta_{+-0}|$ and $|\eta_{000}|$ are much larger than $|\epsilon|$, they can be interpreted as upper limits on $\mathrm{Im}(\eta_{+-0})$ and $\mathrm{Im}(\eta_{000})$ and so as limits on the CP-violating phase of the decay amplitude a_1 .

CP-VIOLATION PARAMETERS IN KO DECAY

 $\begin{array}{l} \text{Im}(\eta_{+-0})^2 = \Gamma(\mathcal{K}_S^0 \to \pi^+\pi^-\pi^0, \textit{CP-violating}) \; / \; \Gamma(\mathcal{K}_L^0 \to \pi^+\pi^-\pi^0) \\ \textit{CPT} \; \text{assumed valid (i.e. } \; \text{Re}(\eta_{+-0}) \simeq \; 0). \end{array}$

Γ_7	$\pi^- e^+ \nu_e$		
Γa	$\pi^+ e^- \overline{\nu}_e$		

 $^{^{24}}$ BARMIN 83 find Re($\eta_{000})=(-0.08\pm0.18)$ and Im($\eta_{000})=(-0.05\pm0.27).$ Assuming CPT invariance they obtain the limit quoted above. 25 GJESDAL 748 uses $K2\pi$, $K_{\mu3}$, and K_{e3} decay results, unitarity, and CPT. Calculates $|(\eta_{000})|=$ 0.26 \pm 0.20. We convert to upper limit.

 $^{^5}$ ARONSON 70 and CARNEGIE 71 use κ_S^0 mean life $= (0.862 \pm 0.006) \times 10^{-10}$ s. We have not attempted to adjust these values for the subsequent change in the K_S^0 mean life or in η_{+-} .

- [a] The value is for the sum of the charge states of particle/antiparticle states
- [b] See the Particle Listings below for the energy limits used in this measurement.
- $\ensuremath{[c]}$ Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ 's.
- [d] $m_{e^+e^-} >$ 470 MeV.
- [e] Allowed by higher-order electroweak interactions.
- [f] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

CONSTRAINED FIT INFORMATION

An overall fit to the mean life, 4 decay rate, and 12 branching ratios uses 46 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2=41.2$ for 39 degrees of

The following off-diagonal array elements are the correlation coefficients $\langle \delta p_i \delta p_j \rangle / (\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this

KI FORM FACTORS

For discussion, see note on form factors in the \mathcal{K}^\pm section of the Particle Listings above.

In the form factor comments, the following symbols are used.

 f_{\perp} and f_{\perp} are form factors for the vector matrix element.

 f_S and f_T refer to the scalar and tensor term.

 $f_0 = f_+ + f_- t/(m_K^2 - m_\pi^2).$

 λ_+ , λ_- , and λ_0 are the linear expansion coefficients of f_+ , f_- , and f_0 .

 λ_+ refers to the $K^0_{\mu3}$ value except in the K^0_{e3} sections.

 $d\xi(0)/d\lambda_+$ is the correlation between $\xi(0)$ and λ_+ in $K^0_{\mu3}$.

 $d\lambda_0/d\lambda_+$ is the correlation between λ_0 and λ_+ in $K_{\mu3}^0$.

 $t = \text{momentum transfer to the } \pi \text{ in units of } m_{\pi}^2.$

DP = Dalitz plot analysis.

 $PI = \pi$ spectrum analysis.

 $MU = \mu$ spectrum analysis.

 $POL = \mu$ polarization analysis.

 ${\rm BR}={\it K}_{\mu 3}^0/{\it K}_{e3}^0$ branching ratio analysis.

E = positron or electron spectrum analysis.

RC = radiative corrections.

λ_+ (LINEAR ENERGY DEPENDENCE OF f_+ IN K_{e3}^0 DECAY)

For radiative correction of κ_{e3}^0 DP, see GINSBERG 67 and BECHERRAWY 70.

$-0.68 + 0.12 \\ -0.20$	-26	16k	⁷⁴ CHIEN	70	ASPK	DP

- 67 BIRULEV 81 error, $d\xi(0)/d\lambda_+$ calculated by us from λ_0 , λ_+ . $d\lambda_0/d\lambda_+=0$ used.
- ⁶⁸ HILL 79 and CHO 80 calculated by us from λ_0 , λ_+ , and $d\lambda_0/d\lambda_+$.
- 69 BUCHANAN 75 is calculated by us from λ_0 , λ_+ and $d\lambda_0/d\lambda_+$ because their appendix A value -0.20 ± 22 assumes $\xi(t)$ constant, i.e. $\lambda_-=\lambda_+$.
- 70 DONALDSON 748 gives $\xi=-0.11\pm0.02$ not including systematics. Above error and $d\xi(0)/d\lambda_+$ were calculated by us from λ_0 and λ_+ errors (which include systematics) and $d\lambda_0/d\lambda_+$.
- 71 PEACH 73 gives $\xi(0)=-0.95\pm0.45$ for $\lambda_{+}=\lambda_{-}=0.025$. The above value is for $\lambda_{-}=$ 0. K.Peach, private communication (1974).
- 72 ALBROW 72 fit has λ_- free, gets $\lambda_-=-$ 0.030 \pm 0.060 or $\Lambda=+$ 0.15 $^{+0.17}_{-0.11}$
- ⁷³ CARPENTER 66 $\xi(0)$ is for $\lambda_+=0$. $d\xi(0)/d\lambda_+$ is from figure 9.
- ⁷⁴ CHIEN 70 errors are statistical only. $d\xi(0)/d\lambda_+$ from figure 4. DALLY 72 is a reanalysis of CHIEN 70. The DALLY 72 result is not compatible with assumption $\lambda_-=0$ so not included in our fit. The nonzero λ_- value and the relatively large λ_+ value found by DALLY 72 come mainly from a single low t bin (figures 1,2). The (f_+,ξ) correlation was ignored. We estimate from figure 2 that fixing $\lambda_{-}=0$ would give $\xi(0)=-1.4\pm0.3$ and would add 10 to χ^2 . $d\xi(0)/d\lambda_+$ is not given.
- $75\,\mathrm{BASILE}$ 70 is incompatible with all other results. Authors suggest that efficiency estimates might be responsible.

$\xi_b = f_-/f_+$ (determined from $K_{\mu3}^0/K_{e3}^0$)

The $K_{\mu 3}^0/K_{e3}^0$ branching ratio fixes a relationship between $\xi(0)$ and λ_+ . We quote the author's $\xi(0)$ and associated λ_+ but do not average because the λ_+ values differ. The fit result and scale factor given below are not obtained from these ξ_b values. Instead they are obtained directly from the authors $K_{\mu3}^0/K_{e3}^0$ branching ratio via the fitted $K_{\mu 3}^0/K_{e3}^0$ ratio $(\Gamma(\pi^{\pm}\mu^{\mp}\nu)/\Gamma(\pi^{\pm}e^{\mp}\nu_e))$. The parameter ξ is redundant with λ_0 below and is not put into the Meson Summary Table.

⁷⁶ EVANS 73 replaces EVANS 69.

 $\xi_{\bf c}=f_-/f_+$ (determined from μ polarization in $K_{\mu 3}^0$)

The μ polarization is a measure of $\xi(t)$. No assumptions on λ_{+-} necessary, t (weighted by sensitivity to $\xi(t)$) should be specified. In λ_+ , $\xi(0)$ parametrization this is $\xi(0)$ for $\lambda_{+}=0$. $d\xi/d\lambda=\xi t$. For radiative correction to μ polarization in $K_{\mu,3}^{0}$, see GINSBERG 73. The parameter ξ is redundant with λ_0 below and is not put into the Meson Summary Table.

CP VIOLATION IN K_L^0 DECAY

(by L. Wolfenstein, Carnegie-Mellon University and T. Trippe, LBNL)

Experimentally Measured Parameters

CP violation has been observed in the semi-leptonic decays $K_L^0 \to \pi^{\mp} \ell^{\pm} \nu$ and in the nonleptonic decay $K_L^0 \to 2\pi$. The experimental numbers that have been measured are [1]

$$\delta = \frac{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) - \Gamma(K_L^0 \to \pi^+ \ell^- \nu)}{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) + \Gamma(K_L^0 \to \pi^+ \ell^- \nu)}$$
(1a)

$$\eta_{+-} = A(K_L^0 \to \pi^+ \pi^-)/A(K_S^0 \to \pi^+ \pi^-)$$

$$= |\eta_{+-}| e^{i\phi_{+-}}$$
(1b)

$$\eta_{00} = A(K_L^0 \to \pi^0 \pi^0) / A(K_S^0 \to \pi^0 \pi^0)$$

= $|\eta_{00}| e^{i\phi_{00}}$. (1c)

Thus there are five real numbers, three magnitudes, and two phases. We list $\delta(\mu)$ for $K_L^0 \to \pi \mu \nu$ and $\delta(e)$ for $K_L^0 \to \pi e \nu$ separately and a weighted average δ . Experimentally for the $K_L^0 \to \pi^0 \pi^0$ decay the quantities directly measured (and also of greatest theoretical interest) are $|\eta_{00}/\eta_{+-}|$ and $\phi_{00} - \phi_{+-}$.

Analysis Based on CPT Invariance [2]

CP violation can occur either in the $K^0 - \overline{K}^0$ mixing or in the decay amplitudes. Assuming CPT invariance, the CPviolation in the mixing is described by a single parameter ϵ :

$$|K_L^0\rangle = \left[(1+\epsilon) \mid K^0 \rangle - (1-\epsilon) \mid \overline{K}^0 \rangle \right]$$

$$/ \left[2(1+\mid \epsilon\mid^2) \right]^{1/2} \qquad (2a)$$

$$|K_S^0\rangle = \left[(1+\epsilon) \mid K^0 \rangle + (1-\epsilon) \mid \overline{K}^0 \rangle \right]$$

$$/ \left[2(1+\mid \epsilon\mid^2) \right]^{1/2} \qquad (2b)$$

The decay amplitudes are written

$$\langle I = 0 \mid T \mid K^0 \rangle = e^{i\delta_0} A_0 \tag{3a}$$

$$\langle I = 2 \mid T \mid K^0 \rangle = e^{i\delta_2} A_2 \tag{3b}$$

where δ_I are the $\pi\pi$ scattering phase shifts at the K^0 mass and I is the isospin of the final state. CP violation is measured by (Im $A_I/\text{Re }A_I$). One can then write

$$\eta_{+-} = \epsilon + \epsilon' \tag{4a}$$

$$\eta_{00} = \epsilon - 2\epsilon' \tag{4b}$$

where

$$\epsilon' = \frac{i}{\sqrt{2}} e^{i(\delta_2 - \delta_0)} \frac{\operatorname{Re} A_2}{\operatorname{Re} A_0} \left[\frac{\operatorname{Im} A_2}{\operatorname{Re} A_2} - \frac{\operatorname{Im} A_0}{\operatorname{Re} A_0} \right]$$
 (5)

neglecting small corrections of order ϵ' times $\operatorname{Re}(A_2/A_0)$. It is possible by a choice of phase convention to set Im A_0 or Im A_2 or $\operatorname{Im} \epsilon$ to 0, but none of these is 0 with the usual phase convention in the Standard Model. The choice Im A_0 =0 is the Wu-Yang phase convention [3].

By applying CPT invariance and unitarity it is possible to relate δ to ϵ and to determine the phases of ϵ and ϵ' . If one assumes the $\Delta S = \Delta Q$ rule (see below note on the " $\Delta S = \Delta Q$ Rule in K^0 Decay") the expression for δ becomes

$$\delta = 2 \operatorname{Re} \epsilon / (1 + |\epsilon|^2) \approx 2 \operatorname{Re} \epsilon$$
 (6)

This quantity is independent of phase convention and is seen from Eq. (2) to equal $\langle K_L^0 | K_S^0 \rangle$. The phase of ϵ is given by

$$\phi(\epsilon) \approx \tan^{-1} \frac{2(m_{K_L} - m_{K_S})}{\Gamma_{K_S} - \Gamma_{K_L}} = 43.49 \pm 0.08^{\circ}$$
 (7a)

while Eq. (5) gives

$$\phi(\epsilon') = \delta_2 - \delta_0 + \frac{\pi}{2} \approx 48 \pm 4^{\circ} . \tag{7b}$$

The approximation in Eq. (7a) depends on the assumption that direct CP violation is negligible in all K^0 decays and is expected to be good to a few tenths of a degree. Eq. (7a)is evaluated using the values of the $K_L^0 - K_S^0$ mass difference $\Delta m = (0.5304 \pm 0.0014) \times 10^{10} h s^{-1}$ and the K_S^0 mean life $\tau_s = (0.8927 \pm 0.0009) \times 10^{-10}$ s from the current edition. The value of the $\pi\pi$ phase shifts is taken from the fit given by Chell and Olsson [4]. The most important point for the analysis is that $\cos[\phi(\epsilon') - \phi(\epsilon)] \simeq 1$. The consequence of this analysis is that only two real quantities need be measured, the magnitude of ϵ and the value of (ϵ'/ϵ) including its sign. The measured quantity $|\eta_{00}/\eta_{+-}|^2$ which is very close to unity, is given to a good approximation by

$$|\eta_{00}/\eta_{+-}|^2 \approx 1 - 6\text{Re}\left(\epsilon'/\epsilon\right)$$

$$= 1 - 6(\epsilon'/\epsilon)\cos\left[\phi(\epsilon') - \phi(\epsilon)\right]. \tag{8}$$

Since the cos in Eq. (8) is expected theoretically to be very close to unity it is customary to say that $|\eta_{00}/\eta_{+-}|^2$ determines ϵ'/ϵ .

It is possible to use the values of ϕ_{+-} and $\phi_{00} - \phi_{+-}$ to set limits on CPT violation. [See Tests of Conservation Laws.]

Models

See key on page 199

In the superweak model [5] CP violation is restricted to the mass mixing so that to a high degree of accuracy one expects $\epsilon' = 0$. The phase $\phi(\epsilon)$ is given in this model exactly by Eq. (7a) so that this has sometimes been referred to as the superweak phase; however, as noted above, all CPT-invariant models give Eq. (7a) as a very good approximation. In the Standard Model CP violation is entirely due to the phase in the Cabibbo-Kobayashi-Maskawa mixing matrix [6](q.v.). Since CP violation occurs in first order in decay amplitudes and in second order in mass-matrix mixing, one expects a significant nonzero value of ϵ' . The calculation is uncertain partly because m_t and V_{td} are not well known and primarily because of the difficulty of estimating hadronic matrix elements [7]. The theoretical results for ϵ'/ϵ in the Standard Model are generally in the range from 10^{-4} to 3×10^{-3} .

Fit for ϕ_{+-} , ϕ_{00} , ϕ_{00} - ϕ_{+-} , Δm , and τ_s

The Fermilab E773 experiment has published new results on the CP-violation phases ϕ_{+-} and ϕ_{00} , the $K_L^0 - K_S^0$ mass difference Δm , and the K_S^0 mean life τ_s (Document ID in our listings: SCHWINGENHEUER 95; reference [8]). The CPLEAR experiment has published new results on ϕ_{+-} (ADLER 95B [9]) and Δm (ADLER 95 [10]).

Fermilab E773 (SCHWINGENHEUER 95 [8]) and E731 (GIBBONS 93 [11]) measure $\phi_{+-} - \phi_f$ and calculate the regeneration phase ϕ_f from the power law momentum dependence of the regeneration amplitude using analyticity and dispersion relations. In the E731 result, a systematic error of ± 0.5 degrees for departures from a pure power-law is included. For the E773 result, they modeled a variety of effects that do distort the amplitude from a pure power law and ascribed a $\pm 0.35^{\circ}$ systematic error from uncertainties in these effects. Even so, the E731 result remains valid within its quoted errors. KLEINKNECHT 94 [12] and KLEINKNECHT 95 [13] argue that these systematic errors should be around 3°, primarily because of the absence of data on the momentum dependence of the regeneration amplitude above 160 GeV/c. BRIERE 95 [14] and BRIERE 95C [15] reply that the current understanding of regeneration is sufficient to allow a precise and reliable correction for the region above 160 GeV/c. The question is one of judgement about the reliability of the assumptions used. In the absence of any contradictory evidence, we choose to accept the judgement of the E731/E773 experimenters in setting their systematic errors.

In this edition we give a joint fit to the data on ϕ_{+-} , ϕ_{00} , $\phi_{00} - \phi_{+-}$, Δm , and τ_s , including the effects of correlations. Measurements of ϕ_{+-} and ϕ_{00} are highly correlated with Δm and τ_s . The correlations are given in the footnotes of the ϕ_{+-} and ϕ_{00} data listings. In earlier editions of the Review we adjusted the experimental values of ϕ_{+-} and ϕ_{00} to account for correlations with Δm and au_s but did not include the effects of these correlations when evaluating Δm and τ_s . When a joint fit is done, the ϕ_{+-} measurements and

their correlations have a strong influence on the fitted value of Δm . This is because the CERN NA31 vacuum regeneration experiments (CAROSI 90 [16] and GEWENIGER 74B [17]), the Fermilab E773/E731 regenerator experiments (SCHWIN-GENHEUER 95 [8] and GIBBONS 93 [11]), and the CPLEAR $K^0 - \overline{K}^0$ asymmetry experiment (ADLER 95B [9]) have very different dependences of ϕ_{+-} on Δm , as can be seen in Fig. 1. The correlations move the fitted Δm lower so that the ϕ_{+-} measurements are in good agreement with each other and with ϕ (superweak).

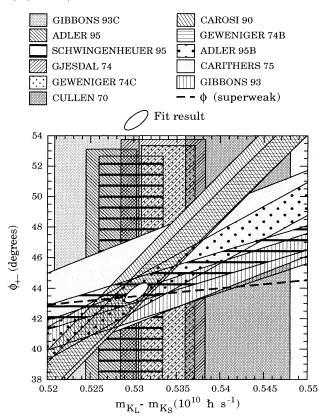

Figure 1: ϕ_{+-} vs Δm . Δm measurements appear as vertical bands spanning $\Delta m \pm 1\sigma$, some of which are cut near the top to aid the eye. The ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-} \pm \sigma_{\phi}$. The dashed line shows ϕ (superweak). The ellipse shows the 1σ contour of the fit result. See Table 1 for data references.

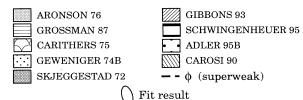

The (ϕ_{+-}, τ_s) correlations influence the τ_s fit result in a similar manner, as can be seen in Fig. 2. The influence of the ϕ_{+-} experiments is not as great on τ_s as it is on Δm because the indirect measurements of τ_s derived from the diagonal crossing bands in Fig. 2 are not as precise as the direct measurements of τ_s from E773/E731 (SCHWINGENHEUER 95 [8] and GIBBONS 93 [11]).

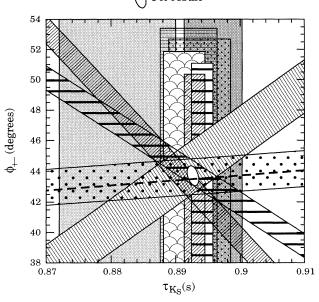

Figure 2: ϕ_{+-} vs τ_s . τ_s measurements appear as vertical bands spanning $\tau_s \pm 1\sigma$, some of which are cut near the top to aid the eye. The ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-}\pm\sigma_{\phi}$. The dashed line shows ϕ (superweak). The ellipse shows the fit result's 1σ contour. See Table 1 for data references.

In Fig. 1 [Fig. 2] the slope of the diagonal ϕ_{+-} bands shows the $\Delta m \ [\tau_s]$ dependence; the unseen $\tau_s \ [\Delta m]$ dependent term is evaluated using the fitted τ_s [Δm]. The vertical half-width σ_{ϕ} of each band is the ϕ_{+-} error for fixed Δm $[\tau_s]$ and includes the systematic error due to the error in the fitted τ_s [Δm].

Table 2 gives the resulting fit values for the parameters and Table 3 gives the correlation matrix.

A similar analysis has been done by the CPLEAR Collaboration [26]. The small differences between their results and ours are due primarily to different treatments of τ_s . Their fit constrains τ_s to the PDG 1994 value, while our fit includes the more recent SCHWINGENHEUER 95 [8] τ measurement.

Table 2: Results of the fit for ϕ_{+-} , ϕ_{00} , $\phi_{00} - \phi_{+-}$, Δm , and τ_s . The fit has $\chi^2 = 12.0$ for 18 degrees of freedom (22 measurements -5parameters +1 constraint).

Fit for $\epsilon'/\epsilon,\, |\eta_{+-}|,\, |\eta_{00}|,\, {
m and}\,\, {
m B}(K_L o \pi\pi)$

We list measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$ and ϵ'/ϵ . Independent information on $|\eta_{+-}|$ and $|\eta_{00}|$ can be obtained from measurements of the K_L^0 and K_S^0 lifetimes (τ_s) and branching ratios (B) to $\pi\pi$, using the relations

$$|\eta_{+-}| = \left[\frac{B(K_L^0 \to \pi^+ \pi^-)}{\tau(K_L^0)} \frac{\tau(K_S^0)}{B(K_S^0 \to \pi^+ \pi^-)} \right]^{1/2} , \quad (9a)$$

$$|\eta_{00}| = \left[\frac{B(K_L^0 \to \pi^0 \pi^0)}{\tau(K_L^0)} \frac{\tau(K_S^0)}{B(K_S^0 \to \pi^0 \pi^0)} \right]^{1/2} . \tag{9b}$$

For historical reasons the branching ratio fits and the CPviolation fits are done separately, but we want to include the influence of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ measurements on $\mathrm{B}(K_L^0 \to \pi^+\pi^-)$ and $\mathrm{B}(K_L^0 \to \pi^0\pi^0)$ and vice versa. We approximate a global fit to all of these measurements by first performing two independent fits: 1) BRFIT, a fit to the K_L^0 branching ratios, rates, and mean life, and 2) ETAFIT, a fit to

the $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{+-}/\eta_{00}|$, and ϵ'/ϵ measurements. The results from fit 1, along with the K_S^0 values from this edition are used to compute values of $|\eta_{+-}|$ and $|\eta_{00}|$ which are included as measurements in the $|\eta_{00}|$ and $|\eta_{+-}|$ sections with a document ID of BRFIT 96. Thus the fit values of $|\eta_{+-}|$ and $|\eta_{00}|$ given in this edition include both the direct measurements and the results from the branching ratio fit.

The process is reversed in order to include the direct $|\eta|$ measurements in the branching ratio fit. The results from fit 2 above (before including BRFIT 96 values) are used along with the K_L^0 and K_S^0 mean lives and the $K_S^0 \to \pi\pi$ branching fractions to compute the K_L^0 branching ratios $\Gamma(K_L^0 \to \pi^+\pi^-)/\Gamma({\rm total})$ and $\Gamma(K_L^0 \to \pi^0\pi^0)/\Gamma(K_L^0 \to \pi^+\pi^-)$. These branching ratio values are included as measurements in the branching ratio section with a document ID of ETAFIT 96. Thus the K_L^0 branching ratio fit values in this edition include the results of direct measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ . A more detailed discussion of these fits is given in the 1990 edition of this Review [27].

- $^{105}\,\mathrm{These}$ values are derived from $|\eta_{00}/\eta_{+-}|$ measurements. They enter the average in this section but enter the fit via the $|\eta_{00}/\eta_{+-}|$ section only.
- $^{106}\,\mathrm{This}$ is the combined results from BARR 93D and BURKHARDT 88, taking into account their common systematic uncertainty.

 ϕ_{+-} , PHASE of η_{+-} The dependence of the phase on Δm and τ_S is given for each experiment in the comments below, where Δm is the κ_L^0 - κ_S^0 mass difference in units $10^{10}~hs^{-1}$ and au_S is the K_S mean life in units 10^{-10} s. For the "used" data, we have evaluated these mass dependences using our 1996 values, $\Delta m = 0.5304 \pm 0.0014$, $au_S = 0.8927 \pm 0.0009$ to obtain the values quoted below. We also give the regeneration phase ϕ_f in the comments below.

- 108 SCHWINGENHEUER 95 reports $\phi_{+-} = 43.53 \pm 0.76 \, + 173 [\Delta m 0.5282] \, 275 [au_{S} 0.5282]$ 0.8926].
- 0.8926].

 109 These experiments measure $\phi_{+-} \phi_f$ and calculate the regeneration phase from the power law momentum dependence of the regeneration amplitude using analyticity and dispersion relations. SCHWINGENHEUER 95 [GIBBONS 93] includes a systematic error of 0.35° [0.5°] for uncertainties in their modeling of the regeneration amplitude. See the discussion of these systematic errors, including criticism that they could be underestimated, in the note on "C violation in K_L^0 decay."
- 110 GIBBONS 93 measures $\phi_+ \phi_f$ and calculates the regeneration phase ϕ_f from the power law momentum dependence of the regeneration amplitude using analyticity. An error of 0.6° is included for possible uncertainties in the regeneration phase. They find $\phi_{+-}=$ 42.21 \pm 0.9 +189 [Δm - 0.5257] - 460 [$\tau_{\rm S}$ - 0.8922]°, as given in SCHWINGENHEUER 95, footnote 8. GIBBONS 93 reports ϕ_{+-} (42.2 \pm 1.4)°
- $^{111} \, {\rm CAROSI} \,\, 90 \,\, \phi_{+-} = 46.9 \,\pm\, 1.4 \,\pm\, 0.7 \,\, +579 \,\, [\Delta m \,\, -0.5351] \,\, +303 \,\, [\tau_{\rm S} \,\, -0.8922]^{\circ}.$
- ¹¹²CARITHERS 75 $\phi_{+-} = (45.5 \pm 2.8) + 224 [\Delta m 0.5348]^{\circ}$. $\phi_{f} = -40.9 \pm 2.6^{\circ}$.
- ¹¹³GEWENIGER 74B $\phi_{+-} = (49.4 \pm 1.0) + 565 [\Delta m 0.540]^{\circ}$.
- 114 ADLER 92B quote separately two systematic errors: ± 0.4 from their experiment and ± 1.0 degrees due to the uncertainty in the value of Δm .
- 115 KARLSSON 90 systematic error does not include regeneration phase uncertainty.
- 116 ARONSON 82 find that ϕ_{+-} may depend on the kaon energy. 117 CARNEGIE 72 ϕ_{+-} is insensitive to $\Delta m.~\phi_f=-$ 56.2 \pm 5.2°.
- 118 BALATS 71 $\phi_{+-}^{-} = (39.0 \pm 12.0) + 198 [\Delta m 0.544]^{\circ}. \; \phi_f = -43.0 \pm 4.0^{\circ}.$
- ¹¹⁹ JENSEN 70 $\phi_{+-}^{'}=(42.4\pm4.0)+576[\Delta m-0.538]^{\circ}.$
- $^{120}\, {\tt BENNETT}$ 69 uses measurement of $(\phi_{+-})-(\phi_f)$ of ALFF-STEINBERGER 668. BEN-NETT 69 $\phi_{+-} = (34.9 \pm 10.0) + 69 [\Delta m - 0.545]^{\circ}$. $\phi_f = -49.9 \pm 5.4^{\circ}$.
- ¹²¹ BOHM 698 $\phi_{+-} = (41.0 \pm 12.0) + 479(\Delta m 0.526)^{\circ}$.
- $^{122}\,\mathrm{FAISSNER}$ 69 error enlarged to include error in regenerator phase. FAISSNER 69 ϕ_{+-} = $(49.3 \pm 7.4) + 205[\Delta m - 0.555]^{\circ}$. $\phi_f = -42.7 \pm 5.0^{\circ}$.
- 123 BENNETT 69 is a re-evaluation of BENNETT 68B.
- 124 Old experiments with large errors not included in average.

ϕ_{00} , PHASE OF η_{00}

See comment in ϕ_{+-} header above for treatment of Δm and au_{S} dependence.

$\Delta S = \Delta Q$ IN K^0 DECAYS

< 0.3

The relative amount of $\Delta S \neq \Delta Q$ component present is measured by the parameter x, defined as

$$x = A(\overline{K}^0 \to \pi^- \ell^+ \nu)/A(K^0 \to \pi^- \ell^+ \nu) \ .$$

We list $Re\{x\}$ and $Im\{x\}$ for K_{e3} and $K_{\mu3}$ combined.

$x = A(\overline{K}^0 \rightarrow \pi^- \ell^+ \nu)/A(K^0 \rightarrow \pi^- \ell^+ \nu) = A(\Delta S = -\Delta Q)/A(\Delta S = \Delta Q)$

141 BURGUN 72 is a 1	inal result	which includes BUF	RGUN 71.	

142 First GRAHAM 72 value is second GRAHAM 72 value combined with MANTSCH 72. 143 Footnote 10 of HILL 67 should read +0.58, not -0.58 (private communication) CHO 70 is analysis of unambiguous events in new data and HILL 67. 144 BALDO-CEOLIN 65 gives x and θ converted by us to Re(x) and Im(x). 145 FOALSTHUR (5) gives +0.58 (c) +0.5

145 FRANZINI 65 gives x and θ for Re(x) and Im(x). See SCHMIDT 67.

CPT-VIOLATION PARAMETERS IN KO DECAY

If $\mathit{CP}\text{-violating}$ interactions include a T conserving part then

$$\begin{split} |\kappa_S\rangle &= [|\kappa_1\rangle + (\epsilon + \Delta)|\kappa_2\rangle]/\sqrt{1 + |\epsilon + \Delta|^2} \\ |\kappa_L\rangle &= [|\kappa_2\rangle + (\epsilon - \Delta)|\kappa_1\rangle]/\sqrt{1 + |\epsilon - \Delta|^2} \\ \text{where} \\ |\kappa_1\rangle &= [|\kappa^0\rangle + |\overline{\kappa}^0\rangle]/\sqrt{2} \\ |\kappa_2\rangle &= [|\kappa^0\rangle - |\overline{\kappa}^0\rangle]/\sqrt{2} \\ \text{and} \\ |\overline{\kappa}^0\rangle &= CP|\kappa^0\rangle. \end{split}$$

The parameter Δ specifies the $\ensuremath{\textit{CPT}}\textsc{-violating}$ part.

Estimates of Δ are given below. See also THOMSON 95 for a test of $\it CPT$ symmetry conservation in $\it K^0$ decays using the Bell-Steinberger relation.

REAL PART OF $\boldsymbol{\Delta}$

A nonzero value violates CPT invariance.

VALUE

VALUE EVTS $O.018 \pm 0.020$.018 $^{146}\,\mathrm{DEMIDOV}$ 95 reanalyzes data from HART 73 and NIEBERGALL 74. IMAGINARY PART OF Δ A nonzero value violates CPT invariance.

 $K^*(892)^0$ mass (MeV)

- ¹ From a partial wave amplitude analysis.
- Inclusive reaction. Complicated background and phase-space effects. 3 Mass errors enlarged by us to Γ/\sqrt{N} . See note.
- ⁴ Number of events in peak reevaluated by us.
- ⁵ From pole extrapolation.

$K^*(892)$ MASSES AND MASS DIFFERENCES

Unrealistically small errors have been reported by some experiments. We use simple "realistic" tests for the minimum errors on the determination of a mass and width from a sample of N events:

$$\delta_{\min}(m) = \frac{\Gamma}{\sqrt{N}}, \quad \delta_{\min}(\Gamma) = 4\frac{\Gamma}{\sqrt{N}} \; .$$

We consistently increase unrealistic errors before averaging. For a detailed discussion, see the 1971 edition of this Note.

CONSTRAINED FIT INFORMATION

An overall fit to the total width and a partial width uses 18 measurements and one constraint to determine 3 parameters. The overall fit has a $\chi^2=15.2$ for 16 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta p_i \delta p_j \right\rangle / \left(\delta p_i \cdot \delta p_j \right)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

CONSTRAINED FIT INFORMATION

An overall fit to the total width and a partial width uses 18 measurements and one constraint to determine 3 parameters. The overall fit has a $\chi^2=18.4$ for 16 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta p_i \delta p_j \right\rangle / (\delta p_i \cdot \delta p_j)$, in percent, from the fit to parameters p_i , including the branching fractions, $x_i \equiv \Gamma_i/\Gamma_{\rm total}$. The fit constrains the x_i whose labels appear in this array to sum to one.

CONSTRAINED FIT INFORMATION

An overall fit to the total width, a partial width, and 10 branching ratios uses 28 measurements and one constraint to determine 8 parameters. The overall fit has a $\chi^2=19.5$ for 21 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta \rho_i \delta \rho_j \right\rangle / (\delta \rho_i \cdot \delta \rho_j) \text{, in percent, from the fit to parameters } \rho_i \text{, including the branch-}$ ing fractions, $x_i \equiv \Gamma_i/\Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to one.

	Mode	Rate (MeV)	Scale factor

CONSTRAINED FIT INFORMATION

An overall fit to 4 branching ratios uses 4 measurements and one constraint to determine 3 parameters. The overall fit has a $\chi^2=2.9$ for 2 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j),$ in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\rm total}.$ The fit constrains the x_i whose labels appear in this array to sum to one.

VALUE (MeV) EVTS

$$I(J^P) = \frac{1}{2}(2^-)$$

THE $K_2(1770)$ AND THE $K_2(1820)$

A partial-wave analysis of the $K^-\omega$ system based on about 100,000 $K^-p \to K^-\omega p$ events (ASTON 93) gives evidence for two $q\bar{q}$ D-wave states near 1.8 GeV. A previous analysis based on about 200,000 diffractively produced $K^-p \to K^-\pi^+\pi^-p$ events (DAUM 81) gave evidence for two $J^P=2^-$ states in this region, with masses \sim 1780 MeV and \sim 1840 MeV and widths \sim 200 MeV, in good agreement with the results of ASTON 93. In contrast, the masses obtained using a single resonance do not agree well: ASTON 93 obtains 1728 \pm 7 MeV, while DAUM 81 estimates \sim 1820 MeV. We conclude that there are indeed two K_2 resonances here.

We list under the $K_2(1770)$ other measurements that do not resolve the two-resonance structure of the enhancement.

CONSTRAINED FIT INFORMATION

An overall fit to 4 branching ratios uses 5 measurements and one constraint to determine 4 parameters. The overall fit has a χ^2 = 2.2 for 2 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j),$ in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\rm total}.$ The fit constrains the x_i whose labels appear in this array to sum to

Meson Particle Listings D MESONS

CHARMED MESONS $(C = \pm 1)$

 $D^+=c\overline{d}$, $D^0=c\overline{u}$, $\overline{D}{}^0=\overline{c}\,u$, $D^-=\overline{c}\,d$, similarly for D^* 's

NOTE ON D MESONS

(by P.R. Burchat, Stanford University)

The new experimental results on charm meson decays reported in this edition are predominantly from CLEO II at the e^+e^- storage ring CESR and from fixed-target experiments, especially photoproduction experiment E687 at Fermilab. The first results from the BES experiment, operating at an e^+e^- center-of-mass energy of 4.0 GeV, also appear in this edition. BES has measured the branching fractions for the purely leptonic decay $D_s^+ \to \mu^+\nu_\mu$ and for $D_s^+ \to \phi\pi^+$, albeit with large statistical uncertainties.

Semileptonic decays

For a detailed discussion of experimental measurements and theoretical predictions for leptonic and semileptonic decays of both charm and bottom hadrons, see the recent review by J.D. Richman and P.R. Burchat [1]. Also see the "Note on Semileptonic Decays of D and B Mesons, Part I," by R.J. Morrison and J.D. Richman, in our 1994 edition [2].

In this edition, we have added to the Particle Listings the measurements of the form-factor ratios for $D^+ \to \overline{K}^{*0} \ell^+ \nu_{\ell}$ and $D_s^+ \to \phi \ell^+ \nu_\ell$. The form factors $A_1(q^2)$, $A_2(q^2)$, and $V(q^2)$ are defined in the "Note on Semileptonic Decays of B Mesons" in the B-meson Particle Listings. The ratios $A_2(0)/A_1(0)$ and $V(0)/A_1(0)$ have been measured by Fermilab fixed-target experiments E691, E687, and E653 for the mode $D^+ \to \overline{K}^{*0} \ell^+ \nu_{\ell}$, and by E687, E653, and CLEO for the mode $D_s^+ \to \phi \ell^+ \nu_{\ell}$. For each semileptonic mode, the averages of the measured form-factor ratios can be combined with the measured decay rate to extract the values of the form factors themselves [3]. The results are $A_1(0) = 0.55 \pm 0.03$, $A_2(0) = 0.40 \pm 0.08$, and $V(0) = 1.0 \pm 0.2 \text{ for } D^+ \to \overline{K}^{*0} \ell^+ \nu_{\ell} \text{ and } A_1(0) = 0.62 \pm 0.06,$ $A_2(0) = 1.0 \pm 0.3$, and $V(0) = 0.9 \pm 0.3$ for $D_s^+ \to \phi \ell^+ \nu_{\ell}$. The measured decay rate for $D \to \overline{K}\ell^+\nu_{\ell}$ can be used to extract the single vector form factor $f_{+}(0)$. The result is $f_{+}(0) = 0.74 \pm 0.03$. Recent quark-model predictions are in good agreement with the D measurements. Lattice gauge calculations are in good agreement with the vector form factors but predict axial form factors that are somewhat higher than the measured values.

Measurements of the ratio $\Gamma(D \to \overline{K}^* \ell^+ \nu_\ell)/\Gamma(D \to \overline{K} \ell^+ \nu_\ell)$ confirm the initial experimental result that the ratio is only a little over one half, whereas initial theoretical expectations were that it would be about one. By taking into account effects originally ignored, such as relativistic corrections, theorists have managed to accommodate the observed ratio of rates in quark-model calculations. Lattice gauge calculations are also in reasonable agreement with the measured ratio. In contrast to

semileptonic B decays, no evidence for higher-mass resonances or nonresonant final states has been observed in semileptonic D decays.

Although the experimental results are statistically limited, the semileptonic decays $D_s^+ \to \phi \ell^+ \nu_\ell$ and $D_s^+ \to (\eta \text{ or } \eta') \ell^+ \nu_\ell$ appear to follow the pattern of D decays, both in terms of form-factor ratios and of the relative decay rates to vector and pseudoscalar mesons.

Searches for D^0 - \overline{D}^0 mixing

There have been a number of papers published recently concerning both the sensitivity of $D^0\overline{D}{}^0$ mixing to new physics and the validity of various assumptions made in existing searches [4]. We have reorganized the mixing limits in the Listings and have added more detailed comments regarding the assumptions made in various searches.

Absolute branching fractions for D_s^+

Two model-independent measurements of the absolute branching fraction for $D_s^+ \to \phi \pi^+$, from BES and CLEO, appear in this edition. All previous measurements depended on theoretical models or on estimates of D_s^+ production cross sections. We no longer use these older results when calculating the average and fit values for $B(D_s^+ \to \phi \pi^+)$. The BES collaboration (BAI 95C) uses $e^+e^- \rightarrow D_s^+D_s^-$ events in which one or both of the D_s^{\pm} decays are reconstructed to obtain a measurement of the $D_s^+ \to \phi \pi^+$ branching fraction without assumptions on the cross section for D_s^{\pm} production. However, with only two events in which both D_s^{\pm} decays are reconstructed, the result, $B(D_s^+ \to \phi \pi^+) = (3.9^{+5.1+1.8}_{-1.9-1.1})\%$, has a very large statistical uncertainty. For their new measurement, the CLEO collaboration (ARTUSO 96) measures the branching ratio B($D_s^+ \to \phi \pi^+$)/B($D^0 \to K^- \pi^+$) = 0.92 ± 0.20 ± 0.11 by partially reconstructing the decay $\overline{B}^0 \to D^{*+}D_s^{*-}$. They then use their measured value of $B(D^0 \to K^-\pi^+)$ to determine $B(D_s^+ \to \phi \pi^+) = (3.59 \pm 0.77 \pm 0.48)\%.$

In the past, we of necessity relied heavily on estimates of $\mathrm{B}(D_s^+ \to \phi \pi^+)$ based on measurements of $\Gamma(D_s^+ \to$ $\phi \ell^+ \nu_\ell / \Gamma(D_s^+ \to \phi \pi^+)$, combined with theoretical predictions for $F = \Gamma(D_s^+ \to \phi \ell^+ \nu_\ell) / \Gamma(D^+ \to \overline{K}^{*0} \ell^+ \nu_\ell)$ and measurements of $B(D^+ \to \overline{K}^{*0}\ell^+\nu_\ell)$ and the relative D_s^+ and D^+ lifetimes. Although we include the measured values of $\Gamma(D_s^+ \to \infty)$ $\phi \ell^+ \nu_\ell / \Gamma(D_s^+ \to \phi \pi^+)$ in the Listings, we no longer use the individual estimates of $B(D_s^+ \to \phi \pi^+)$ since they are each based on different (and sometimes obsolete) estimates of the measured and theoretical correction factors. Here we apply the current best estimates of the correction factors to the current world average, $\Gamma(D_s^+ \to \phi \ell^+ \nu_\ell)/\Gamma(D_s^+ \to \phi \pi^+) = 0.54 \pm 0.05$. When we use the world averages $B(D^+ \to \overline{K}^{*0} \ell^+ \nu_{\ell}) = (4.8 \pm 0.4)\%$ and $\tau(D_s^+)/\tau(D^+) = 0.442 \pm 0.017$, we calculate $B(D_s^+ \to \phi \pi^+)$ to be $(3.9 \pm 0.5)\% \cdot F$. Theoretical estimates for F are near 1.0 with a theoretical uncertainty conservatively estimated to be about 25%. Therefore, this estimate for $B(D_s^+ \to \phi \pi^+)$ is in good agreement with the two new model-independent measurements.

D^+ and D_s^+ decay constants

For the leptonic decays $D^+ \to \ell^+ \nu_\ell$ and $D_s^+ \to \ell^+ \nu_\ell$ only one parameter for each, called the decay constant, is required to describe the nonperturbative physics. (See also the "Note on Pseudoscalar-Meson Decay Constants" in the π^{\pm} Particle Listings.) Decay constants are also used to describe other processes, such as $D^0\overline{D}{}^0$ and $B^0\overline{B}{}^0$ mixing, and hence are quite important. Unfortunately, leptonic decays of heavy mesons have small branching fractions and are difficult to reconstruct. However, observations of leptonic D_s^+ decays have now been published by WA75 (AOKI 93), CLEO II (ACOSTA 94), and BES (BAI 95). The systematic and statistical uncertainties on the D_s^+ decay constant are still large. The branching fractions for leptonic B decays are expected to be so small that observation will not be experimentally feasible for some time. Therefore, as the errors on the D_s^+ decay constant decrease with larger data samples, we would benefit from more theoretical work relating the B decay constant to the more easily measured D^+ and D_s^+ decay constants.

D+ DECAY MODES

 D^- modes are charge conjugates of the modes below

	3 33		C1- f+/
	Mode	Fraction (Γ_i/Γ)	Scale factor/ Confidence level
	inclusiv	ve modes	
Γ1	e ⁺ anything	(17.2 ±1.9) %	
Γ2	K ⁻ anything	(24.2 ±2.8)%	S=1.4
Γ3	\overline{K}^0 anything $+ K^0$ anything	(59 ±7)%	
Γ₄	K ⁺ anything	(5.8 ±1.4)%	
Γ ₅	η anything	[a] < 13 %	CL=90%
Γ ₆	μ^+ anything		
Γ ₇	$\mu^+\mu^-$ anything		
	Leptonic and se	mileptonic modes	
Γ8	$\mu^+ \nu_{\mu}$	< 7.2 × 1	10 ⁻⁴ CL=90%
Г9	$\overline{K}^0 \ell^+ \nu_\ell$	[b] (6.7 ±0.8)%	
Γ ₁₀	$\overline{K}^0 e^+ \nu_e$	$(6.6 \pm 0.9)\%$	
Γ11	$\overline{K}{}^0\mu^+ u_\mu$	$(7.0 \begin{array}{c} +3.0 \\ -2.0 \end{array})\%$	
Γ ₁₂	$K^-\pi^+e^+\nu_e$	(4.2 +0.9) %	
Γ ₁₃	K*(892)0 e+,,	(3.2 ±0.33) %	
' 13	$\overline{K}^*(892)^0 e^+ \nu_e \times B(\overline{K}^{*0} \to K^- \pi^+)$	(3.2 ±0.33) /6	
Γ ₁₄	$K^-\pi^+e^+\nu_e$ nonresonant	< 7 × 1	10 ⁻³ CL=90%
Γ ₁₅	$K^-\pi^+\mu^+\nu_\mu$	(3.2 ±0.4) %	S=1.1
. 15	In the fit as $\frac{2}{3}\Gamma_{27} + \Gamma_{17}$, where		
Γ ₁₆	$\overline{K}^*(892)^0 \mu^+ \nu_{\mu}$	(3.0 ±0.4) %	
. 10	$\times \ B(\overline{K}^{*0} \to K^-\pi^+)$	(5.5 ± 5.1) //	
Γ ₁₇	$\kappa^-\pi^+\mu^+\nu_\mu$ nonresonant	(2.7 ±1.1)×1	10-3
Γ ₁₈	$\overline{K}^0 \pi^+ \pi^- e^+ \nu_e$	(2.1 ±1.1) ~ .	
Γ ₁₉	$K^-\pi^+\pi^0e^+\nu_e$		
Γ ₂₀	$(\overline{K}^*(892)\pi)^0 e^+ \nu_e$	< 1.2 %	CL=90%
Γ ₂₁	$(\overline{K}\pi\pi)^0 e^+ \nu_e \text{ non-} \overline{K}^*(892)$		10 ⁻³ CL=90%
Γ ₂₂	$K^{-}\pi^{+}\pi^{0}\mu^{+}\nu_{\mu}$		10 ⁻³ CL=90%
Γ ₂₃	$\pi^0 \ell^+ \nu_\ell$	[c] (5.7 ±2.2)×1	
Γ ₂₄	$\pi^+\pi^-e^+\nu_e$	[6] (5.7 ±2.2) × 1	10
	Fractions of some of the following appeared above as submodes of par		
Γ_{25}	\overline{K}^* (892) ⁰ $\ell^+ \nu_\ell$	[b] (4.8 \pm 0.4) %	
Γ ₂₆	$\overline{K}^*(892)^0 e^+ \nu_e$	(4.8 \pm 0.5) %	
Γ ₂₇	$\overline{K}^*(892)^0 \mu^+ \nu_{\mu}$	(4.5 \pm 0.6) %	S=1.1
Γ ₂₈	$ ho^0e^+ u_e$		10 ⁻³ CL=90%
Γ ₂₉	$ ho^0 \mu^+ u_\mu$	$(2.0 \ ^{+1.5}_{-1.3}) \times 1$	10-3
Γ ₃₀	$\phi e^+ u_e$	< 2.09 %	CL=90%
Γ_{31}	$\phi \mu^+ \nu_{\mu}$	< 3.72 %	CL=90%
Γ_{32}	$\eta'(958) \mu^+ \nu_{\mu}$	< 9 × 1	10 ⁻³ CL=90%

³ PALKA 87B observes this in $D^+ \to \overline{K}^*(892) e \nu$.

 Γ_{155} A dummy mode used by the fit.

- (36 ± 5) %
- [a] This is a weighted average of D^\pm (44%) and D^0 (56%) branching fractions. See " D^+ and $D^0 \to (\eta \, \text{anything}) / (\text{total } D^+ \, \text{and } D^0)$ " under " D^+ Branching Ratios" in these Particle Listings.
- [b] This value averages the e^+ and μ^+ branching fractions, after making a small phase-space adjustment to the μ^+ fraction to be able to use it as an e^+ fraction; hence our ℓ^+ is really an e^+ .
- [c] ℓ indicates e or μ mode, not sum over modes.
- [d] The branching fractions for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers.
- [e] The two experiments determining this ratio are in serious disagreement. See the Particle Listings.
- [f] This mode is not a useful test for a $\Delta C=1$ weak neutral current because both quarks must change flavor in this decay.
- $[g] \ \mbox{The value}$ is for the sum of the charge states of particle/antiparticle states indicated.

CONSTRAINED FIT INFORMATION

An overall fit to 23 branching ratios uses 37 measurements and one constraint to determine 14 parameters. The overall fit has a $\chi^2=13.8$ for 24 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

D^{\pm} PRODUCTION CROSS SECTION AT $\psi(3770)$

A compilation of the cross sections for the direct production of D^\pm mesons at or near the $\psi(3770)$ peak in e^+e^- production.

VALUE (nanobarns)	DOCUMENT ID	TECN	COMMENT
• • • We do not use the	following data for average	s, fits, limits	, etc. • • •
$4.2 \pm 0.6 \pm 0.3$			3 e ⁺ e [−] 3.768 GeV
5.5 ±1.0	⁶⁴ PARTRIDGE	84 CBAL	e ⁺ e ⁻ 3.771 GeV
$6.00 \pm 0.72 \pm 1.02$			e ⁺ e [−] 3.771 GeV
9.1 ±2.0	⁶⁶ PERUZZI	77 MRK1	. e ⁺ e ⁻ 3.774 GeV

 ⁶³ This measurement compares events with one detected D to those with two detected D mesons, to determine the the absolute cross section. ADLER 88c measure the ratio of cross sections (neutral to charged) to be 1.36 ± 0.23 ± 0.14. This measurement does not include the decays of the ψ(3770) not associated with charmed particle production.
 64 This measurement comes from a scan of the ψ(3770) resonance and a fit to the cross section. PARTRIDGE 84 measures 6.4 ± 1.15 nb for the cross section. We take the phase space division of neutral and charged D mesons in ψ(3770) decay to be 1.33, and we assume that the ψ(3770) is an isosinglet to evaluate the cross sections. The noncharm decays (e.g. radiative) of the ψ(3770) are included in this measurement and may amount to a few percent correction.

 D^{\pm} , D^{0}

65 This measurement comes from a scan of the $\psi(3770)$ resonance and a fit to the cross section. SCHINDLER 80 assume the phase space division of neutral and charged D mesons in $\psi(3770)$ decay to be 1.33, and that the $\psi(3770)$ is an isosinglet. The noncharm decays (e.g. radiative) of the $\psi(3770)$ are included in this measurement and may amount to a few percent correction.
66 This measurement comes from a scan of the $\psi(3770)$ resonance and a fit to the cross section. The phase space division of neutral and charged D mesons in $\psi(3770)$ decay is taken to be 1.33, and $\psi(3770)$ is assumed to be an isosinglet. The noncharm decays (e.g. radiative) of the $\psi(3770)$ are included in this measurement and may amount to a few percent correction. We exclude this measurement from the average because of uncertainties in the contamination from τ lepton pairs. Also see RAPIDIS 77.

 1 PERUZZI 77 and SCHINDLER 81 errors do not include the 0.13% uncertainty in the absolute SPEAR energy calibration. TRILLING 81 uses the high precision $J/\psi(1.5)$ and $\psi(2.5)$ measurements of ZHOLENTZ 80 to determine this uncertainty and combines the PERUZZI 77 and SCHINDLER 81 results to obtain the value quoted. TRILLING 81 enters the fit in the D^\pm mass, and PERUZZI 77 and SCHINDLER 81 enter in the $m_{D^\pm}-m_{D^0}$, below.

² Error does not include possible systematic mass scale shift, estimated to be less than 5

$|m_{D_1^0} - m_{D_2^0}|$

The D_1^0 and D_2^0 are the mass eigenstates of the D^0 meson.

 $\Gamma_{184}~$ A dummy mode used by the fit.

S=

[a] This value is calculated from the ratio $\Gamma(K^-\,\mu^+\,\nu_\mu)/\Gamma(\mu^+\,{\rm anything})$ in these Particle Listings.

 $(23.8 \pm 3.5)\%$

- [b] This is a weighted average of D^\pm (44%) and D^0 (56%) branching fractions. See " D^+ and $D^0 \to (\eta \, \text{anything}) / (\text{total } D^+ \, \text{and } D^0)$ " under " D^+ Branching Ratios" in these Particle Listings.
- [c] This value averages the e^+ and μ^+ branching fractions, after making a small phase-space adjustment to the μ^+ fraction to be able to use it as an e^+ fraction; hence our ℓ^+ is really an e^+ .
- [d] The branching fractions for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers.
- $[\emph{e}]$ The two experiments determining this ratio are in serious disagreement. See the Particle Listings.
- [f] The experiments on the division of this charge mode amongst its submodes disagree, and the submode branching fractions here add up to considerably more than the charged-mode fraction.
- [g] This mode is not a useful test for a $\Delta C=1$ weak neutral current because both quarks must change flavor in this decay.
- [h] The value is for the sum of the charge states of particle/antiparticle states indicated.

CONSTRAINED FIT INFORMATION

An overall fit to 49 branching ratios uses 114 measurements and one constraint to determine 27 parameters. The overall fit has a $\chi^2=60.3$ for 88 degrees of freedom.

The following off-diagonal array elements are the correlation coefficients $\left\langle \delta x_i \delta x_j \right\rangle / (\delta x_i \cdot \delta x_j)$, in percent, from the fit to the branching fractions, $x_i \equiv \Gamma_i / \Gamma_{\text{total}}$. The fit constrains the x_i whose labels appear in this array to sum to

 \Gamma(K^-\pi^+\rho^0 \text{total})/\Gamma(K^-\pi^+\pi^+\pi^-)
          This includes K^- a<sub>1</sub>(1260)<sup>+</sup>, K^*(892)<sup>0</sup> \rho^0, etc. The next entry gives the specifically 39-body fraction. We rely on the MARK III and E691 full amplitude analyses of the K^-\pi^+\pi^+\pi^- channel for values of the resonant substructure.
