(Received 1 June 2005; published 9 August 2005)

We present a measurement of the $t\bar{t}$ production cross section using 194 pb^{-1} of CDF II data using events with a high transverse momentum electron or muon, three or more jets, and missing transverse energy. The measurement assumes 100% $t \rightarrow Wb$ branching fraction. Events consistent with $t\bar{t}$ decay are found by identifying jets containing heavy-flavor semileptonic decays to muons. The dominant backgrounds are evaluated directly from the data. Based on 20 candidate events and an expected background of 9.5 ± 1.1 events, we measure a production cross section of $5.3 \pm 3.3_{-1.0}^{+1.3}$ pb, in agreement with the standard model.

I. INTRODUCTION

Top quark pair production in the standard model proceeds via either quark-antiquark annihilation or gluon-gluon fusion. At the Fermilab Tevatron collider, with a center-of-mass energy of 1.96 TeV, quark-antiquark annihilation is expected to dominate. For a top mass of

$175 \text{ GeV}/c^2$, the calculated cross section is $6.7_{-0.9}^{+0.7}$ pb [1], and is approximately 0.2 pb smaller for each $1 \text{ GeV}/c^2$ increase in the value of the top mass over the range $170 \text{ GeV}/c^2 < M_{\text{top}} < 190 \text{ GeV}/c^2$.

Measurements of the cross section for top quark pair production provide a test of QCD, as well as the standard

model decay $t \rightarrow Wb$. Nonstandard model production mechanisms, such as the production and decay of a heavy resonance into $t\bar{t}$ pairs [2], could enhance the measured cross section. Nonstandard model top quark decays, such as the decay into supersymmetric particles [3], could suppress the measured value, for which a $t \rightarrow Wb$ branching fraction of nearly 100% is assumed.

In this paper we report a measurement of the $t\bar{t}$ production cross section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV with the CDF II detector at the Fermilab Tevatron. The standard model decay $t \rightarrow Wb$ of the top quark results in a final state from $t\bar{t}$ production of two W bosons and two bottom quarks. We select events consistent with a decay of one of the W bosons to an electron or muon plus a neutrino, both of which have large momentum transverse to the beam direction (P_T). We refer to these high P_T electrons or muons as the “primary lepton.” The neutrino is undetected and results in an imbalance in transverse momentum. The imbalance is labeled “missing E_T ” (\cancel{E}_T) since it is reconstructed based on the flow of energy in the calorimeter [4]. The other W boson in the event decays to a pair of quarks. The two quarks from the W boson and the two b quarks from the top decays hadronize and are observed as jets of charged and neutral particles. This mode is referred as W plus jets. We take advantage of the semileptonic decay of b hadrons to muons to identify final-state jets that result from hadronization of the bottom quarks. Such a technique, called “soft-lepton tagging” (SLT), is effective in reducing the background to the $t\bar{t}$ signal from W boson produced in association with several hadronic jets with large transverse momentum. The production cross section is measured in events with three or more jets and at least one SLT tagged jet.

This measurement is complementary to other measurements from CDF II, which use secondary vertex tagging, kinematic fitting, or a combination of the two [5–7]. A forthcoming paper [8] will present a combined cross section measurement based on the result of these four analyses.

Previous measurements [9] from run I at the Tevatron have measured production cross sections statistically consistent with the standard model prediction. This and other run II measurements are made at a slightly higher center-of-mass energy (1.96 TeV vs 1.8 TeV) and with nearly twice as much integrated luminosity.

The organization of this paper is as follows: Section II reviews the detector systems relevant to this analysis. The trigger and event selection, the data and the Monte Carlo samples and the SLT tagging algorithm are described in Sec. III. The estimate of the background is presented in Sec. IV. The acceptance and the $t\bar{t}$ event tagging efficiency are described in Sec. V. The evaluation of the systematic uncertainties on the measurement is presented in Sec. VI. The $t\bar{t}$ production cross section measurement and the conclusions are presented in Secs. VII and VIII.

II. THE CDF II DETECTOR

The CDF II detector is described in detail in [10], only the components relevant to this measurement are summarized here. The CDF II detector is a nearly azimuthally and forward-backward symmetric detector designed to study $p\bar{p}$ interactions at the Fermilab Tevatron. It consists of a magnetic spectrometer surrounded by calorimeters and muon chambers. An elevation view of the CDF II detector is shown in Fig. 1.

Charged particles are tracked inside a 1.4 T solenoidal magnetic field by an 8-layer silicon strip detector covering radii from 1.5 to 28 cm, followed by the central outer tracker (COT), an open-cell drift chamber that provides up to 96 measurements of charged-particle position over the radial region from 40 to 137 cm. The 96 COT measurements are arranged in 8 “superlayers” of 12 sense wires each alternating between axial and 2° stereo. The COT and the silicon detectors track charged particles for $|\eta| < 1$ and $|\eta| < 2$, respectively.

Surrounding the tracking system are electromagnetic and hadronic calorimeters, used to measure charged and neutral particle energies. The electromagnetic calorimeter is a lead-scintillator sandwich and the hadronic calorimeter is an iron-scintillator sandwich. Both calorimeters are segmented in azimuth and polar angle to provide directional information for the energy deposition. The segmentation varies with position on the detector and is 15° in azimuth by 0.1 units of η in the central region ($|\eta| < 1.1$). Segmentation in the plug region ($1.1 < |\eta| < 3.6$) is 7.5° up to $|\eta| < 2.1$, and 15° for $|\eta| > 2.1$ in azimuth, while ranging from 0.1 to 0.64 units of η in pseudorapidity (a nearly constant 2.7° change in polar angle). The electromagnetic calorimeters are instrumented with proportional and scintillating strip detectors that measure the transverse profile of electromagnetic showers at a depth corresponding to the shower maximum.

Outside the central calorimeter are four layers of muon drift chambers covering $|\eta| < 0.6$ (CMU). The calorimeter provides approximately 1 m of steel shielding. Behind an additional 60 cm of steel in the central region sit an additional four layers of muon drift chambers (CMP) arranged in a box-shaped layout around the central detector. Central muon extension (CMX) chambers, which are arrayed in a conical geometry, provide muon detection for the region $0.6 < |\eta| < 1$ with four to eight layers of drift chambers, depending on polar angle. All the muon chambers measure the coordinates of hits in the drift direction, x , via a drift time measurement and a calibrated drift velocity. The CMU and the CMX also measure the longitudinal coordinate, z . The longitudinal coordinate is measured in the CMU by comparing the height of pulses, encoded in time-over-threshold, at opposite ends of the sense wire. In the CMX, the conical geometry provides a small stereo angle from which the z coordinate of track segments can be determined. Reconstructed track

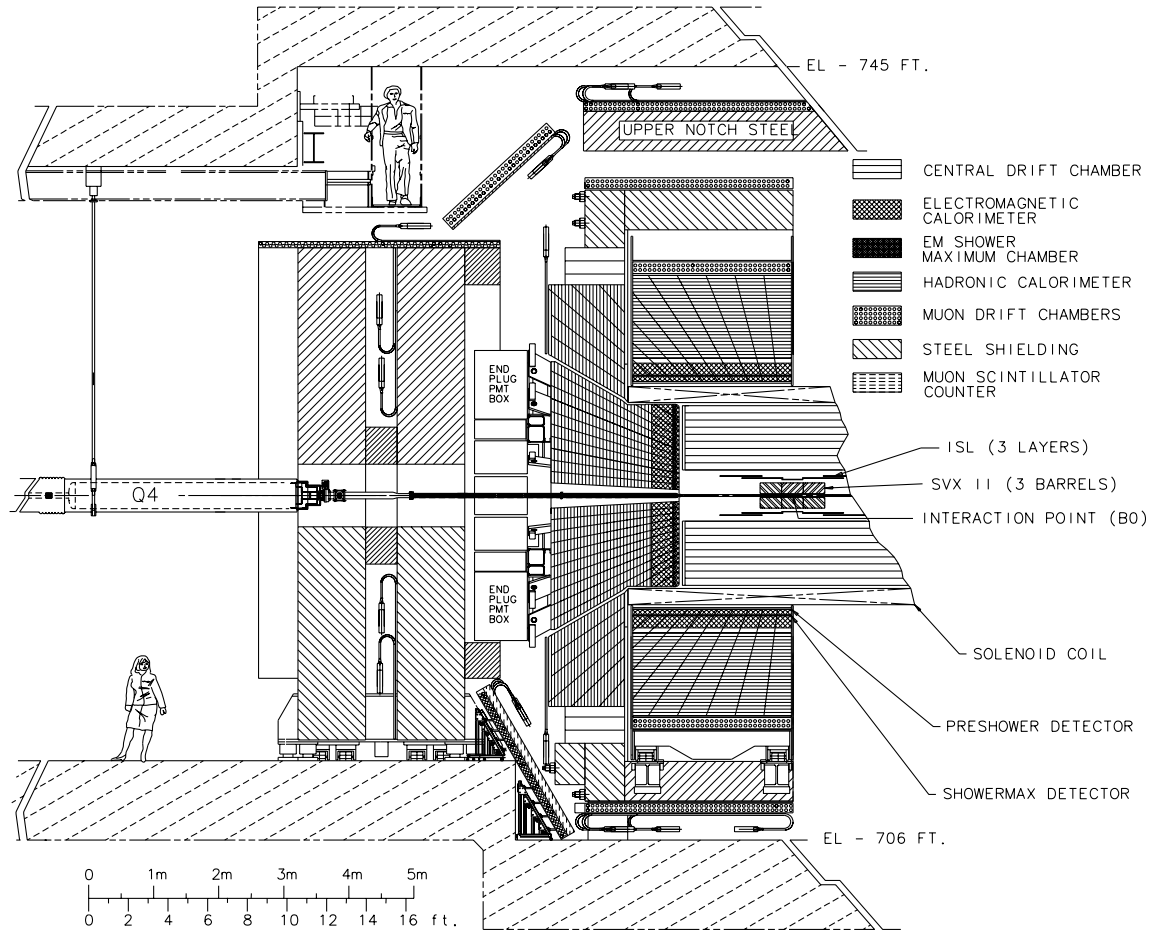

FIG. 1. Elevation view of the CDF II detector.

segments have a minimum of three hits, and a maximum of four hits in the CMU and the CMP, and 8 hits in the CMX.

III. DATA SAMPLE AND EVENT SELECTION

In this section we describe the collision data and the Monte Carlo samples used in this analysis. Section III A outlines the trigger system used for the initial selection of events from the $p\bar{p}$ collisions. Section III B describes the Monte Carlo samples used for acceptance and background studies. The selection of the $W + \text{jets}$ data sets from the triggered data samples is presented in Sec. III C. The $t\bar{t}$ signal is extracted from the $W + \text{jets}$ events through the identification of candidate b hadron semileptonic decays to muons. The algorithm for identifying these decays is summarized in Sec. III D, and its application to the $W + \text{jets}$ data set is described in Sec. III E.

This analysis is based on an integrated luminosity of $194 \pm 11 \text{ pb}^{-1}$ [11] collected with the CDF II detector between March 2002 and August 2003 (175 pb^{-1} with the CMX detector operational).

A. $p\bar{p}$ collision data

CDF II employs a three-level trigger system, the first two consisting of special purpose hardware and the third consisting of a farm of commodity computers. Triggers for this analysis are based on selecting high transverse momentum electrons and muons. The electron sample is triggered as follows: At the first trigger level events are selected by requiring a track with $P_T > 8 \text{ GeV}/c$ matched to an electromagnetic calorimeter tower with $E_T > 8 \text{ GeV}$ and little energy in the hadronic calorimeter behind it. At the second trigger level, calorimeter energy clusters are assembled and the track found at the first level is matched to an electromagnetic cluster with $E_T > 16 \text{ GeV}$. At the third level, offline reconstruction is performed and an electron candidate with $E_T > 18 \text{ GeV}$ is required. The efficiency of the electron trigger is measured from $Z \rightarrow ee$ data and found to be $(96.2 \pm 0.6)\%$ [12]. The selection of the muon sample begins at the first trigger level with a track with $P_T > 4 \text{ GeV}/c$ matched to hits in the CMU and the CMP chambers or a track with $P_T > 8 \text{ GeV}/c$ matched to hits in the CMX chambers. At the second level, a track with $P_T > 8 \text{ GeV}/c$ is required in the event for about 70% of the integrated luminosity, while for the remainder, trig-

gers at the first level are fed directly to the third level. At the third trigger level, a reconstructed track with $P_T > 18$ GeV/ c is required to be matched to the muon chamber hits. The efficiency of the muon trigger, measured from $Z \rightarrow \mu\mu$ data, is $(88.7 \pm 0.7)\%$ for CMU/CMP muons and $(95.4 \pm 0.4)\%$ for CMX muons [12].

B. Monte Carlo data sets

The detector acceptance of $t\bar{t}$ events is modeled using PYTHIA v6.2 [13] and HERWIG v6.4 [14]. These are leading-order event generators with parton showering to simulate radiation and fragmentation effects. The generators are used with the CTEQ5L parton distribution functions [15]. Decays of b and c hadrons are modeled using QQ v9.1 [16]. Estimates of backgrounds from diboson production (WW , WZ , ZZ) are derived using the ALPGEN generator [17] with parton showering provided by HERWIG. The background from single top production (e.g. $W^* \rightarrow t\bar{b}$) is simulated using PYTHIA. Samples of the remaining backgrounds are derived directly from the data as described in Sec. IV.

The detector simulation reproduces the response of the detector to particles produced in $p\bar{p}$ collisions. The same detector geometry database is used in both the simulation and the reconstruction, and tracking of particles through matter is performed with GEANT3 [18]. The drift model for the COT uses a parametrization of a GARFIELD simulation [19] with parameters tuned to match COT collider data. The calorimeter simulation uses the GFLASH [20] parametrization package interfaced with GEANT3. The GFLASH parameters are tuned to test beam data for electrons and high- P_T pions and checked by comparing the calorimeter energy of isolated tracks in the collision data to their momenta as measured in the COT. Further details of the CDF II simulation can be found in [21].

C. $W + \text{jets}$ data set

From the inclusive lepton data set produced by the electron and muon triggers described in Sec. III A, we select events with an isolated lepton E_T (muon P_T) greater than 20 GeV and $\cancel{E}_T > 20$ GeV. The isolation I of the electron or muon is defined as the calorimeter transverse energy in a cone of $\Delta R \equiv \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.4$ around the lepton (not including the lepton energy itself) divided by the E_T (P_T) of the lepton. We require $I < 0.1$. The $W + \text{jets}$ data set is categorized according to the number of jets with $E_T > 15$ GeV and $|\eta| < 2.0$. The decay of $t\bar{t}$ pairs gives rise to events with typically at least three such jets, while the W plus one or two jet samples provide a control data set with little signal contamination. Jets are identified using a fixed-cone algorithm with a cone size of 0.4 and are constrained to originate from the $p\bar{p}$ collision vertex. Their energies are corrected to account for detector response variations in η , calorimeter gain instability, and multiple interactions in an event. A

FIG. 2 (color online). H_T distributions, normalized to unity, for $t\bar{t}$ (solid line) and $W + \text{jets}$ (dotted line) PYTHIA Monte Carlo events with three or more jets after the event selection described in the text.

complete description of $W + \text{jets}$ event selection is given in [6].

The $W + \text{jets}$ data set consists mainly of events of direct production of W bosons with multiple jets. This amounts also to the largest background to $t\bar{t}$ signal. As a first stage of background reduction, we define a total event energy, H_T , as the scalar sum of the electron E_T or muon P_T , the event \cancel{E}_T and jet E_T for jets with $E_T > 8$ GeV and $|\eta| < 2.4$. Because of the large mass of the top quark, a $t\bar{t}$ event is expected to have a large H_T compared to a W plus three or more jets event, as illustrated in Fig. 2. We studied the expected amount of signal (S) and background (B) as a function of H_T using the PYTHIA Monte Carlo program to model the signal H_T distribution. Data is used to model the background H_T distribution. We optimized the selection of events by imposing a minimum H_T requirement which maximizes $S/\sqrt{S+B}$. We select events with $H_T > 200$ GeV, rejecting approximately 40% of the background while retaining more than 95% of the $t\bar{t}$ signal.

There are 337 W plus three or more jet events with $H_T > 200$ GeV in 194 pb^{-1} of data, 115 from $W \rightarrow \mu\nu$ candidates and 222 from $W \rightarrow e\nu$ candidates.

Even after the H_T cut, the expected $S:B$ in W plus three or more jet events is only of order 1:3. To further improve the signal to background ratio, we identify events with one or more b -jets by searching inside jets for semileptonic decays of b hadrons into muons.

D. Soft lepton tagging algorithm

Muon identification at CDF proceeds by extrapolating tracks found in the central tracker, through the calorimeter to the muon chambers, and matching them to track segments reconstructed in the muon chambers. Matching is done in the following observables: extrapolated position

along the muon chamber drift direction (x), the longitudinal coordinate along the chamber wires (z) when such information is available, and the extrapolated slope compared to the slope of the reconstructed muon chamber track segment (ϕ_L). Tracks are paired with muon chamber track segments based on the best match in x for those track segments that are within 50 cm of an extrapolated COT track. In what follows we refer to the difference between the extrapolated and measured positions in x and z as dx and dz , respectively, and the extrapolated and measured slope as $d\phi_L$. The distributions of these variables over an ensemble of events are referred to as the matching distributions. In addition to selection based on dx and dz , the standard muon identification also requires consistency with minimum ionizing energy deposition in the calorimeters. However, in order to retain sensitivity for muons embedded in jets, the muon SLT algorithm makes full usage of the muon matching information without any requirement on the calorimeter information. The algorithm starts with high-quality reconstructed tracks in the COT, selected by requiring at least 24 axial and 24 stereo hits on the track. Some rejection for pion and kaon decays in flight is achieved by requiring that the impact parameter of the reconstructed track be less than 3 mm with respect to the beam line. The track is also required to originate within 60 cm in z of the center of the detector. Only tracks passing these cuts and extrapolating within $3\sigma(P_T)$ in x outside of the muon chambers, where $\sigma(P_T)$ is the multiple scattering width, are considered as muon candidates. Also, when a track extrapolates to greater than $3\sigma(P_T)$ in x inside the muon chambers, but no muon chamber track segment is found, the track is rejected and not allowed to be paired to other muon chamber track segments.

Candidate muons are selected with the SLT algorithm by constructing a quantity L , based on a comparison of the measured matching variables with their expectations. To construct L we first form a sum, Q , of individual χ^2 variables

$$Q = \sum_{i=1}^n \frac{(X_i - \mu_i)^2}{\sigma_i^2}, \quad (1)$$

where μ_i and σ_i are the expected mean and width of the distribution of matching variable X_i . The sum is taken over n selected variables, as described below. L is then constructed by normalizing Q according to

$$L = \frac{(Q - n)}{\sqrt{\text{var}(Q)}}, \quad (2)$$

where the variance $\text{var}(Q)$ is calculated using the full covariance matrix for the selected variables. The normalization is chosen to make L independent of the number of variables n ; note that the distribution of L tends to a

Gaussian centered at zero and with unitary width, for n sufficiently large. The correlation coefficients between each pair of variables are measured from $J/\psi \rightarrow \mu\mu$ data. The calculation proceeds by comparing the variance of the sum with the sum of the variances of each pair of χ^2 variables in Eq. (1). Since the values of the matching variables are either positive or negative, according to the local coordinate system, separate correlation coefficients are used for pairs that have same-sign and opposite-sign values.

The selected variables are the full set of matching variables, x, z, ϕ_L in the CMU, CMP and CMX with the following two exceptions: The CMP chambers do not provide a measurement of the longitudinal coordinate z , and matching in ϕ_L is not included for track segments in the muon chambers that have only three hits. Because of their significantly poorer resolution, track segments reconstructed in the CMU chambers with three hits are not used. Note that a muon that traverses both the CMU and the CMP chambers yields two sets of matching measurements in x and ϕ_L and one z matching measurement, and are referred as CMUP muons. All available matching variables are used in the calculation of L for a given muon candidate. By placing an appropriate cut on L , background is preferentially rejected because hadrons have broader matching distributions than muons since the track segments in the muon chambers from hadrons are generally a result of leakage of the hadronic shower.

The widths of the matching distributions that enter into L are a combination of intrinsic resolution of the muon chambers and multiple scattering. The multiple scattering term varies inversely with P_T and is dominant at low P_T . The expected widths of the matching distributions are based on measurements of muons from J/ψ decays at low P_T (see Fig. 3) and W and Z boson decays at high P_T .

The mean values [μ_i in Eq. (1)] are typically zero, except for a small offset in the CMU dz . We parametrize the widths as a function of up to three variables: P_T , η and ϕ . These variables describe to first order the effects of multiple scattering in the detector. For the CMU detector, P_T is sufficient since the material traversed by a muon candidate is approximately homogenous in η and ϕ . The widths are parametrized with a second-order polynomial in $1/P_T$ with an exponential term that describes the P_T range below 3 GeV/ c . For the CMP detector we parametrize the widths as functions of P_T and ϕ to take into account the rectangular shape of the absorber outside the central calorimeter. For the CMX detector we use P_T , η and ϕ to account for a number of irregularities in the amount of absorber between $\eta = 0.6$ and $\eta = 1.0$. The measurement of the widths of the matching distributions as functions of P_T , overlaid with their fits, are shown in Fig. 4.

Figure 5 (left) shows an example of the distribution of L from J/ψ decays. The number of variables used varies from two to five. Figure 5 (right) shows the efficiency of

FIG. 3 (color online). Examples of muon matching distributions for the CMU in (left to right) drift direction, x , the longitudinal coordinate, z , and angle, ϕ_L . For each variable we show two P_T ranges, $2.5 \leq P_T \leq 3$ GeV/ c (wide distribution) and $5 \leq P_T \leq 6$ GeV/ c (narrow distribution). For the longitudinal coordinate z , we plot the product of dz by $\sin\theta$, which is the projection orthogonal to the direction of flight.

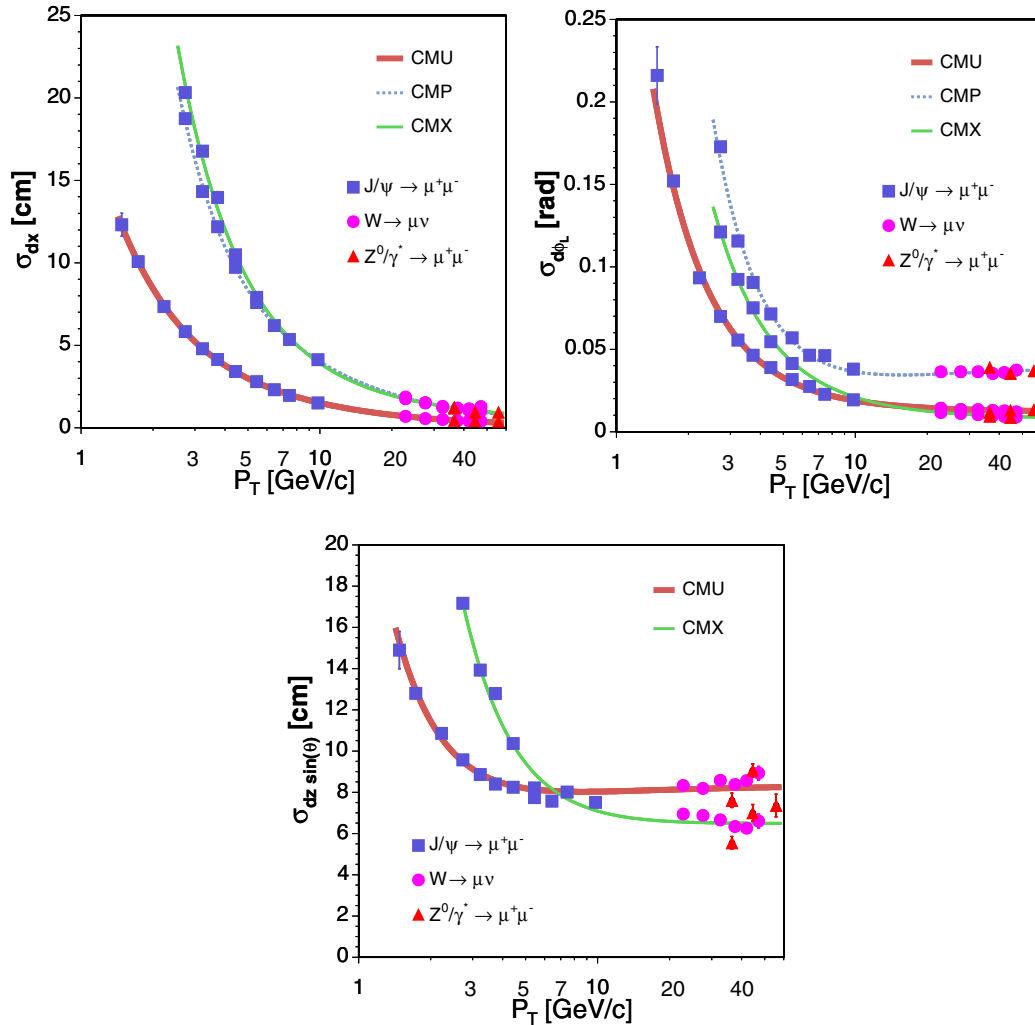

FIG. 4 (color online). Width of the matching variable distributions (dx , $dz \sin\theta$, $d\phi_L$) vs P_T for each of the muon chambers. The data points, from J/ψ , W and Z decays, are fit to the parametrizations described in the text.

the SLT algorithm as a function of L from J/ψ data. The efficiency plateaus at about 85% for $|L| \geq 3.5$.

E. Event tagging

In this analysis we seek to identify semileptonic decays of b hadrons inside jets in $t\bar{t}$ events. The transverse momentum spectrum of these muons, covering a broad range from a few GeV/c to over $40 \text{ GeV}/c$, is shown in Fig. 6 from the PYTHIA Monte Carlo sample. Within the W + jets data set defined in Sec. III C, we isolate a subset of events with at least one “taggable” track. A taggable track is defined as any track, distinct from the primary lepton, passing the track quality requirements described in Section III D, with $P_T > 3 \text{ GeV}/c$, within $\Delta R < 0.6$ of a jet axis and pointing to the muon chambers to within a 3σ multiple scattering window (the σ of the multiple scattering window is defined as the σ_{dx} shown in Fig. 3). The

FIG. 6 (color online). P_T distribution of muons from b hadron decays in PYTHIA Monte Carlo top events. The circles are all muons from b hadron decays. The triangles are direct $B \rightarrow \mu\nu X$ decays and the squares are sequential $B \rightarrow D \rightarrow \mu\nu X$ (where “ B ” indicates a b hadron).

z -coordinate of the track at the origin must be within 5 cm of the reconstructed event vertex (the vertex reconstruction is described in detail in [5]). Jets are considered “SLT tagged” if they contain a taggable track, which is also attached to a track segment in the muon chambers and the resulting muon candidate has $|L| < 3.5$.

A potentially large background arises from J/ψ decay and sequential, double semileptonic $b \rightarrow c \rightarrow s$ decay, resulting in one lepton from the b decay and an oppositely charged lepton from the c decay. Therefore, events are rejected if the primary lepton is of opposite charge to a SLT muon tag and the invariant mass of the pair is less than $5 \text{ GeV}/c^2$. Similarly, events are also rejected if the primary lepton is a muon that together with an oppositely charged SLT muon tag forms an invariant mass between 8 and $11 \text{ GeV}/c^2$ or 70 and $110 \text{ GeV}/c^2$, consistent with an Y or a Z particle, respectively. The sequential decay cut and the Y and Z removal reduce the $t\bar{t}$ acceptance by less than 1%.

Events passing all event selection cuts that have at least one taggable track are referred to as the “pretag” sample. There are 319 pretag events with three or more jets, 211 in which the primary lepton is an electron and 108 in which it is a muon. Out of these events we find 20 events with a SLT tag, 15 in which the primary lepton is an electron and 5 in which it is a muon. This set of events is the $t\bar{t}$ candidate sample from which we measure the $t\bar{t}$ production cross section in Sec. VII.

IV. BACKGROUNDS

In this section we describe the evaluation of background events in the $t\bar{t}$ candidates sample. The background contributions are mostly evaluated directly from the data. The dominant background in this analysis is from W plus jets events where one jet produces an SLT tag. The estimate of this background relies on our ability to predict the number of such SLT tags starting from the pretag sample. The

prediction is based on the probability for a given track in a jet to yield an SLT tag, and is measured in $\gamma + \text{jets}$ events. We then evaluate the systematic uncertainty on the $W + \text{jets}$ background estimate by testing the predictive power of the measured probabilities in a variety of data samples. The $W + \text{jets}$ background evaluation and its systematic uncertainty is described in Sec. IVA. After $W + \text{jets}$ production, the next largest background is due to QCD multijet events. The evaluation of the QCD multijet contribution also relies on tagging probabilities measured in $\gamma + \text{jets}$ events. However, we must account for the possible difference between the tagging probabilities for the QCD events that populate the $t\bar{t}$ candidate sample because the \cancel{E}_T often comes from a mismeasured jet and not from a neutrino. The evaluation of the QCD background is described in Sec. IV B. An additional small source of background is due to Drell-Yan events and is estimated from the data and described in Sec. IV C. The remaining background contributions are relatively small and are evaluated using Monte Carlo samples, as described in Sec. IV D.

A. Backgrounds from $W + \text{jets}$

W plus jets events enter the signal sample either when one of the jets is a b -jet or a c -jet with a semileptonic decay to a muon, or a light quark jet is misidentified as containing a semileptonic decay (“mistagged”). We refer to these background events as $W + \text{heavy flavor}$ and $W + \text{“fakes”}$, respectively. $W + \text{heavy flavor}$ events include $Wb\bar{b}$, $Wc\bar{c}$ and Wc production. One way of estimating

these backgrounds would be to use a Monte Carlo program, such as ALPGEN to predict the $W + \text{heavy flavor}$ component, and the data to predict the $W + \text{fakes}$ (because the data provides a more reliable measure of mistags than the simulation). However, to avoid double-counting, this would require an estimate of mistags that is uncontaminated by tags from heavy flavor. Instead we have chosen to estimate both background components directly from the data, and we test the accuracy of the prediction as described below. We measure the combined $W + \text{heavy flavor}$ and $W + \text{fakes}$ background by constructing a “tag matrix” that parametrizes the probability that a taggable track with a given P_T , η and ϕ , in a jet with $E_T > 15$ GeV, will satisfy the SLT tagging requirement described in Sec. III E. The variables η and ϕ are measured at the outer radius of the COT with respect to the origin of the CDF II coordinate system. The tag matrix is constructed using jets in $\gamma + \text{jets}$ events with one or more jets. The tag probability is approximately 0.7% per taggable track, and includes tags from both fakes and heavy flavor. The tag rate as a function of each of the matrix parameters (integrated over the remaining two) is shown in Fig. 7. The features in the tag rate vs η and ϕ plots are a result of calorimeter gaps and changes in the thickness of the absorber before the muon chambers. The matrix is binned to take account of these variations. The bottom right plot shows the tag rate as the function of the $|L|$ cut for each muon category. The tag rate is higher for the CMP-only muons due to the smaller amount of absorber material that results from cracks in the

FIG. 7. Tag rates in the photon plus jets sample as a function of each of the tag-rate matrix parameters. Each plot is integrated over the two parameters not shown. The bottom right plot shows the tag rate as the function of the $|L|$ cut for each of the muon categories.

TABLE I. Number of tagged events and the background summary. The $H_T > 200$ GeV requirement is made only for events with at least 3 jets.

Background	$W + 1$ jet	$W + 2$ jets	$W + 3$ jets	$W + \geq 4$ jets	$W + \geq 3$ jets
Pretag events	9117	2170	211	108	319
Fake, $Wb\bar{b}$, $Wc\bar{c}$, Wc	116.3 ± 11.6	40.5 ± 4.1	7.0 ± 0.7	4.3 ± 0.4	11.3 ± 1.1

Tagged events	139	48	13	7	20

calorimeter where there is no coverage by the CMU chambers.

We apply the tag matrix to all pretag events in the signal region according to

$$N_{\text{predicted}}^{\text{tag}} = \sum_{\text{events}} \left[1 - \prod_{i=1}^{N_{\text{trk}}} (1 - \mathcal{P}_i) \right], \quad (3)$$

where the sum runs over each event in the pretag sample, and the product is over each taggable track in the event. \mathcal{P}_i is the probability from the tag matrix for tagging the i -track with parameters P_{T_i} , η_i and ϕ_i . Note that the sum over the events in Eq. (3) includes any $t\bar{t}$ events that are in the pretag sample. We correct for the resulting overestimate of the background at the final stage of the cross section calculation, since the correction depends on the measured tagging efficiency (see Sec. VII).

A fraction, F_{QCD} , of the events in the signal region are QCD events (such as $b\bar{b}$ or events in which a jet fakes an isolated lepton, see Sec. IV B) for which the background is estimated separately. Therefore, we explicitly exclude their contribution to $N_{\text{predicted}}^{\text{tag}}$ and obtain the predicted number of tagged $W + \text{jets}$ background events

$$N_{\text{predicted}}^{Wj\text{-tag}} = (1 - F_{\text{QCD}}) \cdot N_{\text{predicted}}^{\text{tag}}. \quad (4)$$

The estimated $W + \text{fakes}$ and $W + \text{heavy flavor}$ background is given in the third line of Table I.

The above technique relies on the assumption that the tagging rate in jets of the $\gamma + \text{jets}$ sample is a good model for the tagging rate of the jets in $W + \text{jets}$ events. The assumption is plausible because the SLT tagging rate in generic jet events is largely due to fakes. We have studied the heavy-flavor content of the tags in the $\gamma + \text{jets}$ sample using the overlap sample between SLT tags and displaced vertex tags identified with the silicon tracker [5]. We find that $(21.0 \pm 1.4)\%$ of the tags in the $\gamma + \text{jets}$ sample are from heavy flavor. We have used MADEVENT [22] to do

generator-level comparisons of the heavy-flavor fractions of $W + \text{jets}$ events with those from the $\gamma + \text{jets}$ events that make up the tag matrix. We find that the $\gamma + \text{jets}$ sample used to make the tag matrix has approximately 30% more heavy flavor than the $W + \geq 3$ jet events. Since SLT tags in $\gamma + \text{jets}$ events are dominantly fakes, this difference affects the background prediction in $W + \text{jets}$ events at only the few-percent level.

FIG. 8. The percent difference between the number of predicted and measured tags in a variety of samples for different jet multiplicities, as marked. Jet multiplicities do not include the trigger object (photon or jet). The three photon points contain the events that make up the tag matrix. Their average is zero by definition and is shown by the line centered at zero. The dashed lines at $\pm 10\%$ indicate the systematic uncertainty as determined from these data.

Given the limitations of a generator-level, matrix element Monte Carlo study of the heavy flavor content of the γ + jets and W + jets samples, we do not use the MADEVENT study to evaluate the systematic uncertainty on the background due to tagged W + jets events. Instead we test the accuracy of the tag matrix for predicting SLT muon tags by using it to predict the number of tags in a variety of samples with different heavy-flavor content. We check Z plus jets events, events triggered on a jet with E_T thresholds of 20, 50, 70 and 100 GeV (called Jet 20, Jet 50, Jet 70 and Jet 100), or triggered on four jets and the scalar sum of transverse energy in the detector (called SumET). We find that the matrix predicts the observed number of tags in each of these samples to within 10%, as shown in Fig. 8, and we use this as the systematic uncertainty on the prediction from the tag matrix.

B. QCD background

We refer to events with two or more jets in which the decay of a heavy-flavor hadron produces a high- P_T isolated lepton, or in which a jet fakes such a lepton, as QCD events. These events enter the sample when, in addition to the high- P_T isolated lepton, a muon from a heavy-flavor decay gives an SLT tag, or there is a fake tag. We measure this background directly from the data.

To estimate the QCD component we first use the distribution of pretag events in the plane of \cancel{E}_T vs isolation, I , of the primary lepton. We populate this plane with lepton plus jets events according to the event \cancel{E}_T and I . We consider four regions in the plane:

$$\begin{aligned} \text{A: } \cancel{E}_T < 15 \quad I > 0.2 & \quad \text{B: } \cancel{E}_T < 15 \quad I < 0.1 \\ \text{C: } \cancel{E}_T > 20 \quad I > 0.2 & \quad \text{D: } \cancel{E}_T > 20 \quad I < 0.1 \end{aligned}$$

where region D is the $t\bar{t}$ signal region. The distribution of events, with one or more jets, in the \cancel{E}_T vs I regions is shown in Fig. 9.

In order to populate regions A, B and C with only QCD events, we correct the number of events for the expected contamination of W + jets and $t\bar{t}$ events in those regions using expectations from PYTHIA $t\bar{t}$ and W Monte Carlo simulations. The corrections range from less than 1% in electron plus one-jet events in region A, to $(57 \pm 15)\%$ in muon plus three or more jet events.

Assuming that the variables \cancel{E}_T and I are uncorrelated for the QCD background, the ratio of the number of QCD events in region A to those in region B should be the same as the ratio of the number of QCD events in region C to those in region D. Therefore we calculate the fraction of QCD events in region D, F_{QCD} , as

$$F_{\text{QCD}} = \frac{N_D^{\text{QCD}}}{N_D} \Bigg|_{\text{pretagged}} = \frac{N_B \cdot N_C}{N_A \cdot N_D} \Bigg|_{\text{pretagged}}, \quad (5)$$

where N_D^{QCD} is the total number of pretag QCD events in

FIG. 9 (color online). Distribution of events with ≥ 1 jet in \cancel{E}_T vs I . Regions A,B,C are defined in the text and are used to calculate the fraction of QCD events in region D (the signal region) according to Eq. (5).

the signal region, and N_i represent the number of events in region i . The measured fractions are shown in Table II.

To estimate the number of tagged QCD events in the signal region, we multiply F_{QCD} by the tagging probability for QCD events. However, this tagging probability is not necessarily given by the tag matrix probabilities which are designed for jets in W + jets events. Mismeasurement in the jet energies and differences in kinematics between W + jets and QCD events can affect the tagging probabilities. W + jets events have \cancel{E}_T from the undetected neutrino, whereas QCD events have \cancel{E}_T primarily from jet mismeasurement. Jet mismeasurement is correlated with fake tags due to energy leakage from the calorimeter through calorimeter gaps or incomplete absorption of the hadronic shower, both of which can result in track segments in the muon chambers. W + jets events have a primary lepton from the W decay, whereas QCD events have a primary lepton that is either a fake or a result of a semileptonic decay of heavy flavor. The presence of a lepton from heavy-flavor decay typically enhances the tag rate. Figure 10 shows the ratio of the number of measured tags in the Jet 20 sample to the number of tags predicted by the tag matrix as a function of \cancel{E}_T . As expected, in QCD events with large \cancel{E}_T we find a tag rate significantly larger than that described by the tag matrix.

We find that the prediction of the tag matrix can be renormalized to properly account for the tag rates in QCD events with a single multiplicative factor, which we call k . We measure k using events in region C by comparing the number of SLT tags found to the number predicted by the tag matrix. Since the signal region contains only isolated ($I < 0.1$) primary leptons, we reject events in the measurement of k in which the SLT tag is within $\Delta R < 0.5$ of the primary lepton. After this requirement we do not find

TABLE II. QCD fraction, given by Eq. (5), and the H_T -averaged product of k and the QCD fraction.

Jet multiplicity	1 jet	2 jet	3 jets	≥ 4 jets	≥ 3 jets
Muons

$\langle k_e \cdot F_{\text{QCD}} \rangle$	0.24 ± 0.31	0.41 ± 0.12	0.16 ± 0.046	0.20 ± 0.07	0.17 ± 0.04

any dependence of k on the isolation of the primary lepton. Figure 11 shows the ratio of measured to predicted tags in events in region C as a function of H_T . The tag rate above $H_T = 200$ GeV is approximately flat and is not much different from the prediction of the tag matrix (dashed line in Fig. 11). However, QCD events at lower H_T have a significantly different tag rate than that predicted by the tag matrix. As shown in Fig. 12, F_{QCD} also has an H_T dependence for events with 1 or 2 jets, but is flat within the statistical uncertainty for three or more jets.

The number of QCD background events is calculated as

$$N_{\text{QCD}} = \langle F_{\text{QCD}} \cdot k \rangle \cdot N_{\text{predicted}}^{\text{tag}}, \quad (6)$$

where $N_{\text{predicted}}^{\text{tag}}$ is given in Eq. (3) and the brackets represent the product of F_{QCD} and k convoluted with the H_T distribution of QCD events from region C. In the control region (1 and 2 jets), the fits of F_{QCD} vs H_T , shown in Fig. 12, are convoluted with k vs H_T , shown in Fig. 11. For events with three or more jets, since there is no visible H_T dependence for either F_{QCD} or k , we simply multiply their average values for $H_T > 200$ GeV. Measured values of k times F_{QCD} are given in Table II. The procedure by which F_{QCD} is determined as a function of H_T is important

FIG. 10. The ratio of the number of observed tags to tags predicted using the tag matrix, as a function of \cancel{E}_T , in events with at least one jet with measured energy above 20 GeV.

because the ratios between the four different regions of the \cancel{E}_T and I kinematic plane, calculated in separate ranges of H_T and then averaged, does not necessarily correspond to the same ratios taken while integrating over the full H_T range. The uncertainties on the 1 and 2 jet events are conservatively taken as the difference between the central value and the result of the straight product of F_{QCD} and k . The straight product corresponds to ignoring the H_T dependence as well as any other variable's dependence of F_{QCD} and k .

C. Drell-Yan background

Drell-Yan events can enter the sample when they are produced with jets and one muon is identified as the primary muon while the second muon is close enough to a jet to be tagged. Residual Drell-Yan background that is not removed by the dimuon and sequential decay rejection described in Sec. III E, is estimated from the data. We use events inside the Z-mass window ($76-106$ GeV/ c^2), which are otherwise removed from the analysis by the Z-mass cut, to measure the number of events that would pass all our selection requirements including the SLT tag, $N_{\text{inside}}^{\text{tags}}$. Because of the limited sample size of Z + jets events, we

FIG. 11. The ratio of the observed rate of tags to that predicted, as a function of H_T in region C for events with one or more jets. The arrow at 200 GeV shows where the selection cut for the $t\bar{t}$ signal sample is placed.

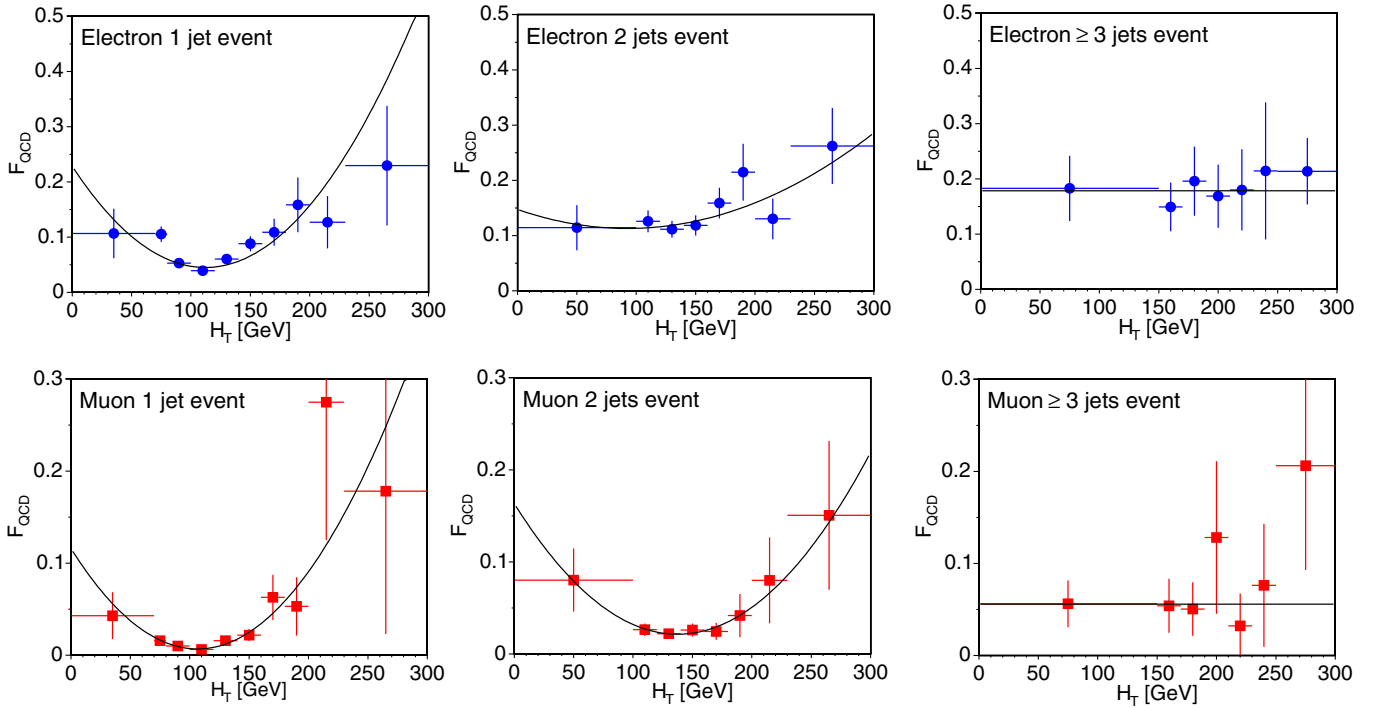

FIG. 12 (color online). F_{QCD} measured according to Eq. (5) as a function of H_T in electron events (top) and muon events (bottom) with (left to right) 1, 2 or ≥ 3 jets.

use $Z + 0$ jet events without the \cancel{E}_T and H_T requirements to find the ratio of events outside the Z -mass window to those inside the window, $R_{Z/\gamma^*}^{\text{out/in}}$, and a first-order estimate of the number of expected Drell-Yan events outside of the Z -mass window is calculated as

$$N_{DY} = N_{\text{inside}}^{\text{tags}} \cdot R_{Z/\gamma^*}^{\text{out/in}}. \quad (7)$$

This estimate assumes that $R_{Z/\gamma^*}^{\text{out/in}}$ does not depend on the number of jets in the event. We assign a systematic uncertainty of 33% for this assumption based on the largest deviation between $R_{Z/\gamma^*}^{\text{out/in}}$ for ALPGEN Z/γ^* plus zero jet events compared with 1, 2 or ≥ 3 jets events.

The first-order estimate is then corrected by the relative efficiency inside and outside the Z -mass window of the \cancel{E}_T , H_T , and SLT-jet requirements, which we measure using $Z/\gamma^* + \text{jets}$ Monte Carlo events. The Drell-Yan background estimates are listed in the sixth line of Table I.

D. Other backgrounds

Remaining background sources are due to WW , WZ , ZZ , $Z \rightarrow \tau\tau$ and single top production. Diboson events can enter the sample when there are two leptons from a Z and/or a W decay and jets. One lepton passes the primary lepton requirements while the second is available to pass the SLT requirement if it is close to a jet. The \cancel{E}_T in these events can either come from a W -boson decay or from an undetected lepton in a Z -boson decay. $Z \rightarrow \tau\tau$ events can enter the

sample when the Z is produced in association with jets and one τ decays to a high- P_T isolated electron or muon, while the second τ produces an SLT muon in its decay. Electroweak single top production gives rise to an event signature nearly identical to $t\bar{t}$ when there are additional jets from gluon radiation.

None of the above background sources are completely accounted for by the application of the tag matrix to the pretag event sample because these backgrounds have a significant source of muons from, for instance, W and Z decay. Therefore, we independently estimate their contributions to the background using Monte Carlo samples normalized to the cross sections referenced in Table III. In modeling the SLT tagging of such events in the Monte Carlo samples, we explicitly exclude the mistag contribution which is taken into account in the application of the tag matrix to the pretag sample. The background for each source is estimated as

$$N_i = \sigma_i \cdot A_i \cdot \epsilon_{\text{tag},i} \cdot \int \mathcal{L} dt, \quad (8)$$

where σ_i is the theoretical cross section for the particular background source, A_i is the acceptance for passing the pretag event selection, $\epsilon_{\text{tag},i}$ is the SLT tagging efficiency and $\int \mathcal{L} dt$ is the integrated luminosity of the overall data sample. The expected background contributions are shown, as a function of jet multiplicity, in Table III.

TABLE III. Summary of the expected number of background events for those sources derived from Monte Carlo simulations, and the cross sections used in Eq. (8). The quoted uncertainties come from the respective Monte Carlo sample sizes and the uncertainty on the theoretical cross sections.

V. TOTAL $t\bar{t}$ ACCEPTANCE

We factorize the efficiency for identifying $t\bar{t}$ events into the geometric times kinematic acceptance and the SLT tagging efficiency. The acceptance includes all the cuts described in Secs. III C as well as the invariant mass cut described in Sec. III E, and is evaluated assuming a top mass of $175 \text{ GeV}/c^2$. The tagging efficiency is the efficiency for SLT tagging at least one jet in events that pass the geometric and kinematic selection. We describe each piece below.

A. Geometric and kinematic acceptance

The acceptance is measured in a combination of data and Monte Carlo simulations. Simulations are done using the PYTHIA Monte Carlo program [13]. The primary lepton identification efficiency is measured in Z -boson decays acquired with a trigger that requires a single high- P_T electron or muon. The efficiency is measured using the lepton from the Z -boson decay that is unbiased by the trigger, and the identification efficiency in the Monte Carlo sample is scaled to that measured in the data [6]. The acceptance, as a function of the number of identified jets above 15 GeV , is shown in Table IV. These numbers include the measured efficiencies of the high- P_T lepton triggers.

B. SLT efficiency

The efficiency for the reconstruction of the COT track is taken directly from Monte Carlo simulation. The reconstruction efficiencies of muon chamber track segments are also taken from the simulation and scaled to the values measured in the data using the lepton in Z -boson decays unbiased by the trigger. The muon identification efficiency of the SLT algorithm is measured in data using J/ψ and Z

decays. We use events acquired with triggers that demand a single muon, and use only the muon not biased by the trigger. The efficiency is defined as the ratio of muons that satisfy the SLT tagging requirement over the number of taggable tracks attached to track segments in the muon chambers. In the calculation of the efficiency a background linear in invariant mass is subtracted from the J/ψ and Z peaks. The measured efficiency vs P_T is shown in Fig. 13 for muons with $|\eta| < 0.6$ (CMU and/or CMP) and for muons with $0.6 \leq |\eta| \leq 1.0$ (CMX). The decrease in efficiency with increasing P_T is a result of non-Gaussian tails in the components of L .

Since the efficiency measurement is dominated by isolated muons, whereas the muons in b -jets tend to be surrounded by other tracks, we have studied the dependence of the efficiency on the number of tracks, N_{trk} , above $1 \text{ GeV}/c$ in a cone of $\Delta R = 0.4$ around the muon track. We find no significant efficiency loss, although the precision of the measurement is poor near $N_{\text{trk}} = 6$, the mean expected in $t\bar{t}$ events. We include a systematic uncertainty to account for this by fitting the efficiency vs N_{trk} to a linear function and evaluating this function at the mean N_{trk} expected in $t\bar{t}$ events. The systematic uncertainty on the efficiency for at least one SLT tag in a $t\bar{t}$ event from this effect is $+0\%$, -8% .

The detector simulation does not properly reproduce the non-Gaussian tails of the muon matching distributions. Therefore the measured efficiencies, shown in Fig. 13, are applied directly to a generated muon in the Monte Carlo sample when evaluating the efficiency for tagging a $t\bar{t}$ event. This accounts for tagging of semileptonic heavy-flavor decays in $t\bar{t}$ events (including charm decays from $W \rightarrow c\bar{s}$). Events from $t\bar{t}$ can also be mistagged when a tag results from a fake muon or a decay-in-flight. We account for this effect in the tagging efficiency evaluation by al-

FIG. 13 (color online). The SLT efficiency for $|\eta| < 0.6$ (left) and $|\eta| \geq 0.6$ (right) as a function of P_T , measured from J/ψ and Z data for $|L| < 3.5$. The dotted lines are the $\pm 1\sigma$ statistical uncertainty on the fit which is used in the evaluation of the systematic uncertainty.

lowing events that are not tagged by muons from heavy-flavor decays to be tagged by other charged tracks using the tagging probabilities from the tag matrix, as described in Sec. IV. Since the heavy-flavor component of the tagging efficiency has already been accounted for, the generic-track tagging probabilities are corrected downwards for the measured 21% heavy-flavor component of the tag matrix (Sec. IVA). The overall efficiency for finding one or more SLT tags in a $t\bar{t}$ event (“tagging efficiency”) is shown in Table V. Mistags account for approximately 25% of the $t\bar{t}$ tagging efficiency. Because a small portion of the integrated luminosity was accumulated before the CMX was fully functional, we break the efficiency into pieces with and without the CMX. This is taken into account in the final cross section denominator. The total $t\bar{t}$ detection efficiency is the product of the acceptance and the tagging efficiency.

As noted above, the SLT efficiency has been parametrized using muons that tend to be isolated from other activity. To further check that this efficiency measurement is representative of muons in or near jets, we use a high-purity $b\bar{b}$ sample, derived from events triggered on 8 GeV electrons or muons. These events are enriched in semileptonic b -hadron decays. To select this sample, we require that the events have two jets above 15 GeV. One jet must be

within $\Delta R = 0.4$ of the primary electron or muon (the “lepton jet”). For jets associated with muons, the energy is corrected to account for the muon P_T . The second jet (the “away jet”) in the event is chosen as the jet above 15 GeV with maximum separation in azimuth (≥ 2 rad) from the lepton jet. Both jets are required to have a secondary vertex reconstructed and tagged by the SecVtx algorithm [5] (“SecVtx-tagged”). This results in a $b\bar{b}$ sample with a purity of approximately 95% [26]. We measure the SLT acceptance times efficiency for semileptonic decays to muons in the away jet in a HERWIG dijet Monte Carlo sample. Monte Carlo events are subject to the same event selection, as described above, used for the $b\bar{b}$ data sample. The efficiency parametrization measured from the data is applied in the same way as in the $t\bar{t}$ Monte Carlo sample. The derived efficiency times acceptance per b -jet is applied to the data to predict the number of SLT tags in the away jet. There are 7726 SecVtx-tagged away jets in which the lepton jet is from a muon and 2233 in which it is from an electron. In these events we predict 388 ± 54 tags in the away jet opposite a muon jet and 116 ± 17 tags in the away jet opposite an electron jet. We find 353 and 106, respectively. We conclude that the efficiency for SLT tagging muons from semileptonic decays of heavy flavor in jets is well modeled by our simulation.

TABLE V. $t\bar{t}$ event tagging efficiency for SLT muons as a function of jet multiplicity from PYTHIA Monte Carlo sample. Uncertainties are statistical only.

VI. SYSTEMATIC UNCERTAINTIES

Systematic uncertainties in this analysis come from uncertainties in the Monte Carlo modeling of the acceptance, knowledge of the SLT tagging efficiency, the effect on the acceptance of the uncertainty on the jet energy calibration, uncertainties on the background predictions, and the uncertainty on the luminosity.

Uncertainties in the Monte Carlo modeling of acceptance include effects of parton distribution functions (PDFs), initial-state radiation (ISR), final-state radiation (FSR), and the calibration of the measured jet energy. These are estimated by comparing different choices for PDFs, varying ISR, FSR and the jet energy in the Monte Carlo programs and comparing the results from the PYTHIA generator with those from HERWIG. A complete description of the evaluation of these uncertainties appears in [6]. The total systematic uncertainty on the acceptance due to these factors is $\pm 6.1\%$. Possible variations of the lepton ID efficiency in events with multiple jets are an additional source of systematic uncertainty on the acceptance. We use a data to Monte Carlo scale factor for the lepton ID efficiency that is taken from $Z \rightarrow ee$ and $Z \rightarrow \mu\mu$ data and Monte Carlo samples. These samples contain predominantly events with no jets. A 5% systematic uncertainty on the scale factor is estimated by convoluting the scale factor itself, measured as a function of ΔR between the lepton and the nearest jet, with the ΔR distribution of leptons in ≥ 3 jet $t\bar{t}$ events [6]. Adding the uncertainties in quadrature gives a total Monte Carlo modeling systematic uncertainty on the acceptance of $\pm 8.0\%$.

There are several factors that contribute to the systematic uncertainty on the SLT tagging efficiency. The uncertainty due to our knowledge of the P_T dependence is determined by varying the efficiency curves used in the $t\bar{t}$ Monte Carlo sample according to the upper and lower bands in Fig. 13. We find that the tagging efficiency for $t\bar{t}$ changes by $\pm 1\%$ from its central value. An additional source of systematic uncertainty for the tagging efficiency comes from the fact that we implicitly use the Monte Carlo tracking efficiency for taggable tracks. As these tracks can

be in dense environments in or near jets, we expect the efficiency to be somewhat less than for isolated tracks. Studies done by embedding Monte Carlo tracks in jets in both data and Monte Carlo events indicate that the Monte Carlo tracking efficiency in dense environments is a few percent higher than in data. We assign a $\pm 5\%$ systematic uncertainty to the tagging efficiency for this effect. As described in Sec. VB the systematic uncertainty due to the modeling of the isolation dependence of the tagging efficiency is $+0\%$, -8% . Finally, the statistical uncertainty on the measurement of the SLT tagging efficiency in $t\bar{t}$ events, differences between PYTHIA and HERWIG, the uncertainty on the semileptonic branching fraction for B mesons and the estimation of the heavy-flavor content of the mistag matrix also contribute to the systematic uncertainties. Adding these contributions in quadrature gives an overall systematic uncertainty for the tagging efficiency of $+8\%$, -11% . Note that the uncertainty on the tagging efficiency affects also the backgrounds determination. The reason is that $t\bar{t}$ events need to be subtracted from the pretag sample which is used in Eq. (3) to determine the $W + \text{jets}$ background. We take this effect into account when calculating the uncertainty on the cross section.

Uncertainties on the tag matrix are determined by the level of agreement between observed tags and predictions in a variety of samples, as described in Sec. IV. The uncertainty on the $W + \text{fakes}$ and $Wb\bar{b} + Wc\bar{c} + Wc$ prediction is $\pm 10\%$.

To determine the uncertainties on the QCD background prediction in events with three or more jets, we define a control sample from the \cancel{E}_T vs lepton isolation plane, where the primary lepton isolation parameter I is between 0.1 and 0.2 and the event has $\cancel{E}_T > 20$ GeV. After subtracting expected contributions from W and $t\bar{t}$ events, all events in this region are expected to be QCD. We determine the systematic uncertainty on the QCD background using the ratio of the observed over predicted number of events in this control region, which should be 1.0. In the sample where the primary lepton is a muon, we measure 0.5 ± 0.4 . In the sample where the primary lepton is an electron, we measure 0.8 ± 0.2 . A 50% systematic uncertainty is as-

TABLE VI. Summary of systematic uncertainties. The shift $\Delta\sigma_{t\bar{t}}$ of the measured cross section value assumes the cross section calculated in Sec. VII.

Source	Fractional system uncertainty (%)	$\Delta\sigma_{t\bar{t}}$ (pb)
Acceptance modeling	± 8	$\begin{cases} +1.10 \\ -0.70 \end{cases}$
SLT tagging efficiency	$+8, -11$	
Tag matrix prediction	± 10	± 0.68
QCD prediction	$\pm 19(e) \pm 67(\mu)$	± 0.14
Drell-Yan and other MC backgrounds	± 19	± 0.05
Luminosity	± 6	± 0.32
Total systematic uncertainty		$\begin{cases} +1.3 \\ -1.0 \end{cases}$

signed to the F_{QCD} measurement for muons and 20% for electrons. We combine this with the statistical uncertainty on F_{QCD} , the uncertainty on the correction factor k , both given in Table II and the 10% systematic uncertainty due to the application of the tag matrix. The total QCD background uncertainty is $\pm 67\%$ and $\pm 19\%$ for muons and electrons, respectively. These values are determined taking into account the correlation between the estimate of the QCD background and the estimate of the $W + \text{fakes}$ and $W + \text{heavy flavor}$ backgrounds [Eqs. (4) and (6)]. We add in quadrature the separate effects on the cross section of the QCD uncertainties for electrons and muons.

The systematic uncertainty on the small Drell-Yan background is dominated by its statistical uncertainty. We also include a 33% relative uncertainty to account for changes in the shape of the Drell-Yan spectrum with the number of jets in the event, as described in Sec. IV C. Uncertainties on the Monte Carlo background predictions come from uncertainties in the cross sections for the various processes and from the event sizes of the Monte Carlo samples.

The systematic uncertainties and the corresponding shift of the measured cross section value are summarized in Table VI.

VII. RESULTS

Table I shows a summary of the background estimates and the number of SLT tagged events as a function of the number of jets. A “tagged event” is an event with at least one tagged jet. The total background and the $t\bar{t}$ expectation are also listed. The line labeled “Corrected background” corresponds to the background after correcting for the $t\bar{t}$ content of the pretag sample, as described in Sec. IV A.

We calculate the cross section as

$$\sigma_{t\bar{t}} = \frac{N_{\text{obs}} - N_{\text{bgnd}}}{A_{t\bar{t}} \cdot \int \mathcal{L} dt}, \quad (9)$$

where N_{obs} is the number of events with ≥ 3 jets that are tagged with at least 1 SLT, N_{bgnd} is the corrected background and $A_{t\bar{t}}$ is the total acceptance (geometrical acceptance times kinematic acceptance times tagging efficiency), taken from Tables IV and V. For events with three or more jets, the total denominator is $1.98 \pm 0.28 \text{ pb}^{-1}$.

From the number of candidate events with three or more jets, we find a total $t\bar{t}$ production cross section of

$$\sigma(p\bar{p} \rightarrow t\bar{t}) = 5.3 \pm 3.3_{-1.0}^{+1.3} \text{ pb},$$

where the first uncertainty is statistical and the second is systematic. This cross section value uses acceptances and tagging efficiencies appropriate for a top mass of $175 \text{ GeV}/c^2$. The acceptances and efficiencies, and therefore the calculated cross section, change slightly for other

FIG. 14 (color online). The expected background and observed tags in $W + 1, 2, 3$ and 4 or more jet events. The background is corrected for the $t\bar{t}$ content of the pretag sample.

assumed top masses. The calculated cross section is 1% higher assuming a top mass of $170 \text{ GeV}/c^2$, and 5% lower assuming a top mass of $180 \text{ GeV}/c^2$.

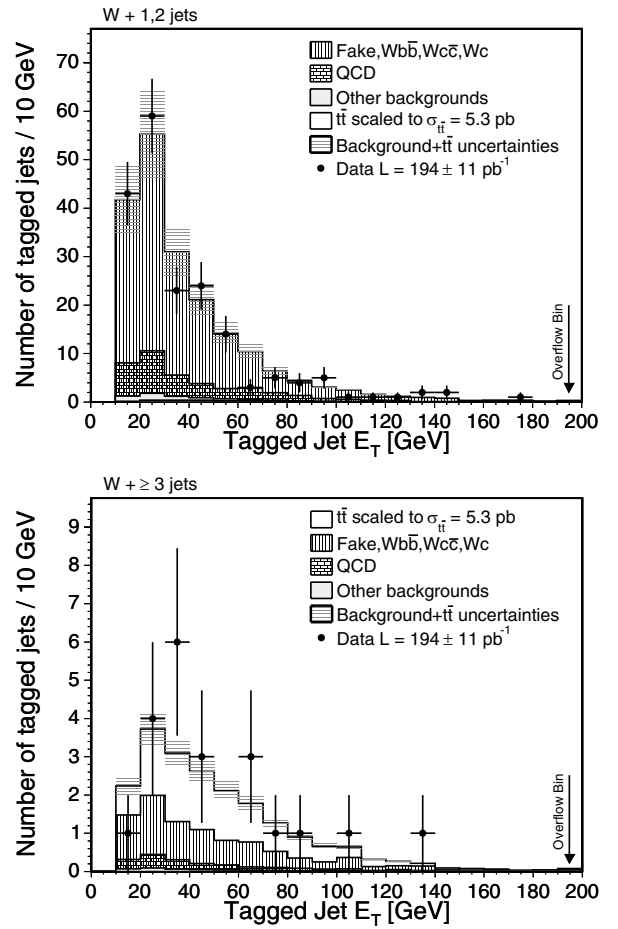

FIG. 15. Comparison of the jet E_T distributions for tagged events and for expectations from fakes, QCD and $t\bar{t}$ events. The upper plot is for $W + 1$ and 2 jet events and the lower plot for $W + \geq 3$ jet events.

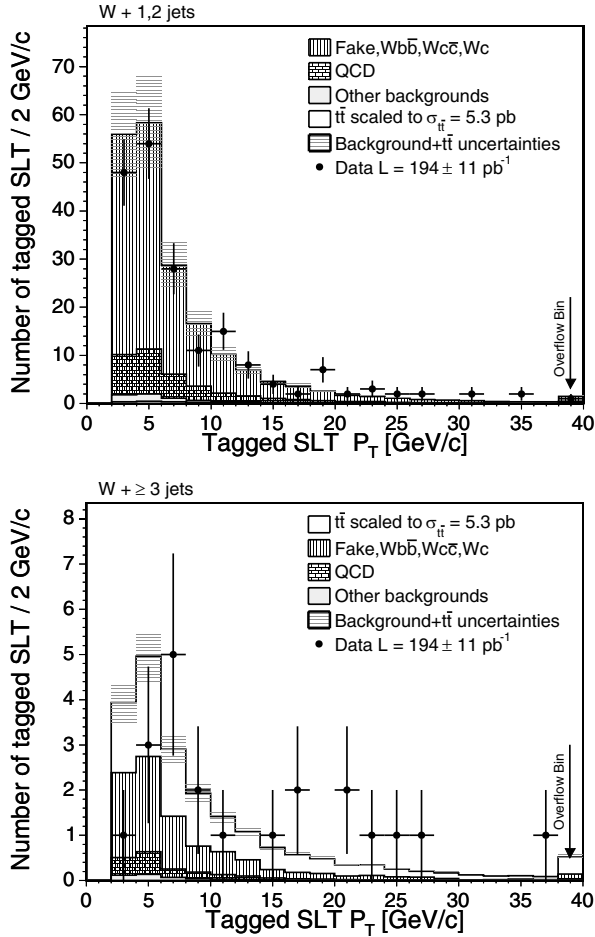

FIG. 16. P_T of the SLT tags. The upper plot is for $W + 1$ and 2 jet events and the lower plot for $W + \geq 3$ jet events.

Figure 14 shows the number of tags in $W + 1, 2, 3, \geq 4$ jet events together with the histograms representing the total corrected background with and without the $t\bar{t}$ signal expectation, based on the theoretical cross section of 6.7 pb for $M_{\text{top}} = 175 \text{ GeV}/c^2$.

We examine a number of kinematic distributions of the tagged events and compare with expectations based on the measured signal plus background. Figure 15 shows the E_T distribution of the tagged jets in $W + 1$ and 2 jets (combined), and in the signal region of W plus three or more jets. The $W + 1$ and 2 jet data-Monte Carlo comparison has a Kolmogorov-Smirnov test (KS) probability of 41%, and the three or more jet comparison has a KS probability of 82%.

Figure 16 compares the P_T distribution of muons identified as SLT tags with expectations from $t\bar{t}$ plus backgrounds. The KS probabilities are 6% for $W + 1$ and 2 jet comparison and 5% for the three or more jet comparison.

Finally, Fig. 17 shows the impact parameter significance, defined as the impact parameter divided by its uncertainty, for the SLT tracks and the expectation from signal plus background. The sign of the impact parameter

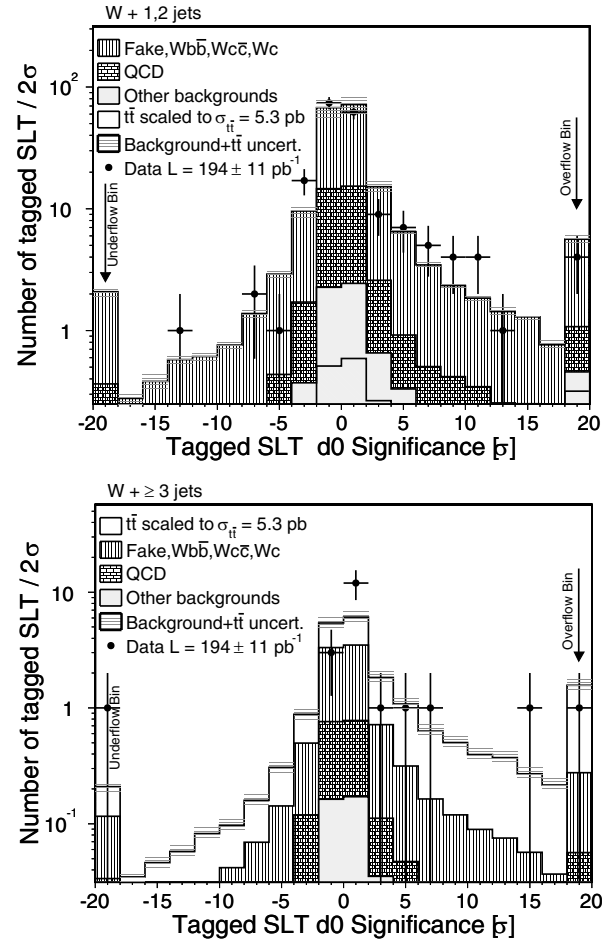

FIG. 17. The impact parameter (d_0) significance for tagged events, compared with expectations from backgrounds plus $t\bar{t}$. The upper plot is for $W + 1$ and 2 jet events and the lower plot for $W + \geq 3$ jet events.

is defined according to whether the track trajectory crosses the jet axis in front of or behind the event primary vertex. The long-lived component from semileptonic b -hadron decays is readily apparent in the shape of the positive impact parameter distribution. The KS probabilities are 12% for $W + 1$ and 2 jet comparison and 23% for the three or more jet comparison. (Note that Figs. 15–17 contain 21 entries since one of the events has two jets tagged with SLT.)

VIII. CONCLUSIONS

We have measured the total cross section for $t\bar{t}$ production through the decay of top pairs into an electron or muon plus multiple jets. We separate signal from background by identifying semileptonic decays of b hadrons into muons. The measured $t\bar{t}$ production cross section is $5.3 \pm 3.3^{+1.3}_{-1.0}$ pb, consistent with the expectation of 6.7 pb for standard model production and decay of top quark pairs with a mass of $175 \text{ GeV}/c^2$. Distributions of Jet E_T and impact parameter significance for the tagged events, and

the distributions of the P_T of the tags, are also consistent with standard model expectations.

The sensitivity of this analysis to test nonstandard model $t\bar{t}$ production or decay mechanisms is limited by the statistical uncertainty. The combination of this measurement with other CDF II measurements [8] will yield a significantly more precise value. Future measurements with the full run II data set of $4\text{--}8\text{ fb}^{-1}$ will provide further factors of approximately four to six in statistical precision. At the same time, significantly larger data sets will provide avenues for reduction of the systematic uncertainties through such things as better understanding of the tag rate in $W + \text{jets}$ events and direct measurement of the tagging efficiency for semileptonic b -hadron decays.

ACKNOWLEDGMENTS

We are grateful to Tim Stelzer for help with studies of the heavy-flavor content of $\gamma + \text{jets}$ and $W + \text{jets}$ events using MADEVENT. We thank the Fermilab staff and the

technical staffs of the participating institutions for their vital contributions. - [4] We use a (z, ϕ, θ) coordinate system where the z -axis is in the direction of the proton beam, and ϕ and θ are the azimuthal and polar angles, respectively. The pseudorapidity, η , is defined as $-\ln(\tan\frac{\theta}{2})$. The transverse momentum of a charged particle is $P_T = P \sin\theta$, where P represents the measured momentum of the charged-particle track. The analogous quantity using calorimeter energies, defined as $E_T = E \sin\theta$, is called transverse energy. The missing transverse energy is defined as $\cancel{E}_T = -|\sum_i E_T^i \hat{n}_i|$ where E_T^i is the magnitude of the transverse energy contained in each calorimeter tower i in the pseudorapidity region $|\eta| < 3.6$ and \hat{n}_i is the direction unit vector of the tower in the plane transverse to the beam direction.
