(Received 22 November 2010; published 28 April 2011)

We study the phenomenology of the type-II seesaw model at a linear e^-e^- collider. We show that the process $e^-e^- \rightarrow \alpha^-\beta^-$ ($\alpha, \beta = e, \mu, \tau$ being charged leptons) mediated by a doubly charged scalar is very sensitive to the neutrino parameters, in particular, the absolute neutrino mass scale and the Majorana CP -violating phases. We identify the regions in parameter space in which appreciable collider signatures in the channel with two like-sign muons in the final state are possible. This includes Higgs triplet masses beyond the reach of the LHC.

I. INTRODUCTION

The origin of neutrino masses and leptonic flavor mixing emerges as one of the most challenging problems in particle physics. Among various theories of this kind, the seesaw mechanism [1–4] attracts a lot of attention in virtue of its naturalness and simplicity in explaining the smallness of neutrino masses. In the standard type-I seesaw model, the fermion sector of the Standard Model (SM) is extended by adding right-handed neutrinos having large Majorana masses M_R . In its natural version the neutrino masses are suppressed with respect to typical SM (Dirac) masses m_D by a factor m_D/M_R . With m_D of weak scale it follows that sub-eV neutrino masses require heavy neutrino masses many orders of magnitude above the center-of-mass energies of realistic colliders. In addition, as right-handed neutrinos possess no gauge couplings, their production is suppressed by a mixing factor of order m_D/M_R , so that all in all the mechanism lacks testability. Only at the price of extreme cancellations [5–8], or by introducing additional gauge groups, one can achieve production of type-I seesaw messengers at colliders.

In contrast, in the type-II seesaw model [9–11] one extends the scalar sector of the SM by introducing an $SU(2)_L$ Higgs triplet, which couples to two lepton doublets and thereby gives rise to a Majorana mass term of neutrinos after electroweak symmetry breaking. This mass is given by a vacuum expectation value times a Yukawa coupling. A Higgs triplet can be naturally embedded in many frameworks, e.g., grand unified, left-right symmetric, or little Higgs models. It is important to note that a tiny neutrino mass by no means requires that the mass of the Higgs triplet is huge. In addition, Higgs triplets do possess gauge couplings, which facilitates their production at colliders [12–15]. In such a scenario, the bilepton decays of the doubly charged component are firmly connected to the neutrino mass matrix, which opens a very promising link between neutrino parameters and collider signatures

[16–24]. Higgs triplets also induce lepton flavor violating (LFV) charged lepton decays, which can be used to constrain the parameters associated with them [25–28]. Moreover, observable nonstandard neutrino interaction effects induced by the singly charged component of the Higgs triplet might be discovered in future long-baseline neutrino oscillation experiments [29].

The Large Hadron Collider is shown to be able to discover Higgs triplets up to 600 GeV \sim 1 TeV depending on the neutrino mass hierarchy [14,15]. Similarly, the doubly charged component of the Higgs triplet may also be pair produced at a linear e^+e^- collider via virtual exchange of Z^* and γ^* [30]. The decay of the Higgs triplet in like-sign lepton pairs is then in analogy to that at the LHC. In this paper, however, we will study the production of doubly charged Higgs triplets at a linear collider in the like-sign lepton mode. A linear e^-e^- collider could provide a substantial and complementary role in identifying new physics beyond the SM. In such a running mode, a number of lepton number violating (LNV) processes mediated by any LNV physics, including Higgs triplets, can be explored to a very good precision, since they are basically free from the SM background. One $\Delta L = 2$ process to be investigated is the inverse neutrinoless double beta decay, i.e., $e^-e^- \rightarrow W^-W^-$, which is however suppressed by the small vacuum expectation value of the Higgs triplet, and is not very promising unless a very narrow resonance is met [31]. In this work, we focus our attention on the phenomena of bilepton production process mediated by a Higgs triplet at a linear e^-e^- collider:

$$e^-e^- \rightarrow \alpha^-\beta^-. \quad (1)$$

We demonstrate that the collider signatures are firmly correlated to neutrino parameters, while appreciable signals can be expected without the need of resonant enhancement. Such a process is impossible at the LHC, and proceeds via s -channel exchange, see Fig. 1. The difference to the aforementioned processes is the absence of gauge couplings and the pure s -channel production of basically massless final state particles; the cross section

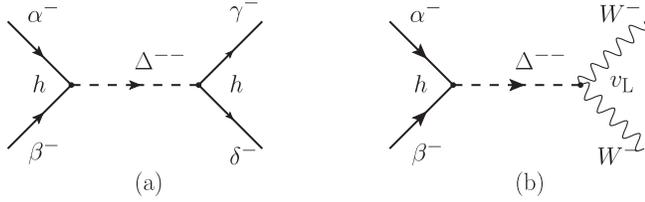

FIG. 1. Feynman diagrams for the doubly charged Higgs mediated bilepton channel (left) and WW channel (right).

depends on Yukawa couplings (and hence the neutrino flavor structure) only.

This work is organized as follows: In Sec. II, we present the framework of the low-scale type-II seesaw model. In Sec. III, we focus on the characteristic features of the processes mediated by the doubly charged scalar, and summarize the current constraints on the relevant Yukawa couplings. In particular, we figure out the intrinsic correlations between neutrino parameters and the bilepton production processes at a linear e^-e^- collider. Numerical analysis and illustrations will be performed in detail in Sec. IV. Finally, in Sec. V, we summarize our results and conclude.

II. NEUTRINO MASSES FROM THE TYPE-II SEESAW

In the simplest type-II seesaw framework, one heavy Higgs triplet with hypercharge $Y = -2$ is introduced besides the SM particle content. Apart from the SM interactions, one can further write down a gauge invariant coupling between the Higgs triplet and two lepton doublets as

$$\mathcal{L}_\Delta = h_{\alpha\beta} \bar{L}_\alpha i \tau_2 \Delta L_\beta^c + \text{H.c.}, \quad (2)$$

where $L_\alpha = (\nu_\alpha, \ell_\alpha)^T$ (for $\alpha = e, \mu, \tau$) denote the lepton doublet, $h_{\alpha\beta}$ is a symmetric Yukawa coupling matrix, and Δ is a 2×2 representation of the Higgs triplet

$$\Delta = \begin{pmatrix} \Delta^-/\sqrt{2} & \Delta^{--} \\ \Delta^0 & -\Delta^-/\sqrt{2} \end{pmatrix}. \quad (3)$$

We further expand Eq. (2) and express the interactions in terms of component fields, i.e.,

$$\mathcal{L}_\Delta = h_{\alpha\beta} \left[\Delta^0 \bar{\nu}_\alpha P_L \nu_\beta^c - \frac{1}{\sqrt{2}} \Delta^- (\bar{\ell}_\alpha P_L \nu_\beta^c + \bar{\nu}_\alpha P_L \ell_\beta^c) - \Delta^{--} \bar{\ell}_\alpha P_L \ell_\beta^c \right] + \text{H.c.} \quad (4)$$

In the language of effective theory, the heavy Higgs triplet should be integrated out from the full theory, and, at tree level, a Majorana mass term of neutrinos is given by [32]

$$\mathcal{L}_\nu = h_{\alpha\beta} \frac{v_L}{\sqrt{2}} \bar{\nu}_{L\alpha} \nu_{L\beta}^c + \text{H.c.} = \frac{1}{2} m_{\alpha\beta} \bar{\nu}_{L\alpha} \nu_{L\beta}^c + \text{H.c.}, \quad (5)$$

where v_L is the vacuum expectation value (VEV) of the Higgs triplet, i.e., $\langle \Delta^0 \rangle = v_L/\sqrt{2}$. The main constraint on v_L stems from the electroweak ρ parameter, and roughly gives $v_L \lesssim 8$ GeV. How exactly v_L is related to the model parameters depends on details of the underlying physics, it may be that $v_L = v^2 \mu/m_\Delta^2$, where μ is a dimensionful coupling of the triplet with two Higgs doublets, or $v_L \propto v^2/v_R$ in left-right symmetric theories, where v_R is the scale of right-handed physics, i.e., the VEV of an $SU(2)_R$ triplet. Compared to the type-I seesaw, tiny light neutrino masses could be attributed to the small dimensionful parameters μ in the full Higgs potential, while the mass of the triplet can be located at a relatively low scale, e.g., the TeV scale. In particular, in the limit $\mu \rightarrow 0$, the lepton number is conserved leading to an enhancement of the total symmetry of the theory, which well satisfies the naturalness criterion [33]. Here we will not speculate on the origin of the magnitude of m_Δ , but assume in a model-independent way that it is not above TeV scale, and that the smallness of v_L is due to other parameters in the underlying physics.

As usual, m can be diagonalized by means of a unitary transformation, viz.

$$m = U \text{diag}(m_1, m_2, m_3) U^T, \quad (6)$$

where m_i ($i = 1, 2, 3$) denote neutrino masses, and U the leptonic mixing matrix. In the standard (CKM-like) parametrization one has

$$U = R_{23} P_\delta R_{13} P_\delta^{-1} R_{12} P_M, \quad (7)$$

where R_{ij} correspond to the elementary rotations in the $ij = 23, 13$, and 12 planes (parametrized by three mixing angles $c_{ij} \equiv \cos\theta_{ij}$ and $s_{ij} \equiv \sin\theta_{ij}$), $P_\delta = \text{diag}(1, 1, e^{i\delta})$, and $P_M = \text{diag}(e^{i\phi_1}, e^{i\phi_2}, 1)$ contain the Dirac and Majorana CP -violating phases, respectively.

According to Eq. (5), the Yukawa coupling matrix h is related to the light neutrino mass matrix as $h = m/(\sqrt{2}v_L)$. Hence, the flavor structure of the Yukawa coupling h is identical to that of the neutrino mass matrix, which allows for a direct test of neutrino parameters via measurements of h . For example, if kinematically accessible, the doubly charged component of the Higgs triplet can be on shell produced at colliders, and its subsequent LNV or LFV decays may bring in significant signatures allowing the determination of flavor structure of h , and therefore m , at current and forthcoming colliders. In particular, the decay branching ratios of Δ are shown to be highly sensitive to the neutrino mixing parameters and the neutrino mass hierarchy.

The possibility of testing the neutrino mass matrix by studying the decays of Higgs triplet at hadron colliders, e.g., the LHC, has been discussed intensively [16–24]. In what follows, we will concentrate on the production of the doubly charged Higgs Δ^{--} at linear e^-e^- colliders, and, in particular, investigate the LFV processes $e^-e^- \rightarrow \alpha^-\beta^-$ in detail.

III. DOUBLY CHARGED HIGGS AT A LINEAR e^-e^- COLLIDER

Among various interesting physics possibilities at a lepton-lepton collider, one of the most promising processes to be investigated is the bilepton production mediated by a doubly charged scalar Δ^{--} . The production of Higgs triplets in like-sign lepton collisions has been discussed in Refs. [31,34–48]. In the current study, we analyze the process (1) while at the same time take into account both the LFV limits and the information on the neutrino mass and mixing parameters, which has not been considered before in the literature. The relevant diagram is shown in the left-hand panel of Fig. 1. In the framework under discussion, the general cross section for $\alpha^-\beta^- \rightarrow \gamma^-\delta^-$, where $\alpha, \beta, \gamma, \delta = e, \mu, \tau$, reads

$$\sigma = \frac{|h_{\alpha\beta}h_{\gamma\delta}|^2}{4\pi(1 + \delta_{\gamma\delta})} \frac{s}{(s - m_\Delta^2)^2 + m_\Delta^2\Gamma_\Delta^2} = \frac{|h_{\alpha\beta}h_{\gamma\delta}|^2}{(1 + \delta_{\gamma\delta})} \sigma_0, \quad (8)$$

where Γ_Δ is the decay width of Δ^{--} , and the bare cross section σ_0 is independent of the flavor indices. Note that, if there are two electrons in the final states, the above formula does not apply, since the SM contributions mediated by γ and Z may play the dominating role.

In addition to the bilepton channel, the inverse neutrinoless double beta decay process $e^-e^- \rightarrow W^-W^-$ can also be used as a probe of LNV [31,34–48]. The corresponding diagram is shown in the right-hand panel of Fig. 1. The cross section is given by

$$\begin{aligned} \sigma &= \frac{G_F^2 v_L^2}{2\pi} |h_{\alpha\beta}|^2 \frac{(s - 2m_W^2)^2 + 8m_W^4}{(s - m_\Delta^2)^2 + m_\Delta^2\Gamma_\Delta^2} \sqrt{1 - 4\frac{m_W^2}{s}} \\ &\simeq \frac{G_F^2 v_L^2}{2\pi} |h_{\alpha\beta}|^2 \frac{s^2}{(s - m_\Delta^2)^2 + m_\Delta^2\Gamma_\Delta^2}, \end{aligned} \quad (9)$$

where the mass of W -boson m_W is neglected in the second line. Depending on the mass splitting within the Higgs triplet, the decays $\Delta^{--} \rightarrow W^-\Delta^-$ and $\Delta^{--} \rightarrow \Delta^-\Delta^-$ may also take place, which may be dominating as they are driven by a gauge coupling. Here we assume a degeneracy among the Higgs triplet components, viz., the above two channels are kinematically suppressed. Accordingly, the relative ratio of the cross sections can be estimated by

$$\begin{aligned} \frac{\sigma(\alpha^-\beta^- \rightarrow W^-W^-)}{\sigma(\alpha^-\beta^- \rightarrow \gamma^-\delta^-)} &\simeq \frac{2G_F^2 v_L^2 (1 + \delta_{\gamma\delta}) s}{|h_{\gamma\delta}|^2} \\ &= \frac{\Gamma(\Delta^{--} \rightarrow W^-W^-)}{\Gamma(\Delta^{--} \rightarrow \gamma^-\delta^-)} \frac{s}{m_\Delta}. \end{aligned} \quad (10)$$

The requirement $\sigma(\alpha^-\beta^- \rightarrow W^-W^-) \ll \sigma(\alpha^-\beta^- \rightarrow \gamma^-\delta^-)$ implies that the bilepton decays dominate the decay of Δ^{--} , which occurs when $v_L < 10^{-4}$ GeV for a TeV scale Higgs triplet [14].

Inserting Eq. (5) into Eq. (8), one can rewrite the cross section in terms of the neutrino mass matrix elements as

$$\sigma(\alpha^-\beta^- \rightarrow \gamma^-\delta^-) = \frac{|m_{\alpha\beta}m_{\gamma\delta}|^2}{4v_L^4(1 + \delta_{\gamma\delta})} \sigma_0. \quad (11)$$

One can then observe that the cross sections are correlated to both the neutrino mass matrix and v_L . If the neutrino mass scale is fixed, a smaller v_L generally corresponds to larger Yukawa couplings and hence larger cross sections. In case of the e^-e^- collider, the above equation reduces to

$$\sigma(e^-e^- \rightarrow \gamma^-\delta^-) = \frac{|m_{ee}|^2 |m_{\gamma\delta}|^2}{4v_L^4(1 + \delta_{\gamma\delta})} \sigma_0, \quad (12)$$

where $|m_{ee}|$ is the effective mass of the neutrinoless double beta decay process,¹ and constrained by current experiments as $|m_{ee}| \lesssim 1$ eV. If the effective mass of neutrinoless double beta decay turns out to be very small, there will be no visible collider signatures either. Then the process might be observed in running a future muon collider in the $\mu^-\mu^-$ mode, or in an $e^-\mu^-$ collider.

The most relevant experimental constraints on the Yukawa coupling matrix h come from the LFV decays $\mu \rightarrow 3e$ and $\tau \rightarrow 3\ell$ (which occur at tree level), the radiative lepton decays $\ell_\alpha \rightarrow \ell_\beta\gamma$ (one-loop), and the muonium to antimuonium conversion. Bounds from Bhabha scattering and universality tests of weak interactions are relatively weaker and will be not elaborated on in our calculations. The constraints at 90% C.L. are summarized in Table I (see also Refs. [25,26,28]).

An interesting feature is that, among all the relevant experimental bounds, at least one off diagonal element in h is involved except for the constraint from muonium-antimuonium conversion. Note further that the most stringent experimental constraint comes from the rare muon decays $\mu \rightarrow 3e$ and $\mu \rightarrow e\gamma$. In order to generate

¹Note that neutrinoless double beta decay is also triggered by Δ^{--} via the reverse diagram of Fig. 1(b), and the corresponding amplitude is proportional to $h_{ee}v_L/m_\Delta^2$. Therefore, compared to the standard contribution from a Majorana mass term of light neutrinos, the triplet mediated diagram is suppressed by a factor q^2/m_Δ^2 (q represents the momentum transfer carried by the exchanged neutrinos, and is typically of order 100 MeV) since $h_{ee}v_L$ is of order m_{ee} (if the triplet contribution dominates the neutrino mass). In case the triplet contribution is subdominant for neutrino masses, the ratio is even smaller.

TABLE I. Constraints (at 90% C.L.) on h from $\ell \rightarrow \ell\ell\ell$, $\ell \rightarrow \ell\gamma$, and $\mu^+e^- \rightarrow \mu^-e^+$ processes. The experimental bounds have been obtained from Refs. [49,50].

Decay	Constraint on	Bound (90% C.L.)
$\mu^- \rightarrow e^-e^+e^-$	$ h_{ee}h_{e\mu} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	2.1×10^{-12}
$\tau^- \rightarrow e^-e^+e^-$	$ h_{ee}h_{e\tau} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	4.4×10^{-7}
$\tau^- \rightarrow \mu^-\mu^+\mu^-$	$ h_{\mu\mu}h_{\mu\tau} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	3.9×10^{-7}
$\tau^- \rightarrow e^-\mu^+e^-$	$ h_{ee}h_{\mu\tau} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	2.4×10^{-7}
$\tau^- \rightarrow \mu^-e^+\mu^-$	$ h_{e\mu}h_{e\tau} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	2.8×10^{-7}
$\tau^- \rightarrow e^-\mu^+\mu^-$	$ h_{e\mu}h_{\mu\tau} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	2.3×10^{-7}
$\tau^- \rightarrow e^-e^+\mu^-$	$ h_{\mu\mu}h_{e\tau} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	1.7×10^{-7}
$\mu^- \rightarrow e^-\gamma$	$ (hh^\dagger)_{e\mu} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	6.5×10^{-9}
$\tau^- \rightarrow e^-\gamma$	$ (hh^\dagger)_{e\mu} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	1.0×10^{-4}
$\tau^- \rightarrow \mu^-\gamma$	$ (hh^\dagger)_{e\mu} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	1.4×10^{-4}
$\mu^+e^- \rightarrow \mu^-e^+$	$ h_{ee}h_{\mu\mu} ^2(\frac{250 \text{ GeV}}{m_\Delta})^4$	9.5×10^{-6}

observable collider signatures and avoid large LFV processes at the same time, one requires the flavor nondiagonal parts of h to be relatively small, in particular, the $e\mu$ component.² One way to achieve this goal requires that m takes an approximately diagonal form, which is the case for a nearly degenerate (ND) neutrino mass spectrum, i.e., $m_1 \simeq m_2 \simeq m_3 = m_0$, together with vanishing CP -violating phases. For example, in the ND case and neglecting the smallest mixing angle θ_{13} , $h_{e\mu}$ is given by

$$|h_{e\mu}|^2 \simeq \frac{2m_0^2}{v_L^2} s_{12}^2 c_{12}^2 c_{23}^2 \sin^2(\phi_1 - \phi_2). \quad (13)$$

Therefore, in the limit $\phi_1 - \phi_2 \simeq 0$, the most stringent constraint in Table I disappears. This situation holds no matter whether the neutrino mass ordering is normal ($m_1 < m_2 < m_3$) or inverted ($m_3 < m_1 < m_2$). Actually, to be precise we should note that $h_{e\mu}$ cannot vanish exactly if $\theta_{13} = 0$ [51], but can be sufficiently small for our purposes.

In the case of a hierarchical neutrino mass spectrum, i.e., $m_1 \simeq 0$ or $m_3 \simeq 0$, there still exists parameter space ensuring the (close-to) vanishing of $h_{e\mu}$. In the extreme case with $m_1 = 0$, one can expand $h_{e\mu}$ according to small quantities s_{13} and $r = m_2/m_3$. Taking $\theta_{23} = \pi/4$, we obtain approximately

$$|h_{e\mu}|^2 \simeq \frac{m_2 m_3 s_{12} c_{12}}{4v_L^2} [r s_{12} c_{12} + 2s_{13} c_{\delta+2\phi_2}], \quad (14)$$

where higher order terms in proportion to s_{13}^2 or r^2 have been neglected. Thus, the severe constraint from the $\mu \rightarrow 3e$ process is evaded if the relation

²Single texture zeros in the neutrino mass matrix have been studied in Ref. [51].

$$r s_{12} c_{12} \simeq -2s_{13} c_{\delta+2\phi_2}, \quad (15)$$

holds. As for the IH case, in the limit $m_3 = 0$, we obtain an estimate of

$$|h_{e\mu}|^2 \simeq \frac{m_2^2 s_{12}^2 c_{12}^2 s_{\phi_1 - \phi_2}^2}{v_L^2}, \quad (16)$$

which again suggests degenerate Majorana CP -violating phases in favor of observable collider signatures. We will see later that typically the di-muon channel $e^-e^- \rightarrow \mu^-\mu^-$ is of interest, and thus we want both h_{ee} and $h_{\mu\mu}$ to be sizable. This implies again that nearly degenerate neutrinos, and to some extent inversely hierarchical mass schemes will be favored over a normal hierarchy, for which the ee entry of the mass matrix is typically much smaller than the $\mu\mu$ element. It is worth noting here that the processes we discuss in this work basically do not suffer from any SM background (whose detailed analysis is beyond the scope of our paper). A signal which could mimic $e^-e^- \rightarrow \mu^-\mu^-$ would be the process $e^-e^- \rightarrow WW\nu_e\nu_e \rightarrow \mu\mu\bar{\nu}_\mu\bar{\nu}_\mu\nu_e\nu_e$, where the neutrinos cause very little missing energy. With suitable angular and p_T cuts [52,53] one could reduce this background significantly.

IV. NUMERICAL RESULTS

In our numerical illustrations, we consider a linear e^-e^- collider with center-of-mass energy $\sqrt{s} = 1$ TeV, while the mass of Higgs triplet is assumed to be $m_\Delta = 800$ GeV. The typical luminosity is $\mathcal{L} = 80 (\sqrt{s}/\text{TeV})^2 \text{fb}^{-1}$. We also make use of the neutrino parameters from a global-fit of the current neutrino oscillation experiments [54]. In the numerical calculations, we fix the neutrino parameters and m_Δ . We let v_L vary between 10^{-10} GeV and 10^{-6} GeV (in order to have the bilepton decays dominate over the W^-W^- mode) and vary the Yukawa coupling matrix h until one of the upper bounds in Table I is saturated. Perturbativity of h is satisfied, and the Yukawas do not exceed 0.35 in all of the results, which we will present in what follows.

In Fig. 2 we illustrate the upper limits of the cross sections $\sigma(e^-e^- \rightarrow \alpha^-\beta^-)$ with respect to the lightest neutrino mass m_1 given the constraints from Table I. The choices for the neutrino mixing parameters are labeled on each plot, and the cross section of the SM process $e^-e^- \rightarrow e^-e^-$ is also shown for the purpose of comparison.³ Because of the experimental difficulty in tau reconstruction, we do not show channels with two tau. As we discussed in the previous section, the upper bounds of the cross sections are very sensitive to the neutrino parameters. Especially, in the ND case and vanishing CP -violating

³In computing the total cross section in the SM framework, $|\cos\theta| < 0.8$ is used with θ being the scattering angle between the initial and final electron in the center-of-mass frame.

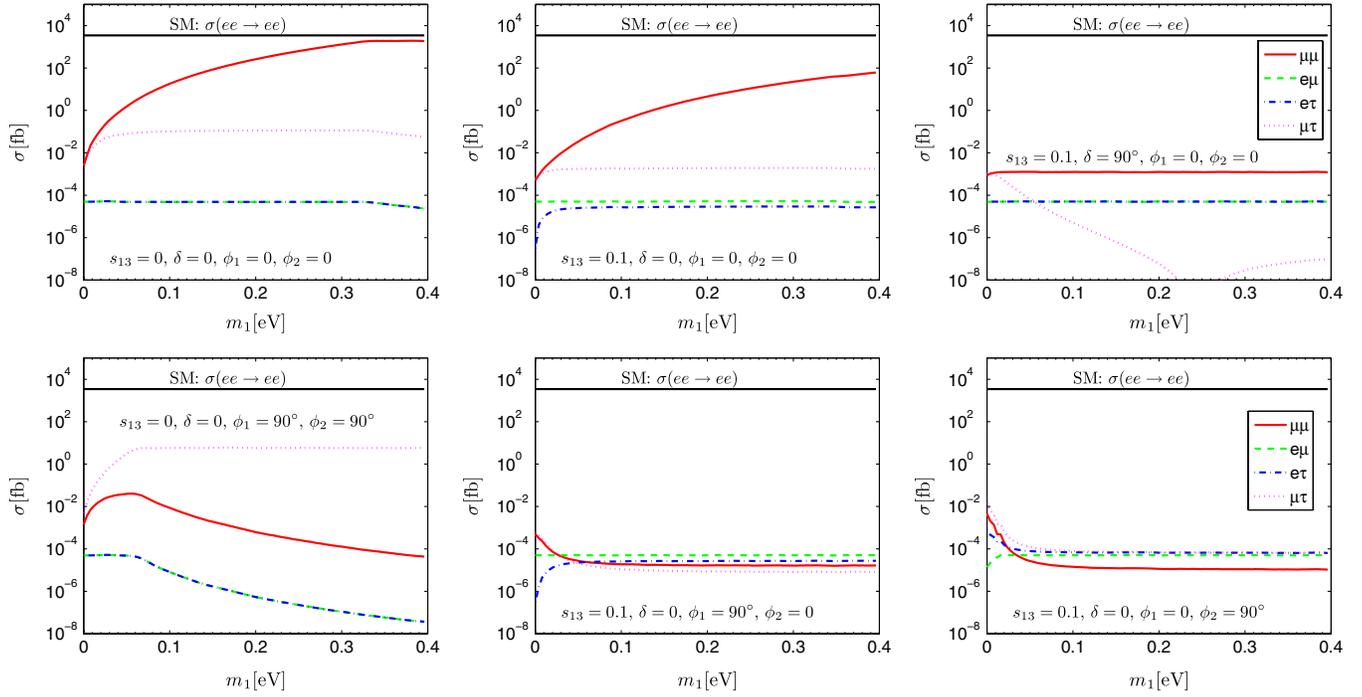

FIG. 2 (color online). Upper limits of cross sections $e^-e^- \rightarrow \alpha^- \beta^-$ with respect to m_1 at a linear collider with $\sqrt{s} = 1$ TeV. The Higgs triplet mass $m_\Delta = 800$ GeV has been assumed as an example, while the choices of $\sin\theta_{13}$ are labeled on each plot. Furthermore, we take the Majorana CP -violating phases ϕ_1 and ϕ_2 to be zero for the plots on the upper panel, and the Dirac CP -violating phase $\delta = 0$ for the plots on the lower panel. For comparison, the SM Møller scattering cross section is also shown on the plots with black solid lines. The luminosity one can assume is 80 fb^{-1} .

phases, e.g., the left upper plot, the cross section of the channel with two muons in the final states could be more than 1000 fb. It turns out that for $m_1 \gtrsim 0.3$ eV the bound coming from $\mu^+e^- \rightarrow \mu^-e^+$ is the dominating one,⁴ which then sets an upper limit on the di-muon channel. Moreover, a nonzero s_{13} will slightly decrease the maximal cross sections. One also observes from plots in the right column that nonvanishing CP -violating phases can suppress the di-muon cross section, mostly because h_{ee} and $h_{\mu\mu}$ cannot simultaneously be large in those cases. We note that some amount of tuning among Majorana CP -violating phases is necessary in order to generate appreciable cross sections. This is because we need to evade stringent LFV bounds. As shown in the left lower plot, a dominating and observable cross section in the $\mu\tau$ channel arises for the Majorana phases $\phi_1 = \phi_2 = \pi/2$. One may check that in this case h takes a special form in which the h_{ee} and $h_{\mu\tau}$ are large and the other entries small. This corresponds to the approximate conservation of the $L_\mu - L_\tau$ flavor symmetry [56].

We conclude from Fig. 2 that the di-muon channel looks most promising among the possible final states, and we therefore study it further. Since both the collider signatures

and the neutrinoless double beta decay process rely on the Majorana feature of light neutrinos, we illustrate in Fig. 3 the interplay between the di-muon channel cross section and neutrinoless double beta decay. We plot the upper bounds of the cross section against $|m_{ee}|$ for both mass orderings, while for simplicity fixing the other oscillation parameters. The necessary tuning of Majorana phases

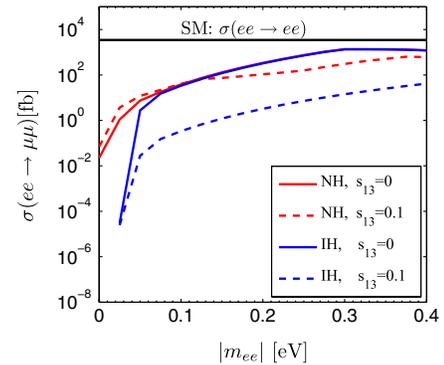

FIG. 3 (color online). Upper bounds of the total cross section $\sigma(e^-e^- \rightarrow \mu^- \mu^-)$ (in units of fb) with respect to the effective mass $|m_{ee}|$. The experimental setup and the mass of the Higgs triplet are the same as those in Fig. 2, while the input values of s_{13} as well as the neutrino mass hierarchies are labeled on the plot. The Majorana CP -violating phases are allowed to vary between 0 and π , while $\delta = 0$ is assumed.

⁴The next generation muon factory may improve this constraint by 1 order of magnitude [55], which however does not seriously change the main conclusion addressed in this work.

mentioned above fixes the effective mass as well. Interestingly, the cross sections are increasing functions of the effective mass, indicating potentially attractive signatures in both collider and nonaccelerator experiments.

The upper bounds of the cross section $\sigma(e^-e^- \rightarrow \mu^- \mu^-)$ with respect to $\sin\theta_{13}$ and δ are illustrated in Fig. 4. One reads from the plots that sizable cross sections could be expected in the case $\delta \sim n\pi$ or $\theta_{13} \sim 0$ if the neutrino mass spectrum is nearly degenerate. Furthermore, even if the light neutrino mass spectrum is hierarchical, there are still certain parameter regions, i.e., $(\delta, \sin\theta_{13}) \sim (\pi, 0.04)$ for the normal mass hierarchy and $(\delta, \sin\theta_{13}) \sim (0, 0.01)$ for the inverted mass hierarchy, that allow for identifying the Higgs triplet since the expected number of events would be greater than 50 for an integrated luminosity 80 fb^{-1} . This is in agreement with our analytical expressions. For example, in the normal mass ordering case, for $\delta = \pi$, Eq. (15) yields $\sin\theta_{13} \simeq 0.04$. In what regards the inverted hierarchy, in the limit $m_3 \sim 0$ the leading order contributions in $h_{e\mu}$ disappear for $\phi_1 = \phi_2 = 0$ as shown in Eq. (16). Thus, one should take into account the ‘‘next-to-leading order’’ contributions, which is given by

$$|h_{e\mu}|^2 \simeq \frac{m_2^2}{4v_L^2} (\varepsilon^2 s_{12}^2 c_{12}^2 - 2\varepsilon s_{12} c_{12} s_{13} \cos\delta + s_{13}^2), \quad (17)$$

where we have expanded the formula based on small parameters $\varepsilon = (m_2 - m_1)/m_2 \simeq 0.016$ and s_{13} . For $\cos\delta = 0(2\pi)$, $h_{e\mu} = 0$ in Eq. (17) requires roughly $s_{13} \simeq s_{12} c_{12} (m_2 - m_1)/m_2$, which corresponds to $\sin\theta_{13} \simeq 0.007$. This result again confirms the numerical analysis.

As discussed before, the cross section relies heavily on the configuration of Majorana CP -violating phases. In particular, in order to obtain observable signatures, one would expect that ϕ_1 and ϕ_2 are almost degenerate. In Fig. 4, we show the upper bounds of the cross section $\sigma(e^-e^- \rightarrow \mu^- \mu^-)$ in the $\phi_1 - \phi_2$ plane in the normal ordering case. The interesting parameter region is, as expected, the diagonal line of $\phi_1 - \phi_2 \simeq 0$. Consequently, collider experiments may play a crucial role in determining the Majorana CP -violating phases. Since h is not sensitive to neutrino mass ordering in the ND limit, e.g., $m_i > 0.05 \text{ eV}$, similar parameter region for ϕ_1 and ϕ_2 also exists in the inverted mass ordering case. If the mass spectrum is hierarchical, it is difficult to acquire visible cross sections unless some fine-tuning exists as shown in Eqs. (14) and (17).

Finally, one may wonder if the above estimate strongly depends on the assumption on the mass of the doubly charged scalar, since resonant production of Δ^{--} requires its mass to be known with reasonable accuracy in order to

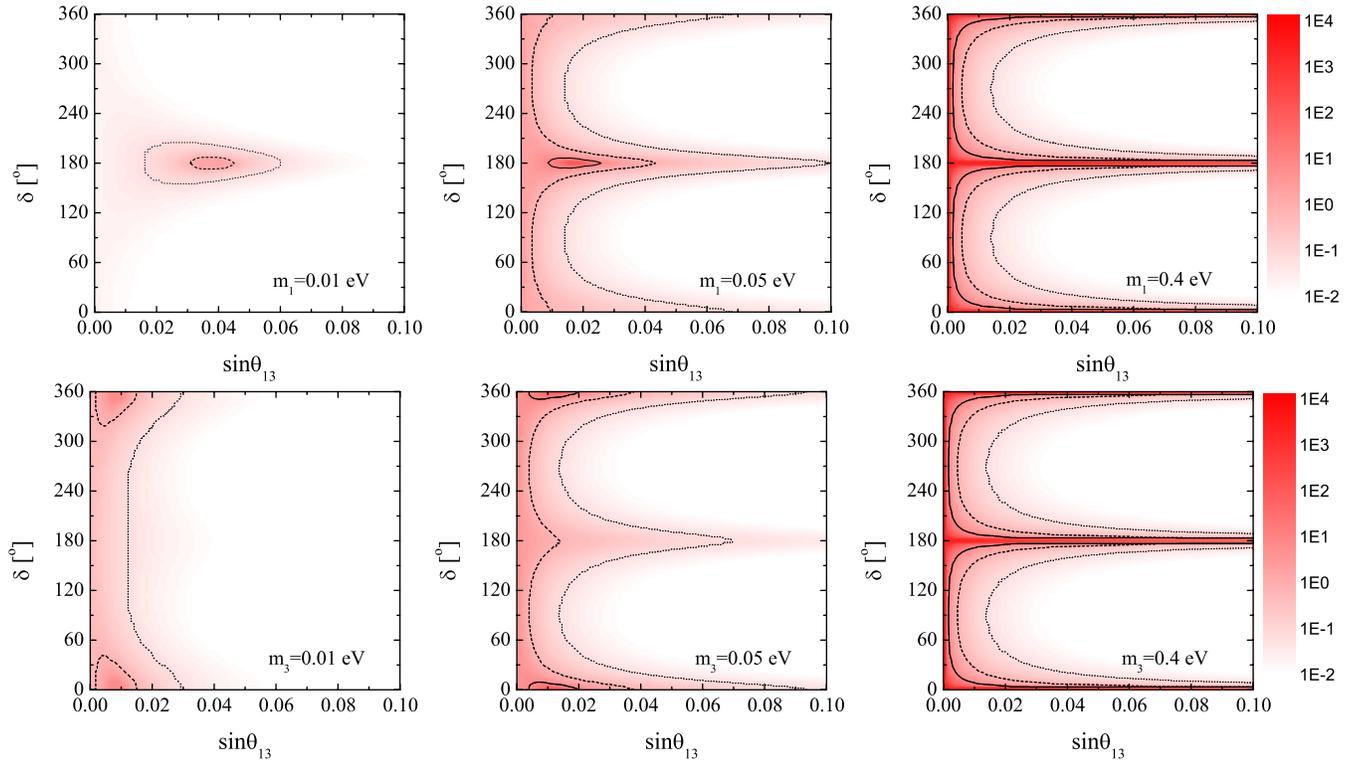

FIG. 4 (color online). Upper bounds of the total cross section $\sigma(e^-e^- \rightarrow \mu^- \mu^-)$ (in units of fb) for $\sqrt{s} = 1 \text{ TeV}$ in the $\sin\theta_{13} - \delta$ plane with the experimental setup and the mass of the Higgs triplet are the same as those in Fig. 2. For the plots in the upper row, we consider the normal mass ordering, while in the lower row the inverted mass ordering is assumed. The lightest neutrino mass can be read off from the plots, and for the sake of simplicity, we take all the Majorana phases to be zero. For an integrated luminosity 80 fb^{-1} , the solid, dashed and dotted curves show the regions with expected number of events greater than 5, 50 and 500, respectively.

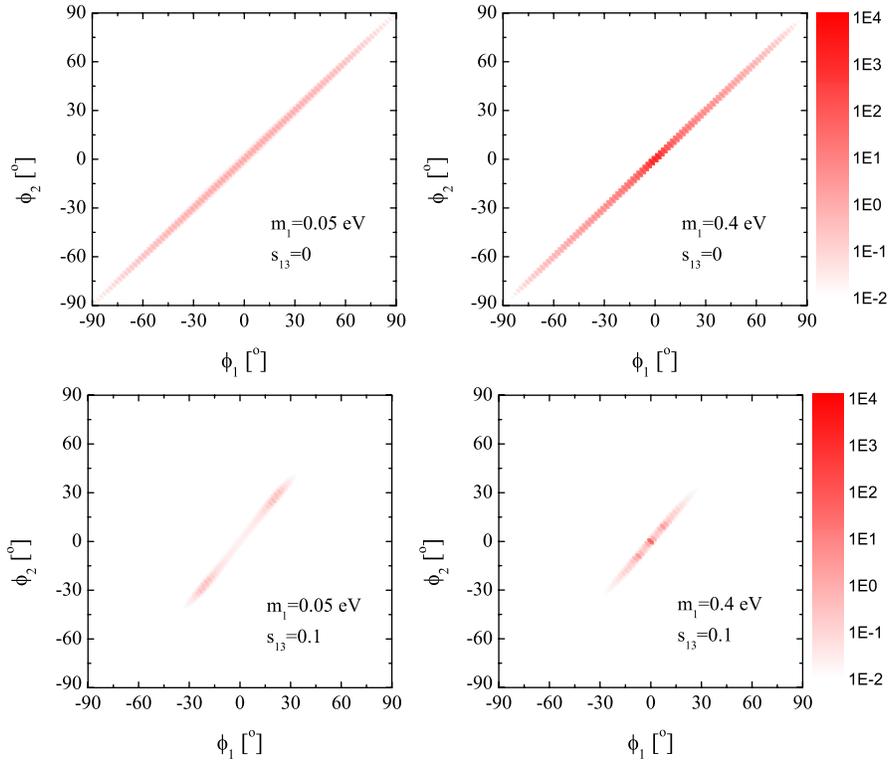

FIG. 5 (color online). Upper bounds of the total cross section $\sigma(e^-e^- \rightarrow \mu^-\mu^-)$ (in units of fb) in the $\phi_1 - \phi_2$ plane with the same experimental setting of Fig. 4. The input values of s_{13} and m_1 are labeled on the plots, while δ is taken to be zero. The luminosity one can assume is 80 fb^{-1} .

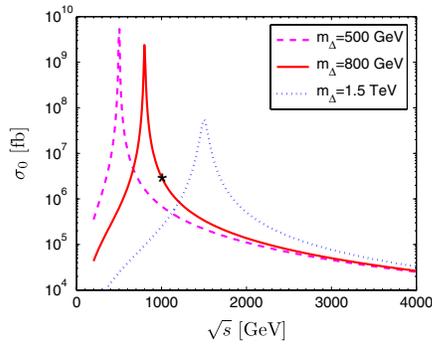

FIG. 6 (color online). The bare cross section σ_0 (in units of fb) as a function of \sqrt{s} , with solid, dashed and dotted lines corresponding to $m_\Delta = 0.8 \text{ TeV}$, 0.5 TeV and 1.5 TeV , respectively. The black star on the plot indicates the values of the parameters used in plotting Figs. 2–6). For the definition of σ_0 , see Eq. (8).

tune the center-of-mass energy of the colliding electrons [42,45,46]. In Fig. 6, we give the bare cross section σ_0 [see Eq. (8)] as a function of \sqrt{s} for different masses of the Higgs triplet. One reads from the plot that remarkable cross sections can be naturally obtained without the need of a severe fine-tuning of the colliding energy. To be concrete, we also present in Fig. 7 the upper limits of the cross section $\sigma(e^-e^- \rightarrow \mu^-\mu^-)$ for the triplet masses $m_\Delta = (0.5, 0.8, 1.5) \text{ TeV}$ and $\sqrt{s} = (1, 4) \text{ TeV}$. Recall that with

the scaling behavior $\mathcal{L} = 80 (\sqrt{s}/\text{TeV})^2 \text{ fb}^{-1}$ one requires for 100 events cross sections of $\sigma = 1.25 \text{ fb}$ and $\sigma = 0.078 \text{ fb}$, if $\sqrt{s} = 1 \text{ TeV}$ and 4 TeV , respectively. Note that the cross sections for $m_\Delta = 0.8 \text{ TeV}$ and $m_\Delta = 1.5 \text{ TeV}$ are almost identical despite σ_0 being different.

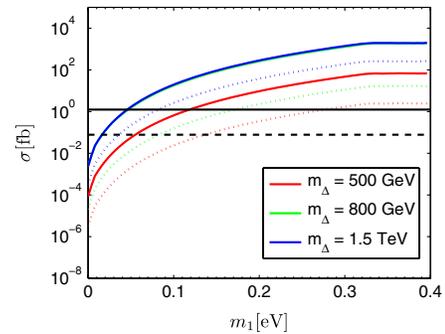

FIG. 7 (color online). Upper limits of the cross section $e^-e^- \rightarrow \mu^-\mu^-$ with $\sqrt{s} = 1 \text{ TeV}$ (solid lines) and $\sqrt{s} = 4 \text{ TeV}$ (dashed lines). The Higgs triplet masses are labeled on the plot. Here we consider the normal mass ordering case, and assume all the CP -violating phases and s_{13} to be zero for simplicity. The black and green solid lines for $\sqrt{s} = 1 \text{ TeV}$ and $m_\Delta = 800$ and 1500 GeV are lying basically on top of each other and are hardly distinguishable. 100 events correspond to $\sigma = 1.25 \text{ fb}$ (black solid line) and $\sigma = 0.078 \text{ fb}$ (black dashed line), respectively.

This can be understood from the LFV constraints on the Yukawa coupling h , which becomes less severe for a larger triplet mass. This feature is compensated by a reduced cross section. Recall that triplet masses larger than 1 TeV cannot be probed at the LHC. Hence a future linear collider running at the TeV scale can be a probe for such particles. The bilepton channel at a linear collider is so spectacular that Δ^{--} , with mass around TeV scale, can be easily probed together with much better sensitivity than that of the LHC.

V. SUMMARY

We have studied the Higgs triplet mediated processes $e^-e^- \rightarrow \alpha^-\beta^-$ at a future linear collider run in a like-sign lepton mode. The strong dependence on neutrino parameters and hence the flavor structure of the Majorana mass matrix m was emphasized and the di-muon channel was identified as the most promising one. In order to avoid strong constraints from lepton flavor violation, suppressing the $e\mu$ element of m is required. The largest cross sections occur for a near-diagonal mass matrix, which implies nearly degenerate neutrino masses. However, even in the

limit of a hierarchical neutrino spectrum observable signatures could still be expected for certain choices of neutrino mixing parameters. Therefore, measurements of bilepton channels at a linear collider could be quite helpful in order to provide valuable information on the neutrino parameters. In addition, triplet masses beyond the reach of the LHC can be probed.

Finally, we would like to note that similar analyses could be performed for a muon collider (e.g., the process $\mu^-\mu^- \rightarrow e^-e^-$), or an electron-muon facility, where in addition interesting and characteristic processes like $e^-\mu^+ \rightarrow e^+\mu^-$ could be studied.

ACKNOWLEDGMENTS

This work was supported by the ERC under the Starting Grant MANITOP and by the Deutsche Forschungsgemeinschaft in the Transregio 27 ‘‘Neutrinos and beyond-weakly interacting particles in physics, astrophysics and cosmology’’.
