(Received 19 August 2012; published 15 November 2012)

We consider the simplest versions of the Nambu–Jona-Lasinio model and the linear sigma model, in the mean field approximation, in order to analyze hot and dense two flavor quark matter subject to strong magnetic fields. We pay special attention to the case of a finite chemical potential, which has not yet been fully explored. Our results, for the Nambu–Jona-Lasinio model, are in qualitative agreement with other recent applications showing that, for stronger fields, the first order segment of the transition line increases with the magnetic strength while the coexistence chemical potential value, at low temperatures, decreases. In the present work, one of the most important results is related to the analysis of how these features affect the phase coexistence region in the $T-\rho_B$ plane. We find that the coexistence boundary oscillates around the $B = 0$ value for magnetic fields of the order $eB \le 9.5m_{\pi}^2$, which can be understood by investigating the filling of Landau layels at vanishing temperature. So far, most investigations have been concerned with filling of Landau levels at vanishing temperature. So far, most investigations have been concerned with the effects of the magnetic field over the $T-\mu$ plane only while other thermodynamical quantities such as the adiabats, the quark number susceptibility, the interaction measure and the latent heat have been neglected. Here, we take a step towards filling this gap by investigating the influence of a magnetic field over these quantities. Finally, we argue that a naive application of the mean field approximation does not seem to be appropriate to treat the linear sigma model in the presence of magnetic fields.

I. INTRODUCTION

The determination of the QCD phase diagram, even in the absence of magnetic fields, is still a matter of great theoretical and experimental activities. In this case, powerful lattice simulations have established that at vanishing baryon chemical potential there is no true phase transition from hadronic matter to a quark gluon plasma, but rather a very rapid raise in the energy density signaling a crossover characterized by a pseudocritical temperature, $T_{pc} \approx$ 160 MeV [\[1\]](#page-10-0). The situation is less clear for the finite chemical potential region since, so far, there is no reliable information available from lattice QCD evaluations. Nevertheless, most finite μ lattice extrapolations for the $\mu = 0$ Columbia plot indicate that the critical first order surface (in the $m_{u,d} - m_s - \mu$ space) will hit the physical
current mass values at some finite *u* thereby characterizing current mass values at some finite μ thereby characterizing a critical end point (CP) [[2\]](#page-10-1), which constitutes the most plausible theoretical scenario. On the other hand, other lattice evaluations [\[3\]](#page-10-2) predict that, as μ increases, this critical first order surface bends in a way which, in principle, would exclude the appearance of a CP and the whole $T-\mu$ plane would then be dominated by a crossover repre-senting an "exotic" scenario [\[2](#page-10-1)]. However, even this situation may be reversed in favor of a critical end point, if a different physics strongly influences the finite density region causing a back bending of the critical surface [\[4–](#page-10-3)[6\]](#page-10-4).

At the same time, the possibility that strong magnetic fields may be produced in noncentral heavy ion collisions [\[7\]](#page-10-5) as well as being present in magnetars [\[8](#page-11-0)], and in the

early universe [\[9](#page-11-1)] leads to the question of how these fields influence the QCD phase diagram. So far, most estimates have been carried out at vanishing chemical potential with the aid of effective theories such as the linear sigma model (LSM) [[10](#page-11-2)] and the Nambu–Jona-Lasinio model (NJL) $[11,12]$ $[11,12]$ within the mean field approximation (MFA). The general outcome is that the (chiral) pseudocritical temperature, at which the crossover takes place, increases with increasing values of the magnetic field. Some of these applications have also considered these effective models with the inclusion of the Polyakov loop to take confinement into account. The results show that the deconfinement pseudocritical temperature also increases with B, but an interesting splitting between this temperature and the one related to chiral symmetry has been observed [[10](#page-11-2)]. At $\mu = 0$, the first lattice attempt to solve the problem considered two quark flavors and high values of pion masses $(m_{\pi} = 200\text{--}400 \text{ MeV})$ confirming that T_{pc} should increase
with R_{F} [13] However, an improved lattice simulation [14] with B [\[13\]](#page-11-5). However, an improved lattice simulation [\[14\]](#page-11-6) which considered 2 + 1 quark flavors at physical pion
mass values (m_{π} = 140 MeV), together with an extrapo-
lation to the continuum predicted that T should decrease lation to the continuum, predicted that T_{pc} should decrease with *B*. No splitting between the chiral and the deconfinement pseudocritical temperatures has been observed within the lattice simulations. A decrease of deconfinement pseudocritical temperature has also been observed with the Massachusetts Institute of Technology bag model [\[15\]](#page-11-7) and, more recently, with the large- N_c limit of QCD [\[16\]](#page-11-8) (see Ref. [[17\]](#page-11-9) for a summary of these results). In Ref. [\[18](#page-11-10)], it is suggested that the behavior observed within the lattice simulations is due to the entanglement with the Polyakov [*m](#page-0-1)arcus@fsc.ufsc.br loop that is affected by magnetic screening as discussed in

Ref. [\[19\]](#page-11-11), where it was shown, within a simplified framework, that the strong electromagnetic fields can play a catalyzing role for a deconfinement transition. However, as referred in Ref. [\[18](#page-11-10)], if only the chiral sector is considered, an enhancement of the chiral condensate, due to finite B, would not be contradictory with the lattice simulations of Ref. [[14\]](#page-11-6). Nevertheless, although the quantitative discrepancy remains to be fully understood, there is a consensus regarding the crossover character of the chiral transition at vanishing chemical potential. On the other hand, the effects of strong magnetic fields at the finite μ regime have not been fully explored to date even within effective theories. Experimentally, the intermediate temperature regime is important regarding current nuclear collisions at the low-energy end of Relativistic Heavy Ion Collider (RHIC) and in the future with FAIR at GSI and NICA at JINR, whose aim is to probe the expected critical point region. At the low temperature end, one expects to find a rather interesting physics related to the expected first order phase transition which may have astrophysical consequences (e.g., regarding the possibility of quark star formation $[20,21]$ $[20,21]$ $[20,21]$).

In the chiral limit, the two flavor version of the NJL model subject to a magnetic field was considered in Ref. [[22](#page-11-14)] with the MFA while the three flavor version, at the physical point, was recently analyzed in Ref. [\[23\]](#page-11-15) within the same approximation. In the latter reference, which concerns the more realistic case, it was observed that T_{pc} , at $\mu = 0$, always increases with B, as in most model applications. In that work, one of the main novelties regards the critical end point location, which moves towards higher temperatures and smaller chemical potential values as B increases. Another interesting result concerns the size of the first order segment of the transition line, which becomes longer, as stronger magnetic fields are considered. Also, at low temperatures, it has been observed that the chemical potential value at which the first order transition occurs decreases with B. The latter result has been previously observed with the two flavor NJL, in the chiral limit [[22](#page-11-14)], as well as with a holographic one-flavor model [[24\]](#page-11-16). The interested reader may find a modelindependent physical explanation for this result, which the authors have termed inverse magnetic catalysis (IMC) in Ref. [[24](#page-11-16)] while a recent review with new analytical results for the NJL can be found in Ref. [[25\]](#page-11-17). Also, very recently, the two flavor NJL model has been considered to investigate the dynamics of neutron mesons in a hot and magnetized medium [\[26\]](#page-11-18). Another important application regards the generalized three flavor NJL model including eight-quark interactions in which the phenomenon of secondary magnetic catalysis sets in Ref. [[27](#page-11-19)].

The LSM with two flavors has also been employed to determine the $T-\mu$ phase diagram with the MFA [[28\]](#page-11-20) and, more recently, with the more powerful functional renormalization group (FRG) [[29](#page-11-21)]. This method has been previously used in an application to the Polyakov quark model demonstrating that at $\mu = 0$ the increase of T_{pc} with B persists even when mesonic fluctuations are considered [\[30\]](#page-11-22). The MFA results of Ref. [\[28\]](#page-11-20) show that when all fermionic contributions are considered, the whole $T-\mu$ plane is dominated by the crossover, irrespective of the magnetic field value while the chiral symmetry broken region expands with B. It is interesting to note here that, in this case, the LSM mimics the exotic theoretical QCD phase diagram scenario mentioned at the beginning of this section. However, as we show here, this is just an artifact of the parametrization adopted in Ref. [[28\]](#page-11-20), where the authors chose a rather high value for the sigma meson mass (m_q = 800 MeV). As a matter of fact, the occurrence of a critical point and first order transition depends crucially on the mass of the sigma meson that one uses in the computation [\[31\]](#page-11-23). Apart from the parametrization issue, one must be very careful when considering the LSM since different approximations may lead to very different results even at the qualitative level (e.g., yielding different types of phase transitions $[28,32,33]$ $[28,32,33]$ $[28,32,33]$. This is mainly due to the fact that within this effective theory one has scalar and pseudoscalar mesons as well as quarks as degrees of freedom. Also, the pure vacuum contributions may be neglected without spoiling the breaking of chiral symmetry, which happens at the classical level. This allows for different approaches in which one or more contributions are neglected, yielding different results. When magnetic fields are present, the phase diagram obtained with the FRG applied to the LSM [\[29](#page-11-21)] agrees, qualitatively, with the ones obtained with the NJL in the MFA $[23,26]$ $[23,26]$. However, sigma masses of the order $m_{\sigma} = 400{\text -}450$ MeV have been considered so that one may wonder if the qualitative agreement between the LSM-FRG and the NJL-MFA predictions for the chiral transition phase diagram are due to the use of smaller m_{τ} values or to the use of a more powerful approximation scheme within the LSM. Here, in order to address this question, we consider the LSM with the MFA using m_{σ} = 600 MeV and also $m_{\sigma} = 450$ MeV showing that the higher value reproduces the exotic scenario also found in Ref. [\[28\]](#page-11-20). On the other hand, using $m_{\sigma} = 450$ MeV, we observe the appearance of a first order line starting at $T = 0$ and terminating at the critical end point. However, when magnetic fields are turned on, we do not observe the same qualitative features observed with the NJL-MFA and the LSM-FRG at intermediate to low values of the temperature. For instance, at $T = 0$, the coexistence chemical potential values do not decrease with B as predicted by the inverse magnetic catalysis mechanism [\[24](#page-11-16)[,25\]](#page-11-17), which points out to the fact that the naive MFA application as performed here, and also in Ref. [\[28\]](#page-11-20), may not be adequate to treat the LSM in the presence of magnetic fields.

Finally, note that despite all the progress made so far in analyzing the influence of B over the $T-\mu$ phase diagram, not much effort has been devoted to investigate particular aspects such as the coexistence and spinodal boundaries associated with the first order transition. Also, the analysis of quantities such as the quark number susceptibility, adiabats, interaction measure, latent heat, etc., may help in the understanding of the phase diagram structure under strong magnetic fields. Therefore, the main goal of the present work is to improve over the simple $T-\mu$ phase diagram by investigating its structure and related physical quantities in more detail. For instance, to the best of our knowledge, the influence of B over the coexistence and the critical regions, for example, has not been addressed before.

In this work, which is concerned only with the chiral transition, we consider the LSM and the NJL model with two flavors in the framework of the MFA in an application which could be viewed as an extension of Ref. [\[34\]](#page-11-26) to the $B \neq 0$ case (the thermodynamics of both models, at $B = 0$, has been recently discussed with great detail in Ref. [\[35](#page-11-27)]). Note that, here, our main focus is on the NJL, which yields the expected phase diagram scenario, even at the MFA level, allowing us to probe the physically rich first order transition region with its associated critical end point. On the other hand, as already mentioned, the MFA treatment of the LSM at $B \neq 0$ does not generate the expected phase diagram in the full $T-\mu$ plane by excluding the IMC phenomenon for example. Here, its investigation is justified for allowing us to trace this problem as being generated by the MFA and not only by a parametrization which considers high m_{σ} values. These two models, extended by the Polyakov loop, have recently been considered in Ref. [[36](#page-11-28)], where quantities like the magnetic susceptibility of the quark condensate as well as the quark polarization have been evaluate at vanishing temperature.

In the next section, we investigate the phase structure of the NJL, paying special attention to the low temperature regime, which has been less explored in the literature. In the same section, we evaluate the effect of B over the coexistence and spinodal regions, isentropic lines, and the quark susceptibility with the aid of the $T-\mu$, $T-\rho_B$ and P -T planes. In Sec. [III](#page-6-0), we consider the LSM in the MFA framework, as in Ref. [[28](#page-11-20)], but extending the analysis so as to consider the effects of B in the sigma meson mass. We also present the $T-\mu$ phase diagram for this model, at the physical point, for the magnetic field values relevant to RHIC and the LHC. This exercise will allow us to compare the MFA results furnished by both models. Our conclusions are presented in Sec. [IV.](#page-9-0)

II. THERMODYNAMICS OF THE NJL UNDER A MAGNETIC FIELD

At vanishing temperature and finite density the NJL model, subject to a magnetic field, has been used to address different questions such as the stability of quark droplets [\[37\]](#page-11-29) and the equation of state (EOS) of magnetars with and without strangeness in Refs. [[20](#page-11-12),[21](#page-11-13)], respectively. The influence of B and instantons at the two extreme parts of the phase diagram ($T = 0$, $\mu \neq 0$ and $T \neq 0$, $\mu = 0$) was studied in Ref. [[38](#page-11-30)]. The whole $T-\mu$ plane was first analyzed in Ref. [[22](#page-11-14)], where only the chiral limit, for the two flavor version, was considered. At the physical point, the same version of the model has been recently considered in Ref. [\[26\]](#page-11-18) whose results, for the phase diagram, qualitatively agree with the ones found in Ref. [\[23\]](#page-11-15) for three flavors. In this section, we will obtain the EOS and then analyze different physical quantities in order to characterize the physical situations which are more sensitive to magnetic effects.

A. The model

The NJL model is described by a Lagrangian density for fermionic fields given by [\[39\]](#page-11-31)

$$
\mathcal{L}_{\text{NJL}} = \bar{\psi}(i\partial \!\!\!/ - m)\psi + G[(\bar{\psi}\psi)^2 - (\bar{\psi}\gamma_5\vec{\tau}\psi)^2], \quad (2.1)
$$

where ψ (a sum over flavors and color degrees of freedom is implicit) represents a flavor iso-doublet (u, d) type of quarks) N_c -plet quark fields, while $\vec{\tau}$ are isospin Pauli matrices. The Lagrangian density (2.1) (2.1) (2.1) is invariant under (global) $U(2)_f \times SU(N_c)$ and, when $m = 0$, the theory is also invariant under chiral $U(2)_L \times U(2)_R$.

Due to the quadratic fermionic interaction, the theory is nonrenormalizable in $3 + 1$ dimensions (G has dimensions of eV^{-2}), meaning that divergences appearing at successive perturbative orders cannot be all eliminated by a consistent redefinition of the original model parameters (fields, masses, and couplings). The renormalizability issue arises during the evaluation of momentum integrals associated with loop Feynman graphs in a perturbative expansion and, in the process, one usually employs regularization prescriptions (e.g., dimensional regularization, sharp cutoff, etc.) to formally isolate divergences. However, the procedure introduces arbitrary parameters with dimensions of energy that do not appear in the original Lagrangian density. Within the NJL model, a sharp cutoff (Λ) is preferred and since the model is nonrenormalizable, one has to fix Λ to a value related to the physical spectrum under investigation. This strategy turns the $3 + 1$ NJL model into an effective model, where Λ is treated as a parameter. The phenomenological values of quantities such as the pion mass (m_π) , the pion decay constant (f_{π}) , and the quark condensate $(\langle \bar{\psi} \psi \rangle)$
are used to fix G_{\perp} and m. Here, we adont the values are used to fix G , Λ , and m . Here, we adopt the values $m = 6$ MeV, $\Lambda = 590$ MeV, and $G\Lambda^2 = 2.435$, which
have also been employed in Ref. [38] (see Refs. [40,41] have also been employed in Ref. [[38\]](#page-11-30) (see Refs. [[40](#page-11-32)[,41\]](#page-11-33) for other possibilities).

B. The NJL free energy in the presence of a magnetic field

The free energy, in the MFA, can be written as follows $[20,40]$ $[20,40]$ (see Ref. $[41]$ $[41]$ $[41]$ for results beyond MFA):

$$
\mathcal{F}^{\text{NJL}} = \frac{(M-m)^2}{4G} + \frac{i}{2} \text{ tr} \int \frac{d^4 p}{(2\pi)^4} \ln[-p^2 + M^2], \quad (2.2)
$$

where M is the constituent quarks mass. In order to study the effect of a magnetic field in the chiral transition at finite temperature and chemical potential a dimensional reduction is induced via the following replacements in Eq. [\(2.2\)](#page-2-1):

$$
p_0 \to i(\omega_\nu - i\mu), \tag{2.3}
$$

$$
p^2 \to p_z^2 + (2n + 1 - s)|q_f|B, \text{ with } s = \pm 1, \quad n = 0, 1, 2...
$$
\n(2.4)

$$
\int_{-\infty}^{+\infty} \frac{d^4 p}{(2\pi)^4} \to i \frac{T|q_f| B}{2\pi} \sum_{\nu=-\infty}^{\infty} \sum_{n=0}^{\infty} \int_{-\infty}^{+\infty} \frac{dp_z}{2\pi}, \qquad (2.5)
$$

where $\omega_{\nu} = (2\nu + 1)\pi T$, with $\nu = 0, \pm 1, \pm 2...$ represents the Matsubara frequencies for fermions *n* represents sents the Matsubara frequencies for fermions, *n* represents the Landau levels, and $|q_f|$ is the absolute value of the quark electric charge $(|q_u| = 2e/3, |q_d| = e/3$ with $e = 1/\sqrt{137}$ representing the electron charge). Following
Ref. [20] we can write the free energy as Ref. [\[20\]](#page-11-12), we can write the free energy as

$$
\mathcal{F}^{\text{NJL}} = \frac{(M-m)^2}{4G} + \mathcal{F}_{\text{vac}}^{\text{NJL}} + \mathcal{F}_{\text{mag}}^{\text{NJL}} + \mathcal{F}_{\text{med}}^{\text{NJL}},\qquad(2.6)
$$

where

$$
\mathcal{F}_{\text{vac}}^{\text{NJL}} = -2N_c N_f \int \frac{d^3 \mathbf{p}}{(2\pi)^3} (\mathbf{p}^2 + M^2)^{1/2}.
$$
 (2.7)

This divergent integral is regularized by a sharp cutoff, Λ , yielding

$$
\mathcal{F}_{\text{vac}}^{\text{NJL}} = \frac{N_c N_f}{8\pi^2} \bigg\{ M^4 \ln \bigg[\frac{(\Lambda + \epsilon_\Lambda)}{M} \bigg] - \epsilon_\Lambda \Lambda [\Lambda^2 + \epsilon_\Lambda^2] \bigg\}, \quad (2.8)
$$

where we have defined $\epsilon_{\Lambda} = \sqrt{\Lambda^2 + M^2}$. The magnetic and the in-medium terms are respectively given by and the in-medium terms are, respectively, given by

$$
\mathcal{F}_{\text{mag}}^{\text{NJL}} = -\frac{N_c}{2\pi^2} \sum_{f=u}^{d} (|q_f|B)^2 \Big\{ \zeta^{(1,0)}(-1, x_f) - \frac{1}{2} [x_f^2 - x_f] \ln(x_f) + \frac{x_f^2}{4} \Big\},\tag{2.9}
$$

and

$$
\mathcal{F}_{\text{med}}^{\text{NJL}} = -\frac{N_c}{2\pi} \sum_{f=u}^{d} \sum_{k=0}^{\infty} \alpha_k |q_f| B
$$

$$
\times \int_{-\infty}^{+\infty} \frac{dp_z}{2\pi} \{ T \ln[1 + e^{-[E_{p,k}(B) + \mu]/T}] + T \ln[1 + e^{-[E_{p,k}(B) - \mu]/T}] \}.
$$
 (2.10)

Note that in the last equation we have replaced the label n by k in the Landau levels in order to account for the degeneracy factor $\alpha_k = 2 - \delta_{0k}$. In Eq. [\(2.7\)](#page-3-0), $N_c = 3$ and $N_c = 2$ are the color and flavor degrees of freedom respec- $N_f = 2$ are the color and flavor degrees of freedom, respec-tively. Also, in Eq. ([2.9](#page-3-1)) we have used $x_f = M^2/(2|q_f|B)$ and $\zeta^{(1,0)}(-1, x_f) = d\zeta(z, x_f)/dz|_{z=-1}$ with $\zeta(z, x_f)$ representing the Biemann-Hurwitz function (the details of the senting the Riemann-Hurwitz function (the details of the manipulations leading to the equations above can be found in the Appendix of Ref. [[20](#page-11-12)]). Finally, in Eq. [\(2.10\)](#page-3-2) we have $E_{p,k}(B) = \sqrt{p_z^2 + 2k|q_f|B + M^2}$, where M is the effective self-consistent quark mass

$$
M = m + \frac{N_c N_f MG}{\pi^2} \Biggl\{ \Lambda \sqrt{\Lambda^2 + M^2} - \frac{M^2}{2} \n\times \ln \Biggl[\frac{(\Lambda + \sqrt{\Lambda^2 + M^2})^2}{M^2} \Biggr] \Biggr\} + \frac{N_c MG}{\pi^2} \sum_{f=u}^d |q_f| \n\times B \Biggl\{ \ln [\Gamma(x_f)] - \frac{1}{2} \ln(2\pi) + x_f - \frac{1}{2} (2x_f - 1) \ln(x_f) \Biggr\} \n- \frac{N_c MG}{2\pi^2} \sum_{f=u}^d \sum_{k=0}^\infty \alpha_k |q_f| B \int_{-\infty}^\infty \frac{dp_z}{E_{p,k}(B)} \n\times \Biggl\{ \frac{1}{e^{[E_{p,k}(B) + \mu]/T} + 1} + \frac{1}{e^{[E_{p,k}(B) - \mu]/T} + 1} \Biggr\}. \tag{2.11}
$$

Note that in principle one should have two coupled gap equations for the two distinct flavors: $M_u =$ $m_u - 2G(\langle \bar{u}u \rangle + \langle \bar{d}d \rangle)$ and $M_d = m_d - 2G(\langle \bar{d}d \rangle + \langle \bar{u}u \rangle)$,
where $\langle \bar{u}u \rangle$ and $\langle \bar{d}d \rangle$ represent the quark condensates where $\langle \bar{u}u \rangle$ and $\langle dd \rangle$ represent the quark condensates which differ, due to the different electric charges. However, in the two flavor case, the different condensates contribute to M_u and M_d in a symmetric way and since $m_u = m_d = m$ one has $M_u = M_d = M$.

C. Numerical results for the NJL model

We can now obtain the phase diagram as well as other important physical quantities for the NJL model in the presence of B. All of the relevant thermodynamical quantities can be readily obtained by recalling that the free energy, evaluated at the mass value which satisfies the gap equation, gives the negative of the pressure, $\mathcal{F}(M) = -P$. Then, then net quark number density is obtained from $\rho = dP/d\mu$. net quark number density is obtained from $\rho = dP/d\mu$, and the entropy density from $s = dP/dT$ while the energy density is $\mathcal{E} = -P + Ts + \mu \rho$. Let us start with the phase
diagram in the T-u, as shown by Fig. 1 which was obtained diagram, in the $T-\mu$, as shown by Fig. [1](#page-4-0) which was obtained for vanishing B as well as for $eB = 6m_{\pi}^2$ and $eB = 15m_{\pi}^2$,
which cover the estimated values for noncentral collisions at which cover the estimated values for noncentral collisions at RHIC and the LHC, respectively [\[42](#page-11-34)]. The first order phase transition line can be obtained by locating the two degenerate minima of the free energy while the crossover line is determined by finding the maximum of $-dM/dT$ [\[23\]](#page-11-15).
At $u = 0$ one observes an increase of T, which is

At $\mu = 0$, one observes an increase of T_{pc} , which was expected to happen within the present model approximation, as discussed in the Introduction. However, at around $\mu \approx 285$ MeV, the T_{pc} value for $eB = 6m_{\pi}^2$ is smaller than
the $B = 0$ value in accordance with the findings of the $B = 0$ value, in accordance with the findings of Refs. $[23, 26, 29]$ $[23, 26, 29]$ $[23, 26, 29]$ $[23, 26, 29]$ $[23, 26, 29]$ $[23, 26, 29]$ $[23, 26, 29]$. The figure also indicates that B induces a noticeable increase of the first order segment of the transition line, which terminates at higher values of T and smaller values of μ . At low temperatures, the coexistence values of the chemical potential decrease with increasing B showing IMC (although μ starts to increase again for values $eB \ge 16m_{\pi}^2 \approx \Lambda^2$ [[23](#page-11-15),[26](#page-11-18)], which we do

FIG. 1 (color online). Phase diagram for the NJL model in the $T-\mu$ plane. The CP, represented by solid symbols, occurs at $(T_c \approx 78.5 \text{ MeV}, \mu_c \approx 328 \text{ MeV})$ for $B = 0$, $(T_c \approx 81.7 \text{ MeV},$ $\mu_c \approx 318$ MeV) for $eB = 6m_{\pi}^2$, and $(T_c \approx 115.6$ MeV, $\mu_c \approx 279.3$ MeV) for $eB = 15m^2$. The continuous lines represent 279.3 MeV) for $eB = 15m_{\pi}^2$. The continuous lines represent cross-
first order phase transitions and the dashed lines represent crossfirst order phase transitions and the dashed lines represent crossovers. The inset shows the crossing of the transition lines.

not consider here). At $T = 0$, this pattern was also observed in Ref. [[37](#page-11-29)]. The CP is located at $(T_c \approx$ 78.5 MeV, $\mu_c \approx 328$ MeV) for $B = 0$, ($T_c \approx 81.7$ MeV, $\mu_c \approx 318$ MeV) for $eB = 6m_\pi^2$, and $(T_c \approx 115.6$ MeV,
 $\mu_s \approx 279.3$ MeV) for $eB = 15m^2$ $\mu_c \approx 279.3$ MeV) for $eB = 15m_\pi^2$.
Figure 2 (left panel) displays the

Figure [2](#page-5-0) (left panel) displays the spinodal lines, also in the $T-\mu$ plane, for the same values of the magnetic field showing that very high fields increase significantly the size of the metastable regions. In the $T-\rho_B$ plane, the coexistence boundary is limited by the two distinct, low (ρ^L) and high (ρ^H), densities with $\rho^L < \rho^H$ for $T < T_c$ and $\rho^L = \rho^H$ at $T = T_c$. The boundaries, for different values of B, are shown in Fig. [2](#page-5-0) (right panel) where we work in terms of the baryon density, $\rho_B = \rho/3$, given in units of the nuclear
matter density, $\rho_0 = 0.17$ fm⁻³. An interesting feature of matter density, $\rho_0 = 0.17 \text{ fm}^{-3}$. An interesting feature of this figure is the oscillation of the coexistence boundary this figure is the oscillation of the coexistence boundary around its value at $B = 0$, which is more pronounced in the ρ^H branch. The decrease in ρ^H for $eB = 6m_{\pi}^2$, at low
temperature, shown in the right panel of Fig. 2 can be temperature, shown in the right panel of Fig. [2](#page-5-0) can be understood in terms of the filling of the Landau levels and, with this aim, we present Fig. [3](#page-5-1) (left panel), which displays the baryonic density and the effective quark mass as functions of the magnetic field at $T = 0$. To analyze the figure, let us recall that, in the limit $T \rightarrow 0$, the baryonic density can be written¹ as $[20]$ $[20]$

$$
\rho_B(\mu, B) = \theta(k_F^2) \sum_{f=u}^d \sum_{k=0}^{k_{f,\text{max}}} \alpha_k \frac{|q_f|BN_c}{6\pi^2} k_F, \qquad (2.12)
$$

where $k_F = \sqrt{\mu^2 - 2|q_f|kB - M^2}$ and

$$
k_{f,\max} = \frac{\mu^2 - M^2}{2|q_f|B},\tag{2.13}
$$

or the nearest integer.

Equation ([2.12\)](#page-4-1) shows that if $k_F^2 < 0$ then $\rho_B = 0$, which
precisely the low density value at $T = 0$, which is easy is precisely the low density value at $T = 0$, which is easy to understand by recalling that the effective mass is double valued when the first order transition occurs presenting a high (M^H) and a low (M^L) value with $M^L < M^H$ for $T < T_c$ and $M^L = M^H$ at $T = T_c$. Now, at $T = 0$, M^H corresponds to the value effective quark mass acquires when $T = 0$ and $\mu = 0$ (the vacuum mass), which corresponds to $M^H \approx 403$ MeV at $B = 0$, $M^H \approx 416$ MeV at $eB = 6m_{\pi}^2$, and $M^H \approx 467$ MeV at $eB = 15m_{\pi}^2$. On the other hand at $T = 0$ the first order transition hannens when other hand, at $T = 0$ the first order transition happens when $\mu \approx 383$ MeV for $B = 0$, $\mu \approx 370$ MeV for $eB = 6m_{\pi}^2$,
and $\mu \approx 339$ MeV for $eB = 15m^2$ so that $a^L = 0$ even at and $\mu \approx 339$ MeV for $eB = 15m_{\pi}^2$ so that $\rho^L = 0$ even at the lowest Landau level as required by $\theta(k^2)$ in Eq. (2.12) the lowest Landau level, as required by $\theta(k_F^2)$ in Eq. [\(2.12\)](#page-4-1).
Then, to understand the oscillations let us concentrate on Then, to understand the oscillations let us concentrate on the ρ^H branch which is shown, together with M^L (the inmedium mass), in Fig. [3](#page-5-1) (left panel) where it is clear that both quantities have an opposite oscillatory behavior. The origin of the oscillations in these quantities can be traced back to the fact that k_{max} (the upper Landau level filled) decreases as the magnetic field increases. The first and second peaks, of the M^L curve, correspond to the change from $k_{\text{max}} = 1$ to $k_{\text{max}} = 0$ for the up and down quark, respectively. As we have seen, for very low temperatures the value of μ at coexistence decreases with B (see Fig. [1\)](#page-4-0) so that, generally, k_{max} and M must vary and when k_{max} decreases, M increases. It then follows, from Eq. [\(2.12\)](#page-4-1), that ρ_B must decrease. When $k_{\text{max}} = 0$ for both quark flavors there are no further changes in the upper Landau level and the low temperature oscillations stop at $eB \ge$ 9.5 m_{π}^2 . The magnetic field seems to cause a big change on the shape of the coexistence region so that the same high density, ρ_B^H , may coexist with distinct low densities, ρ_B^L , for two different values of the temperature. For example, $\rho_B^H \approx 2.5 \rho_0$ coexists with $\rho_B^L \approx 0$ at $T \approx 20$ MeV and with $\rho_L^L \approx 1.8 \rho_0$ at $T \approx 70$ MeV. This pattern is also with $\rho_B^L \approx 1.8 \rho_0$ at $T \approx 70$ MeV. This pattern is also
observed although in a milder way at the high value observed, although in a milder way, at the high value $eB = 15m_{\pi}^2$. Our results also suggest that the highest den-
sity is achieved at temperatures close to T in opposition sity is achieved at temperatures close to T_c , in opposition to the $B = 0$ case where this happens at $T = 0$. Another interesting quantity to be investigated in connection with the density oscillation is the latent heat, $\Delta \mathcal{E}$, which at $T = 0$ is simply given by $\Delta \mathcal{E} = \mu (\rho^H - \rho^L)$ since the two coexisting densities occur at the same pressure and two coexisting densities occur at the same pressure and chemical potential. Figure [3](#page-5-1) (right panel) shows that the latent heat value also oscillates around its $B = 0$ value for $eB \le 9.5m_{\pi}^2$. Figure [4](#page-5-2) presents the more intuitive P-T phase diagram showing the region of broken symmetry, which corresponds to the ''gas'' phase, and the region of (partially) restored chiral symmetry, which corresponds to the ''liquid'' phase in analogy with a liquid-gas transition. The figure shows that the transition from the gas [chiral symmetry breaking (CSB)] phase to the liquid chiral symmetry restoration (CSR) phase occurs at lower pressures when *B* increases, as expected. Although here we prefer

¹There is a misprint in Eq. (30) of Ref. $[20]$ where it should be ρ_B instead of ρ .

FIG. 2 (color online). Left panel: Spinodal boundaries for the NJL model in the $T-\mu$ plane. Right panel: Phase coexistence boundaries in the T- ρ_B plane (ρ_B appears in units of the nuclear matter density, $\rho_0 = 0.17$ fm⁻³). The solid symbols indicate the location of the critical point for each value of B location of the critical point for each value of B.

FIG. 3 (color online). Left panel: The NJL model effective quark mass (squares) at the lowest value occurring at the transition, M^L , and the highest coexisting baryon density (dots), ρ_B^H (in units of ρ_0), as functions of eB/m_π^2 at $T = 0$. The lines are shown just in order to quide the eye. Right panel: The latent heat $\Delta \mathcal{E}$ at $T = 0$ as to guide the eye. Right panel: The latent heat, $\Delta \mathcal{E}$, at $T = 0$, as a function of eB/m_{π}^2 . As expected, this quantity and ρ_B^H behave in a similar way similar way.

to show only the first order transition lines in the P-T (in order to display a cleaner diagram) we remark that it is a trivial matter to also map the crossover lines into this phase diagram if needed. Let us now look at some other thermodynamical quantities, such as interaction measure (or trace anomaly), which is defined by

FIG. 4 (color online). The NJL model phase diagram in the P-T plane indicating the regions of broken, CSB, and (partially) restored chiral symmetry, CSR, which correspond to the ''gas'' and ''liquid'' phase, respectively. All lines represent first order phase transitions which terminate at the CP represented by the solid symbols.

$$
\Delta = \frac{(\mathcal{E} - 3P)}{T^4}.
$$
\n(2.14)

The effect of B over this quantity is shown in Fig. 5 for $\mu = 0$ (crossover) and the critical chemical potential value at $B = 0$, $\mu_c = 328$ MeV (first order transition). The presence of a magnetic field enhances sharper transitions. Next, in order to verify how the magnetic field affects the critical region of the phase diagram, let us consider the quark number susceptibility, which is defined as

$$
\chi_q = \frac{d\rho}{d\mu}.\tag{2.15}
$$

Figure [6](#page-6-2) shows this quantity, in units of Λ^2 , for $B = 0$ and $eR = 15m^2$. In both cases, one observes that the critical $eB = 15m_{\pi}^2$. In both cases, one observes that the critical region set by the contour of ν has an elongated shape due region set by the contour of χ_q has an elongated shape due to the enhancement of this quantity along the first order transition line. As discussed by Schaefer and Wambach [\[43\]](#page-11-35), at $B = 0$, the reason for this behavior is that along the path asymptotically parallel to the first order line the quark number susceptibility scales with the exponent γ_q which, within the MFA, is expected to be $\gamma_q = 1$ while for any other path the divergence scales with ϵ , which in the MFA takes the value $\epsilon = 2/3 < \gamma_q$. Although we do not

FIG. 5 (color online). Left panel: Interaction measure for the NJL model as a function of T, for $\mu = 0$, displaying the crossover behavior. Right panel: Interaction measure for the NJL model as a function of T, $\mu = \mu_c(B = 0) = 328$ MeV displaying the first order transition behavior.

FIG. 6 (color online). Critical regions for the NJL model at $eB = 0$ (left panel) and $eB = 15m_{\pi}^2$ (right panel) given by the contour lines of the quark number susceptibility v_{\perp} in units of Λ^2 . The control pa of the quark number susceptibility, χ_q , in units of Λ^2 . The control parameters have been normalized by T_c and μ_c corresponding to each value of the magnetic field. In both cases, the critical region is elongated in the direction parallel to the first order transition line.

perform the explicit evaluation of the associated critical exponents here we can, nevertheless, take this explanation as being valid also at $B \neq 0$ since the shape of the critical region remains elongated along the first order transition line when a strong magnetic field is present as shown by our results. Note that the main purpose of our comparison was to establish how the presence of a magnetic field would influence the shape of the critical region with respect to the $B = 0$ result and, for consistency, we have used the same MFA in both situations. It is beyond the scope of the present work to further discuss the validity of such approximation in the critical region, which constitutes a separate important problem. Finally, another interesting physical quantity, that is easily obtained from the EOS, is the entropy per baryon number

$$
\frac{S}{A} = 3\frac{(\mathcal{E} + P - \mu\rho)}{T\rho}.
$$
 (2.16)

At $B = 0$, the quantity S/A was considered in Ref. [\[34\]](#page-11-26) in order to check an eventual convergence of the adiabats toward the critical point as claimed in Ref. [[44](#page-11-36)]. However, the authors of Ref. [[34](#page-11-26)] did not observe such an effect and the result was explained by recalling that since there is no change in the degrees of freedom of the two phases one should not expect the focusing effect to arise within the LSM and the NJL type of models. In this case, the adiabats show the typical behavior of an ordinary liquid-gas phase transition represented, respectively, by the chirally symmetric and broken phases [\[45\]](#page-11-37). Our results, displayed in Fig. [7,](#page-7-0) show that the magnetic field does not produce any noticeable effect on the behavior of the adiabats which present a similar pattern at vanishing and high B.

III. THERMODYNAMICS OF THE LSM UNDER A MAGNETIC FIELD

In this section, we follow Ref. [\[28\]](#page-11-20) and consider the LSM in the approximation where the mesonic sector contributes only at the classical (tree) level while one loop quantum corrections, including vacuum contributions, are furnished by the quark sector alone. We will perform our analysis considering two sets of parameter values, which produce a high and a low value for m_{σ} , in order to address

FIG. 7 (color online). The entropy per baryon number, S/A , for the NJL model at $B = 0$ (left panel) and $eB = 15m_{\pi}²$ (right panel). The thin continuous curves correspond to $S/A = 5$, 10, 15, 20, 40, 100. The thick continuous lines represent first order phase transitions while the dashed lines represent crossovers. The focusing effect is not observed.

the efficiency of the MFA in dealing with this particular model in the presence of magnetic fields.

A. The model

The Lagrangian density of the LSM with quarks reads

$$
\mathcal{L}_{\text{LSM}} = \bar{\psi}[i\rlap{/}\theta - g(\sigma + i\gamma_5\vec{\tau}\cdot\vec{\pi})]\psi
$$

$$
+ \frac{1}{2}(\partial_{\mu}\sigma\partial^{\mu}\sigma + \partial_{\mu}\vec{\pi}\cdot\partial^{\mu}\vec{\pi}) - U(\sigma,\vec{\pi}), \quad (3.1)
$$

where ψ is the flavor iso-doublet spinor representing the quarks, and

$$
U(\sigma, \vec{\pi}) = \frac{\lambda}{4} (\sigma^2 + \vec{\pi}^2 - v^2)^2 - h\sigma,
$$
 (3.2)

is the classical potential energy density. In the chiral limit (obtained by setting $h = 0$ in the previous equation) the chiral symmetry $SU(2)_V \times SU(2)_A$ is spontaneously broken at the classical level, and the pion is the associated massless Goldston boson. Here, we are interested in the $h \neq 0$ case, which implies that chiral symmetry is explicitly broken giving the pion a finite mass at $T = 0$ and $\mu = 0$. The parameters are usually chosen so that chiral symmetry is spontaneously broken in the vacuum and the expectation values of the meson fields are $\langle \sigma \rangle = f_{\pi}$ and $\langle \vec{\pi} \rangle = 0$ where $f = 93$ MeV is the pion decay constant $\langle \vec{\pi} \rangle = 0$, where $f_{\pi} = 93$ MeV is the pion decay constant.
When pure vacuum contributions are considered within the When pure vacuum contributions are considered within the MS renormalization scheme, as we do here, an arbitrary mass scale $(\Lambda_{\overline{MS}})$ also appears in the final results. As
discussed in the Introduction for our purposes it will be discussed in the Introduction, for our purposes, it will be necessary to consider two different sets of parameters in order to get a high and a low value for m_{σ} . The first set is given by $\Lambda_{\overline{\text{MS}}} = 16.48 \text{ MeV}$ which, together with $v = 64.29 \text{ MeV}$, $\lambda = 46.06$ and $h = 1.77 \times 10^6 \text{ MeV}^3$ $v = 64.29$ MeV, $\lambda = 46.06$, and $h = 1.77 \times 10^6$ MeV³, yields $m_{\pi} = 138$ MeV and $m_{\sigma} = 600$ MeV. The second set is just like the first except for λ and ν , which are set to set is just like the first except for λ and ν , which are set to $\lambda = 36.96$ and $\nu = 54.96$ MeV yielding $m_{\sigma} = 450$ MeV. In both cases, the sigma meson mass falls within the range of the broad resonance $m_{\sigma} = 400{\text -}800 \text{ MeV}$ [[29](#page-11-21)].

B. The LSM free energy in the presence of a magnetic field

Treating the bosonic degrees of freedom at the tree level implies that the loop contributions to the free energy come entirely from the fermionic sector. This contribution is represented by an integral similar to the one which appears in Eq. (2.2) (2.2) (2.2) so that the free energy is given by

$$
\mathcal{F}^{\text{LSM}} = U(\sigma, \vec{\pi}) + \mathcal{F}^{\text{LSM}}_{\text{vac}} + \mathcal{F}^{\text{LSM}}_{\text{mag}} + \mathcal{F}^{\text{LSM}}_{\text{med}}, \quad (3.3)
$$

where, the magnetic and the in-medium terms bear the same form as their NJL counterparts with the obvious replacement $M^2 \to m_q^2 = g^2(\sigma^2 + \vec{\pi}^2)$. On the other
hand the pure vacuum contribution whose general from hand, the pure vacuum contribution, whose general from is given by Eq. (2.7) (2.7) (2.7) , is treated in different fashion within both models and in many LSM applications it is discarded on the grounds that it does not give significant contributions at high temperature and/or chemical potential values. However, a considerable number of studies have pointed out its importance in the characterization of the phase transition $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$ $[10,28,32,33]$. Here, we follow Ref. $[28]$ by including the pure fermionic vacuum contribution in the free energy. Since this model is renormalizable, the usual procedure is to regularize divergent integrals using dimensional regularization and then to subtract the ultra violet divergences in the $\overline{\text{MS}}$ renormalization scheme. This procedure gives the following finite result

$$
\mathcal{F}_{\text{vac}}^{\text{LSM}} = \frac{N_c N_f m_q^4}{(8\pi)^2} \left[\frac{3}{2} - \ln \left(\frac{m_q^2}{\Lambda_{\text{MS}}^2} \right) \right]. \tag{3.4}
$$

The expectation values, $\langle \sigma \rangle$ and $\langle \vec{\pi} \rangle$ fields are obtained
extremizing the free energy by extremizing the free energy

$$
\frac{\partial \mathcal{F}^{\text{LSM}}}{\partial \sigma} = 0, \qquad \frac{\partial \mathcal{F}^{\text{LSM}}}{\partial \pi_i} = 0, \tag{3.5}
$$

while the mesonic masses are determined by the curvature of the free energy at the global minimum

$$
m_{\sigma}^2 = \frac{\partial^2 \mathcal{F}^{\text{LSM}}}{\partial \sigma^2}, \qquad m_{\pi_i}^2 = \frac{\partial^2 \mathcal{F}^{\text{LSM}}}{\partial \pi_i^2}, \tag{3.6}
$$

evaluated at $\sigma = \langle \sigma \rangle$ and $\pi = \langle \vec{\pi} \rangle$. Here, we follow the usual
procedure 15.6.341 by setting $\langle \vec{\pi} \rangle = 0$ so that $m = g(\sigma)$ procedure [\[5](#page-10-6),[6,](#page-10-4)[34](#page-11-26)] by setting $\langle \vec{\pi} \rangle = 0$ so that $m_q = g\langle \sigma \rangle$.

C. Numerical results for the LSM

Let us start by mapping the $T-\mu$ phase diagram, at the physical point, for three relevant values of the magnetic field $(eB = 0, 6m_{\pi}^2, 15m_{\pi}^2)$. Let us start with the parameter
set which gives $m_{\pi} = 600$ MeV whose result is shown in set which gives $m_{\sigma} = 600$ MeV whose result is shown in the left panel of Fig. [8](#page-8-0) which indicates that the high- $T/low-\mu$ behavior is similar to the one found in the NJL model. Namely, a crossover happens at T_{pc} values which increase with the magnetic field. Note that, qualitatively, this situation does not change even by going beyond the MFA or employing other parametrizations [\[29](#page-11-21)[,30\]](#page-11-22). Here, the results given by the parametrization leading to m_{σ} = 600 MeV start to depart from the ones observed in the NJL case at intermediate values of T and μ since the crossover does not change into the expected first order transition with its associated CP. Then, the whole $T-\mu$ plane is dominated by the crossover exactly as the authors of Ref. [\[28\]](#page-11-20) have observed using $m_{\tau} = 800$ MeV. The situation changes drastically if one uses the parameter set which yields $m_{\sigma} = 450$ MeV as the right panel of Fig. [8](#page-8-0) suggests. Indeed, with this set one observes the crossover/CP/first order transition pattern. However, when the magnetic field increases one does not observe the characteristic effects observed earlier in the NJL model as the decrease of the coexistence chemical potential at low T (IMC), the increase of T_c , and the decrease of μ_c , for example. We can further investigate the strength of the transition by analyzing how the order parameter varies with the temperature as shown in Fig. [9](#page-8-1) for $\mu = 0$ and $\mu_c(B = 0) = 198.52$ MeV. In both cases one sees that the strength, characterized by the peak of $-d\langle\sigma\rangle/dT$
decreases with increasing magnetic fields and the figure decreases with increasing magnetic fields and the figure also suggests that, when $B \neq 0$ and $\mu \neq 0$, the crossover becomes smoother as B increases. Based on the findings of Ref. [[23](#page-11-15)], which show that a magnetic field makes the transition sharper, one would expect the opposite behavior. Since the correlation length is governed by $1/m_{\sigma}$ [\[46\]](#page-11-38) the sigma meson mass, as a function of B, T, and μ is also an interesting quantity to be analyzed and with this aim we present Fig. [10.](#page-9-1) In Ref. [\[30\]](#page-11-22), which considers the Polyakov quark model at $\mu = 0$, it has been demonstrated that the value of m_{σ} at T_{pc} is almost independent of B (both, in the MFA and FRG approaches). Contrary to that, within our approximation, we observe that the difference $m_{\sigma}(T_{\text{pc}}) - m_{\sigma}(0)$ decreases with increasing B which is
also in opposition to the expectations furnished by the also in opposition to the expectations furnished by the

FIG. 8 (color online). The LSM phase diagram in the $T-\mu$ plane for $B = 0$, $eB = 6m_{\pi}^2$, and $eB = 15m_{\pi}^2$. The left panel, in which only crossover occurs refers to $m_{\pi} = 600$ MeV and the right panel to $m_{\pi} = 450$ only crossover occurs, refers to $m_{\sigma} = 600$ MeV and the right panel to $m_{\sigma} = 450$ MeV. In the right panel, the crossover is represented by dashed lines, the first order phase transitions by continuous lines, and the CP by solid symbols which are located at $(T_c \approx 79.32 \text{ MeV}, \mu_c \approx 198.52 \text{ MeV})$ for $B = 0$, $(T_c \approx 12.3 \text{ MeV}, \mu_c \approx 343.4 \text{ MeV})$ for $eB = 6m_{\pi}^2$, and $(T_c \approx 34.2 \text{ MeV}, \mu_c \approx 365.1 \text{ MeV})$ for $eB = 15m^2$. In both cases the region of broken symmetry expands with incr $\mu_c \approx 365.1$ MeV) for $eB = 15m_{\pi}^2$. In both cases, the region of broken symmetry expands with increasing B.

FIG. 9 (color online). The quantity $-d\langle\sigma\rangle/dT$, where $\langle\sigma\rangle$ is the LSM order parameter, as a function of T for $m_{\sigma} = 450$ MeV.
The left panel corresponds to $\mu = 0$ and the right panel to μ ($R = 0$) = 198.52 MeV The left panel corresponds to $\mu = 0$ and the right panel to $\mu_c(B = 0) = 198.52$ MeV.

FIG. 10 (color online). The sigma meson mass, m_{σ} , whose inverse represents the correlation length, as a function of T for $\mu = 0$ (left panel) and $\mu_c(B = 0) = 198.52$ MeV (right panel). For comparison reasons, the mass has been normalized by its value at $T = 0$ $(m_{\sigma} = 450 \text{ MeV})$. The curve corresponding to $B = 0$ in the right panel shows that $m_{\sigma} \to 0$ when $\mu \to \mu_c(B = 0)$, as expected.

FIG. 11 (color online). Left panel: Manifestation of magnetic catalysis, at $T = 0$, for the NJL model (continuous line) and for the LSM (dashed line) with $m_{\sigma} = 450$ MeV. The effective quark mass, $M_q(B)$, which represents the effective quark mass for each model, has been normalized by its $B = 0$ value to allow for comparisons. Right panel: The pseudocritical temperature, as a function of B, for each model. This quantity has also been normalized by its value at $B = 0$ for comparison reasons and the LSM is taken with m_{σ} = 450 MeV.

results of Ref. [\[23\]](#page-11-15). Within the NJL model the behavior of $m_{\sigma}(T, \mu, B)$ has also been recently addressed [\[26](#page-11-18)] furnishing results which predict that $m_{\sigma}(T_{\text{pc}}) - m_{\sigma}(0)$ increases
with increasing R and also that the transition appears to be with increasing B and also that the transition appears to be sharper as μ increases. These comparisons suggest that the naive application of the MFA to the LSM at finite T , μ , and B indeed misses some important physics, especially at finite densities. This conclusion is not only supported by the NJL-MFA results of Refs. [\[22](#page-11-14)[–26\]](#page-11-18) but also by the LSM-FRG results obtained by Andersen and Tranberg [\[29](#page-11-21)].

D. Comparing magnetic catalysis in the LSM and the NJL model at $\mu = 0$

In the previous subsection, we have pointed out that the MFA does not seem to furnish reliable results for the LSM. However, this issue seems to be less severe at $\mu = 0$ where at least the predicted type of transition is in agreement with other model applications as well as with lattice simulations. We can then address the question of how magnetic catalysis [\[47\]](#page-11-39) (see Ref. [[48](#page-11-40)] for an updated review) affects each model by comparing the dimensionless quantities T_{BC}^B/T_{pc}^0 and $M_q(B)/M_q(0)$ where, now, M_q is representing
the effective quark mass in each case, that is M in the NII the effective quark mass in each case, that is, M in the NJL model and m_q in the LSM. The result, shown in Fig. [11](#page-9-2), suggests that within our approximations the effective quark mass of the LSM is more sensitive to the presence of a magnetic field. At $eB = 15m_{\pi}^2$ the LSM quark mass has
increased by about 20% while the NII quark mass has increased by about 20% while the NJL quark mass has increased by about 15%. The increase of T_{pc} is even more dramatic within the LSM and at $eB = 15m_{\pi}^2$ it increases by
about 50% in relation to the $B = 0$ value while in the NIL about 50% in relation to the $B = 0$ value while in the NJL the increase is about 9%. At low values of B the LSM pseudocritical temperature suffers a sudden increase which again may be an indication of the failure of the approximations we have adopted for this particular model. We have tested the small B region (to about $eB \approx = 0.01 m_{\pi}^2$)
always observing a discontinuity in T with respect to the always observing a discontinuity in T_{pc} with respect to the $B = 0$ value which, in the light of the LSM-FRG results [\[29\]](#page-11-21) we interpret as an artifact of the model approximations adopted here.

IV. CONCLUSIONS

We have considered both, the LSM and the NJL model, in the description of hot and dense two flavor quark matter subject to strong magnetic fields, such as the ones expected to be created in noncentral heavy ion collisions. Here, the simplest version of these models, which do not consider the Polyakov loop, have been treated within the MFA. In this approximation, one loop fermionic contributions have been considered, allowing for the determination of the phase diagram associated with chiral symmetry breaking/ restoration. So far, most applications [\[22,](#page-11-14)[23](#page-11-15)[,28](#page-11-20)[,29\]](#page-11-21) at finite T , μ , and B have mainly focused in the determination of the $T-\mu$ phase diagram without analyzing the effects of the magnetic fields over important physical quantities such as the coexistence boundaries, the quark number susceptibilities, the interaction measure, and the mesonic masses among others. Therefore, our aim was to perform this analysis in order to understand the effects of B in more detail, especially at low temperatures, which is the less explored region. We have started by considering the NJL model, with physical quark masses, obtaining a $T-\mu$ phase diagram which is in qualitative agreement with the one obtained in Ref. [\[23\]](#page-11-15) for three quark flavors and also with Ref. [[26](#page-11-18)] for two quark flavors. One of the most important features of this diagram is related to the position of the critical end point that appears to be located at higher temperatures and smaller chemical potentials when B increases. One also observes that the first order segment of the transition line increases with B while the coexistence chemical potential value decreases at low temperatures. These observations suggest that the magnetic field has a direct effect in the physics associated with the first order transition and may influence the size and shape of the coexistence region for example. In order to check that we have mapped the $T - \mu$ plane into the $T - \rho_B$ plane showing
that for $\rho B \le 9.5m^2$ the high density branch of the coexthat for $eB \le 9.5m_{\pi}^2$ the high density branch of the coexistence phase diagram oscillates around its $B = 0$ value as a consequence of filling the Landau levels which influences the values of quantities such as the latent heat as we have shown. This finding may also have consequences regarding, e.g., the physics of phase conversion whose dynamics requires the knowledge of the EOS inside the coexistence region. For example, at a given temperature, the surface tension between the two coexisting bulk phases (ρ^L and ρ^H) depends on the value of their difference [[49](#page-11-41)[,50](#page-11-42)] which will, possibly, be affected by the oscillations suffered by the coexistence boundary due to the presence of a magnetic field. This feature of the phase diagram deserves further investigation since it may be important in the description

of the EOS inside the boundaries. Then, using the quark number susceptibility, we have mapped the critical region observing that its shape, which is elongated along the first order transition line, is not affected by the presence of a magnetic field. We have also investigated the behavior of the adiabats in the presence of B observing the same pattern which was observed at $B = 0$ [\[34\]](#page-11-26). The two latter results indicate that general model characteristics, associated with the shape of the critical region and the isentropic trajectories, are unaffected by the presence of B. For the NJL model, we conclude that magnetic fields appear to cause a significant effect at the intermediate and low temperature parts of the phase diagram causing the crossing of the transition lines representing different values of B. The presence of magnetic fields also promotes a change on the size and location of the first order line. It is important to mention that here, for simplicity, we did not take into account color superconductivity which is an important ingredient of the high density and low temperature region where the effects of quark Cooper pairing are very likely to affect the present results.

Our results for the LSM indicate that the MFA treatment as performed here does not seem to be appropriate, especially at higher values of the chemical potential where, as discussed, the magnetic field has a strong influence. However, one should carefully note that this conclusion is reached in the light of the results furnished by the more powerful FRG [[29](#page-11-21)[,30\]](#page-11-22). In principle, one could argue that the intermediate-low temperature part of the phase diagram is not known from first principles and that our LSM-MFA should be equally plausible. However, the fact that the LSM-FRG is more complete (by also considering mesonic fluctuations) furnishing results which are in qualitative agreement with the NJL-MFA results $[22-26]$ $[22-26]$ $[22-26]$ hints that the LSM-MFA, which does not include meson fluctuations, seems to be inadequate to treat the low temperature part of the phase diagram in the presence of strong magnetic fields.

ACKNOWLEDGMENTS
